To Our Teachers

Paul R. Burton
Albert Finholt
William P. Jencks
Eugene P. Kennedy
Homer Knoss
Arthur Kornberg
I. Robert Lehman
Earl K. Nelson
David E. Sheppard
Harold B. White
David L. Nelson, born in Fairmont, Minnesota, received his BS in Chemistry and Biology from St. Olaf College in 1964 and earned his PhD in Biochemistry at Stanford Medical School under Arthur Kornberg. He was a postdoctoral fellow at the Harvard Medical School with Eugene P. Kennedy, who was one of Albert Lehninger’s first graduate students. Nelson joined the faculty of the University of Wisconsin-Madison in 1971 and became a full professor of biochemistry in 1982. He is the Director of the Center for Biology Education at the University of Wisconsin-Madison.

Nelson’s research has focused on the signal transductions that regulate ciliary motion and exocytosis in the protozoan *Paramecium*. The enzymes of signal transductions, including a variety of protein kinases, are primary targets of study. His research group has used enzyme purification, immunological techniques, electron microscopy, genetics, molecular biology, and electrophysiology to study these processes.

Dave Nelson has a distinguished record as a lecturer and research supervisor. For 36 years he has taught an intensive survey of biochemistry for advanced biochemistry undergraduates in the life sciences. He has also taught a survey of biochemistry for nursing students, and graduate courses on membrane structure and function and on molecular neurobiology. He has sponsored numerous PhD, MS, and undergraduate honors theses, and has received awards for his outstanding teaching, including the Dreyfus Teacher-Scholar Award, the Atwood Distinguished Professorship, and the Unterkofler Excellence in Teaching Award from the University of Wisconsin System. In 1991–1992 he was a visiting professor of chemistry and biology at Spelman College. His second love is history, and in his dotage he has begun to teach the history of biochemistry to undergraduates and to collect antique scientific instruments.

Michael M. Cox was born in Wilmington, Delaware. In his first biochemistry course, Lehninger’s *Biochemistry* was a major influence in refocusing his fascination with biology and inspiring him to pursue a career in biochemistry. After graduating from the University of Delaware in 1974, Cox went to Brandeis University to do his doctoral work with William P. Jencks, and then to Stanford in 1979 for postdoctoral study with I. Robert Lehman. He moved to the University of Wisconsin-Madison in 1983, and became a full professor of biochemistry in 1992.

Cox’s doctoral research was on general acid and base catalysis as a model for enzyme-catalyzed reactions. At Stanford, he began work on the enzymes involved in genetic recombination. The work focused particularly on the RecA protein, designing purification and assay methods that are still in use, and illuminating the process of DNA branch migration. Exploration of the enzymes of genetic recombination has remained the central theme of his research.

Mike Cox has coordinated a large and active research team at Wisconsin, investigating the enzymology, topology, and energetics of genetic recombination. A primary focus has been the mechanism of RecA protein–mediated DNA strand exchange, the role of ATP in the RecA system, and the regulation of recombinational DNA repair. Part of the research program now focuses on organisms that exhibit an especially robust capacity for DNA repair, such as *Deinococcus radiodurans*, and the applications of those repair systems to biotechnology. For the past 24 years he has taught (with Dave Nelson) the survey of biochemistry to undergraduates and has lectured in graduate courses on DNA structure and topology, protein-DNA interactions, and the biochemistry of recombination. A more recent project has been the organization of a new course on professional responsibility for first-year graduate students. He has received awards for both his teaching and his research, including the Dreyfus Teacher-Scholar Award and the 1989 Eli Lilly Award in Biological Chemistry. His hobbies include gardening, wine collecting, and assisting in the design of laboratory buildings.
In this twenty-first century, a typical science education often leaves the philosophical underpinnings of science unstated, or relies on oversimplified definitions. As you contemplate a career in science, it may be useful to consider once again the terms *science*, *scientist*, and *scientific method*.

**Science** is both a way of thinking about the natural world and the sum of the information and theory that result from such thinking. The power and success of science flow directly from its reliance on ideas that can be tested: information on natural phenomena that can be observed, measured, and reproduced and theories that have predictive value. The progress of science rests on a foundational assumption that is often unstated but crucial to the enterprise: that the laws governing forces and phenomena existing in the universe are not subject to change. The Nobel laureate Jacques Monod referred to this underlying assumption as the “postulate of objectivity.” The natural world can therefore be understood by applying a process of inquiry—the scientific method. Science could not succeed in a universe that played tricks on us. Other than the postulate of objectivity, science makes no inviolate assumptions about the natural world. A useful scientific idea is one that (1) has been or can be reproducibly substantiated and (2) can be used to accurately predict new phenomena.

Scientific ideas take many forms. The terms that scientists use to describe these forms have meanings quite different from those applied by nonscientists. A *hypothesis* is an idea or assumption that provides a reasonable and testable explanation for one or more observations, but it may lack extensive experimental substantiation. A *scientific theory* is much more than a hunch. It is an idea that has been substantiated to some extent and provides an explanation for a body of experimental observations. A theory can be tested and built upon and is thus a basis for further advance and innovation. When a scientific theory has been repeatedly tested and validated on many fronts, it can be accepted as a fact.

In one important sense, what constitutes science or a scientific idea is defined by whether or not it is published in the scientific literature after peer review by other working scientists. About 16,000 peer-reviewed scientific journals worldwide publish some 1.4 million articles each year, a continuing rich harvest of information that is the birthright of every human being.

**Scientists** are individuals who rigorously apply the scientific method to understand the natural world. Merely having an advanced degree in a scientific discipline does not make one a scientist, nor does the lack of such a degree prevent one from making important scientific contributions. A scientist must be willing to challenge any idea when new findings demand it. The ideas that a scientist accepts must be based on measurable, reproducible observations, and the scientist must report these observations with complete honesty.

The **scientific method** is actually a collection of paths, all of which may lead to scientific discovery. In the *hypothesis and experiment* path, a scientist poses a hypothesis, then subjects it to experimental test. Many of the processes that biochemists work with every day were discovered in this manner. The DNA structure elucidated by James Watson and Francis Crick led to the hypothesis that base pairing is the basis for information transfer in polynucleotide synthesis. This hypothesis helped inspire the discovery of DNA and RNA polymerases.

Watson and Crick produced their DNA structure through a process of *model building and calculation*. No actual experiments were involved, although the model building and calculations used data collected by other scientists. Many adventurous scientists have applied the process of *exploration and observation* as a path to discovery. Historical voyages of discovery (Charles Darwin's 1831 voyage on H.M.S. *Beagle* among them) helped to map the planet, catalog its living occupants, and change the way we view the world. Modern scientists follow a similar path when they explore the ocean depths or launch probes to other planets. An analog of hypothesis and experiment is *hypothesis and deduction*. Crick reasoned that there must be an adaptor molecule that facilitated translation of the information in messenger RNA into protein. This adaptor hypothesis led to the discovery of transfer RNA by Mahlon Hoagland and Paul Zamecnik.

Not all paths to discovery involve planning. *Serenity* often plays a role. The discovery of penicillin by Alexander Fleming in 1928, and of RNA catalysts by Thomas Cech in the early 1980s, were both chance discoveries, albeit by scientists well prepared to exploit them. *Inspiration* can also lead to important advances. The polymerase chain reaction (PCR), now a central part of biotechnology, was developed by Kary Mullis after a flash of inspiration during a road trip in northern California in 1983.

These many paths to scientific discovery can seem quite different, but they have some important things in common. They are focused on the natural world. They rely on *reproducible observation* and/or *experiment*. All of the ideas, insights, and experimental facts that arise from these endeavors can be tested and reproduced by scientists anywhere in the world. All can be used by other scientists to build new hypotheses and make new discoveries. All lead to information that is properly included in the realm of science. Understanding our universe requires hard work. At the same time, no human endeavor is more exciting and potentially rewarding than trying, and occasionally succeeding, to understand some part of the natural world.
The first edition of *Principles of Biochemistry*, written by Albert Lehninger twenty-five years ago, has served as the starting point and the model for our four subsequent editions. Over that quarter-century, the world of biochemistry has changed enormously. Twenty-five years ago, not a single genome had been sequenced, not a single membrane protein had been solved by crystallography, and not a single knockout mouse existed. Ribozymes had just been discovered, PCR technology introduced, and archaea recognized as members of a kingdom separate from bacteria. Now, new genomic sequences are announced weekly, new protein structures even more frequently, and researchers have engineered thousands of different knockout mice, with enormous promise for advances in basic biochemistry, physiology, and medicine. This fifth edition contains the photographs of 31 Nobel laureates who have received their prizes for Chemistry or for Physiology or Medicine since that first edition of *Principles of Biochemistry*.

One major challenge of each edition has been to reflect the torrent of new information without making the book overwhelming for students having their first encounter with biochemistry. This has required much careful sifting aimed at emphasizing principles while still conveying the excitement of current research and its promise for the future. The cover of this new edition exemplifies this excitement and promise: in the x-ray structure of RNA polymerase, we see DNA, RNA, and protein in their informational roles, in atomic dimensions, caught in the central act of information transfer.

We are at the threshold of a new molecular physiology in which processes such as membrane excitation, secretion, hormone action, vision, gustation, olfaction, respiration, muscle contraction, and cell movements will be explicable in molecular terms and will become accessible to genetic dissection and pharmacological manipulation. Knowledge of the molecular structures of the highly organized membrane complexes of oxidative phosphorylation and photophosphorylation, for example, will certainly bring deepened insight into those processes, so central to life. (These developments make us wish we were young again, just beginning our careers in biochemical research and teaching. Our book is not the only thing that has acquired a touch of silver over the years!)

In the past two decades, we have striven always to maintain the qualities that made the original Lehninger text a classic—clear writing, careful explanations of difficult concepts, and communicating to students the ways in which biochemistry is understood and practiced today. We have written together for twenty years and taught together for almost twenty-five. Our thousands of students at the University of Wisconsin—Madison over those years have been an endless source of ideas about how to present biochemistry more clearly; they have enlightened and inspired us. We hope that this twenty-fifth anniversary edition will enlighten and inspire current students of biochemistry everywhere, and perhaps lead some of them to love biochemistry as we do.

Major Recent Advances in Biochemistry

Every chapter has been thoroughly revised and updated to include the most important advances in biochemistry including:

- Concepts of **proteomes and proteomics**, introduced earlier in the book (Chapter 1)
- New discussion of **amyloid diseases** in the context of protein folding (Chapter 4)
- New section on **pharmaceuticals** developed from an understanding of enzyme mechanism, using penicillin and HIV protease inhibitors as examples (Chapter 6)
- New discussion of **sugar analogs** as drugs that target viral neuraminidase (Chapter 7)
- New material on **green fluorescent protein** (Chapter 9)
- New section on **lipidomics** (Chapter 10)
- New descriptions of **volatile lipids** used as signals by plants, and of bird feather pigments derived from colored lipids in plant foods (Chapter 10)
- Expanded and updated section on **lipid rafts and caveolae** to include new material on membrane curvature and the proteins that influence it, and introducing amphitropic proteins and annular lipids (Chapter 11)
- New section on the emerging role of **ribulose 5-phosphate** as a central regulator of glycolysis and gluconeogenesis (Chapter 15)
- New Box 16–1, Moonlighting Enzymes: **Proteins with More Than One Job**
- New section on the role of transcription factors (**PPARs**) in regulation of lipid catabolism (Chapter 17)
- Revised and updated section on **fatty acid synthase**, including new structural information on FAS I (Chapter 21)
■ Updated coverage of the nitrogen cycle, including new Box 22–1, Unusual Life Styles of the Obscure but Abundant, discussing **anammox bacteria** (Chapter 22)

■ New Box 24–2, Epigenetics, Nucleosome Structure, and Histone Variants describing the role of **histone modification and nucleosome deposition** in the transmission of epigenetic information in heredity

■ New information on the initiation of replication and the dynamics at the replication fork, introducing **AAA+ ATPases** and their functions in replication and other aspects of DNA metabolism (Chapter 25)

■ New section on the expanded understanding of the roles of RNA in cells (Chapter 26)

■ New information on the **roles of RNA in protein biosynthesis** (Chapter 27)

■ New section on **riboswitches** (Chapter 28)

■ New Box 28–1, Of Fins, Wings, Beaks, and Things, describing the connections between **evolution and development**

---

**Biochemical Methods**

An appreciation of biochemistry often requires an understanding of how biochemical information is obtained. Some of the new methods or updates described in this edition are:

■ Circular dichroism (Chapter 4)

■ Measurement of glycated hemoglobin as an indicator of average blood glucose concentration, over days, in persons with diabetes (Chapter 7)

■ Use of MALDI-MS in determination of oligosaccharide structure (Chapter 7)

■ Forensic DNA analysis, a major update covering modern STR analysis (Chapter 9)

■ More on microarrays (Chapter 9)

■ Use of tags for protein analysis and purification (Chapter 9)

■ PET combined with CT scans to pinpoint cancer (Chapter 14)

■ Chromatin immunoprecipitation and ChIP-chip experiments (Chapter 24)

■ Development of bacterial strains with altered genetic codes, for site-specific insertion of novel amino acids into proteins (Chapter 27)
Medically Relevant Examples

This icon is used throughout the book to denote material of special medical interest. As teachers, our goal is for students to learn biochemistry and to understand its relevance to a healthier life and a healthier planet. We have included many new examples that relate biochemistry to medicine and to health issues in general. Some of the medical applications new to this edition are:

- The role of polyunsaturated fatty acids and trans fatty acids in cardiovascular disease (Chapter 10)
- G protein-coupled receptors (GPCRs) and the range of diseases for which drugs targeted to GPCRs are being used or developed (Chapter 12)
- G proteins, the regulation of GTPase activity, and the medical consequences of defective G protein function (Chapter 12), including new Box 12–2, G Proteins: Binary Switches in Health and Disease
- Box 12–5, Development of Protein Kinase Inhibitors for Cancer Treatment
- Box 14–1, High Rate of Glycolysis in Tumors Suggests Targets for Chemotherapy and Facilitates Diagnosis

Special Theme: Understanding Metabolism through Obesity and Diabetes

Obesity and its medical consequences—cardiovascular disease and diabetes—are fast becoming epidemic in the industrialized world, and we include new material on the biochemical connections between obesity and health throughout this edition. Our focus on diabetes provides an integrating theme throughout the chapters on metabolism and its control, and this will, we hope, inspire some students to find solutions for this disease. Some of the sections and boxes that highlight the interplay of metabolism, obesity, and diabetes are:

- Untreated Diabetes Produces Life-Threatening Acidosis (Chapter 2)
- Box 7–1, Blood Glucose Measurements in the Diagnosis and Treatment of Diabetes, introducing hemoglobin glycation and AGEs and their role in the pathology of advanced diabetes
- Box 11–2, Defective Glucose and Water Transport in Two Forms of Diabetes
- Glucose Uptake Is Deficient in Type 1 Diabetes Mellitus (Chapter 14)
- Ketone Bodies Are Overproduced in Diabetes and during Starvation (Chapter 17)
- Some Mutations in Mitochondrial Genomes Cause Disease (Chapter 19)
- Diabetes Can Result from Defects in the Mitochondria of Pancreatic β Cells (Chapter 19)
- Box 15–3, Genetic Mutations That Lead to Rare Forms of Diabetes
- Mutations in citric acid cycle enzymes that lead to cancer (Chapter 16)
- Pernicious anemia and associated problems in strict vegetarians (Chapter 18)
- Updated information on cyclooxygenase inhibitors (pain relievers Vioxx, Celebrex, Bextra) (Chapter 21)
- HMG-CoA reductase (Chapter 21) and Box 21–3, The Lipid Hypothesis and the Development of Statins
- Box 24–1, Curing Disease by Inhibiting Topoisomerases, describing the use of topoisomerase inhibitors in the treatment of bacterial infections and cancer, including material on ciprofloxacin (the antibiotic effective for anthrax)
- Adipose Tissue Generates Glycerol 3-phosphate by Glyceroneogenesis (Chapter 21)
- Diabetes Mellitus Arises from Defects in Insulin Production or Action (Chapter 23)
- Section 23.4, Obesity and the Regulation of Body Mass, discusses the role of adiponectin and insulin sensitivity and type 2 diabetes
- Section 23.5, Obesity, the Metabolic Syndrome, and Type 2 Diabetes, includes a discussion of managing type 2 diabetes with exercise, diet, and medication

FIGURE 23–42
Advances in Teaching Biochemistry

Revising this textbook is never just an updating exercise. At least as much time is spent reexamining how the core topics of biochemistry are presented. We have revised each chapter with an eye to helping students learn and master the fundamentals of biochemistry. Students encountering biochemistry for the first time often have difficulty with two key aspects of the course: approaching quantitative problems and drawing on what they learned in organic chemistry to help them understand biochemistry. Those same students must also learn a complex language, with conventions that are often unstated. We have made some major changes in the book to help students cope with all these challenges: new problem-solving tools, a focus on organic chemistry foundations, and highlighted key conventions.

New Problem-Solving Tools

- **New in-text Worked Examples** help students improve their quantitative problem-solving skills, taking them through some of the most difficult equations.
- **More than 100 new end-of-chapter problems** give students further opportunity to practice what they have learned.
- **New Data Analysis Problems** (one at the end of each chapter), contributed by Brian White of the University of Massachusetts–Boston, encourage students to synthesize what they have learned and apply their knowledge to the interpretation of data from the literature.

Focus on Organic Chemistry Foundations

- **New Section 13.2**, *Chemical logic and common biochemical reactions*, discusses the common biochemical reaction types that underlie all metabolic reactions.
- **Chemical logic** is reinforced in the discussions of central metabolic pathways.
- **Mechanism figures** feature step-by-step descriptions to help students understand the reaction process.
- In the presentation of reaction mechanisms, we consistently use a set of conventions introduced and explained in detail with the first enzyme mechanism encountered (chymotrypsin, pp. 208–209). Some of the new problems focus on chemical mechanisms and reinforce mechanistic themes.

Key Conventions

In this edition, many of the conventions that are so necessary for understanding each biochemical topic and the biochemical literature are broken out of the text and highlighted. These **Key Conventions** include clear statements of many assumptions and conventions that students are often expected to assimilate without being told (for example, peptide sequences are written from amino-to carboxyl-terminal end, left to right; nucleotide sequences are written from 5’ to 3’ end, left to right).
Media and Supplements

A full package of media resources and supplements provides instructors and students with innovative tools to support a variety of teaching and learning approaches. All these resources are fully integrated with the style and goals of the fifth edition textbook.

**eBook**

This online version of the textbook combines the contents of the printed book, electronic study tools, and a full complement of student media specifically created to support the text. The eBook also provides useful material for instructors.

- **eBook study tools** include instant navigation to any section or page of the book, bookmarks, highlighting, note-taking, instant search for any term, pop-up key-term definitions, and a spoken glossary.
- The text-specific **student media**, fully integrated throughout the eBook, include animated enzyme mechanisms, animated biochemical techniques, problem-solving videos, molecular structure tutorials in Jmol, Protein Data Bank IDs in Jmol, living graphs, and online quizzes (each described under “Additional Student Media” below).
- **Instructor features** include the ability to add notes or files to any page and to share these notes with students. Notes may include text, Web links, animations, or photos. Instructors can also assign the entire text or a custom version of the eBook.

**Additional Instructor Media**

**Instructors** are provided with a comprehensive set of teaching tools, each developed to support the text, lecture presentations, and individual teaching styles. All instructor media are available for download on the book Web site (www.whfreeman.com/lehninger5e) and on the **Instructor Resource CD/DVD** (ISBN 1-4292-1912-2). These media tools include:

- **Fully optimized JPEG files** of every figure, photo, and table in the text, with enhanced color, higher resolution, and enlarged fonts. The files have been reviewed by course instructors and tested in a large lecture hall to ensure maximum clarity and visibility. The JPEGs are also offered in separate files and in PowerPoint® format for each chapter.
- The 150 most popular images in the textbook are available in an **Overhead Transparency Set** (ISBN 1-4292-1911-4), fully optimized for maximum visibility in the lecture hall.
- **Animated Enzyme Mechanisms** and **Animated Biochemical Techniques** are available in Flash files and preloaded into PowerPoint, in both PC and Macintosh formats, for lecture presentation. (See list of animation topics on the inside front cover.)
- A list of **Protein Data Bank IDs** for the structures in the text is provided, arranged by figure number. A new feature in this edition is an index to all structures in the Jmol interactive Web browser applet.
- **Living Graphs** illustrate key equations from the textbook, showing the graphic results of changing parameters.
- A comprehensive **Test Bank** in PDF and editable Word formats includes 150 multiple-choice and short-answer problems per chapter, rated by level of difficulty.

**Additional Student Media**

**Students** are provided with media designed to enhance their understanding of biochemical principles and improve their problem-solving ability. All student media, along with the **PDB Structures** and **Living Graphs**, are also in the eBook, and many are available on the book Web site (www.whfreeman.com/lehninger5e). The student media include:

- **New Problem-Solving Videos**, created by Scott Ensign of Utah State University provide 24/7 online problem-solving help to students. Through a two-part approach, each 10-minute video covers a key textbook problem representing a topic that students traditionally struggle to master. Dr. Ensign first describes a proven problem-solving strategy and then applies the strategy to the problem at hand in clear, concise steps. Students can easily pause, rewind, and review any steps as they wish until they firmly grasp not just the solution but also the reasoning behind it. Working through the problems in this way is designed to make students better and more confident at applying key strategies as they solve other textbook and exam problems.
- **Student versions of the Animated Enzyme Mechanisms** and **Animated Biochemical Techniques** help students understand key mechanisms and techniques at their own pace. For a complete list of animation topics, see the inside front cover.
Molecular Structure Tutorials, using the Jmol-Web browser applet, allow students to explore in more depth the molecular structures included in the textbook, including:

- Protein Architecture
- Bacteriorhodopsin
- Lac Repressor
- Nucleotides
- MHC Molecules
- Trimeric G Proteins
- Oxygen-Binding Proteins
- Restriction Endonucleases
- Hammerhead Ribozyme

Online Quizzes include approximately 20 challenging multiple-choice questions for each chapter, with automatic grading and text references and feedback on all answers.

Discussion Questions: provided for each section; designed for individual review, study groups, or classroom discussion

A Self-Test: "Do you know the terms?"; crossword puzzles; multiple-choice, fact-driven questions; and questions that ask students to apply their new knowledge in new directions—plus answers!

Acknowledgements

This book is a team effort, and producing it would be impossible without the outstanding people at W. H. Freeman and Company who supported us at every step along the way. Randi Rossignol (Senior Editor) and Kate Ahr (Executive Editor) arranged reviews, made many helpful suggestions, encouraged us, kept us on target, and tried valiantly (if not always successfully) to keep us on schedule. Our outstanding Project Editor, Liz Geller, somehow kept the book moving through production in spite of our missed deadlines and last-minute changes, and did so with her usual grace and skill. We thank Vicki Tomaselli for developing the design, and Marsha Cohen for the beautiful layout. We again had the good fortune to work with Linda Strange, a superb copy editor who has edited all five editions of Principles of Biochemistry (as well as the two editions of its predecessor, Lehninger's Biochemistry). Her contributions are invaluable and enhance the text wherever she touches it. We were also again fortunate to have the contributions and insights of Morgan Ryan, who worked with us on the third and fourth editions. We thank photo researcher Dena Digilio Betz for her help locating images, and Nick Tymoczko and Whitney Clench for keeping the paper and files flowing among all participants in the project. Our gratitude also goes to Debbie Clare, Associate Director of Marketing, for her creativity and good humor in coordinating the sales and marketing effort.

In Madison, Brook Soltvedt is (and has been for all the editions we have worked on) our first-line editor and critic. She is the first to see manuscript chapters, aids in manuscript and art development, ensures internal consistency in content and nomenclature, and keeps us on task with more-or-less gentle prodding. As she did for the fourth edition, Shelley Lusetti, now of New Mexico State University, read every word of the text in proofs, caught numerous mistakes, and made many suggestions that improved the book.

The new art in this edition, including the new molecular graphics, was done by Adam Steinberg, here in Madison, who often made valuable suggestions that led to better and clearer illustrations. This edition also contains many molecular graphics produced for the third and fourth editions by Jean-Yves Sgro, another Madison
colleague. We feel very fortunate to have such gifted partners as Brook, Shelley, Adam, and Jean-Yves on our team.

We are also deeply indebted to Brian White of the University of Massachusetts–Boston, who wrote the new data analysis problems at the end of each chapter.

Many colleagues played a special role throughout the project and their timely input. Prominent among these are Laurens Anderson of the University of Wisconsin–Madison; Jeffrey D. Esko of the University of California, San Diego; Jack Kirsch and his students at the University of California, Berkeley; and Dana Aswad, Shiou-Chuan (Sheryl) Tsai, Michael G. Cumsky, and their colleagues (listed below) at the University of California, Irvine. Many others helped us shape this fifth edition with their comments, suggestions, and criticisms. To all of them, we are deeply grateful:

Richard M. Amasino, University of Wisconsin–Madison
Louise E. Anderson, University of Illinois at Chicago
Cheryl Bailey, University of Nebraska, Lincoln
Kenneth Balazovich, University of Michigan
Thomas O. Baldwin, University of Arizona
Vahe Bandarian, University of Arizona
Eugene Barber, University of Rochester
Sebastian Y. Bednarek, University of Wisconsin–Madison
Ramachandra Bhat, Lincoln University
James Blankenship, Cornell University
Sandra J. Bonetti, Colorado State University, Pueblo
Barbara Bowman, University of California, Berkeley
Scott D. Briggs, Purdue University
Jeff Brodsky, University of Pittsburgh
Ben Caldwell, Missouri Western State University
David Camerini, University of California, Irvine
Guillaume Chanfreau, University of California, Los Angeles
Melanie Cocco, University of California, Irvine
Jeffrey Cohlbberg, California State University, Long Beach
Kim D. Collins, University of Maryland
Charles T. Dameron, Duquesne University
Richard S. Eisenstein, University of Wisconsin–Madison
Gerald W. Feigenson, Cornell University
Robert H. Fillingame, University of Wisconsin–Madison
Brian Fox, University of Wisconsin–Madison
Gerald D. Frenkel, Rutgers University
Perry Frey, University of Wisconsin–Madison
David E. Graham, University of Texas–Austin
William J. Grimes, University of Arizona
Martyn Gunn, Texas A&M University
Olivia Hanson, University of Central Oklahoma
Amy Hark, Muhlenberg College
Shaun V. Hernandez, University of Wisconsin–Madison
Peter Hinkle, Cornell University
P. Shing Ho, Oregon State University
Charles G. Hoogstraten, Michigan State University
Gerwald Jogi, Brown University
Sir Hans Kornberg, Boston University
Bob Landick, University of Wisconsin–Madison
Patrick D. Larkin, Texas A&M University, Corpus Christi
Ryan P. Liegel, University of Wisconsin–Madison
Maria Linder, California State University, Fullerton
Andy C. LiWang, Texas A&M University
John Makemson, Florida International University
John C. Matthews, University of Mississippi, School of Pharmacy
Benjamin J. McFarland, Seattle Pacific University
Anant Menon, Weill Cornell Medical College
Sabeeha Merchant, University of California, Los Angeles

We lack the space here to acknowledge all the other individuals whose special efforts went into this book. We offer instead our sincere thanks—and the finished book that they helped guide to completion. We, of course, assume full responsibility for errors of fact or emphasis.

We want especially to thank our students at the University of Wisconsin–Madison for their numerous comments and suggestions. If something in the book does not work, they are never shy about letting us know it. We are grateful to the students and staff of our research groups and of the Center for Biology Education, who helped us balance the competing demands on our time; to our colleagues in the Department of Biochemistry at the University of Wisconsin–Madison, who helped us with advice and criticism; and to the many students and teachers who have written to suggest ways of improving the book. We hope our readers will continue to provide input for future editions.

Finally, we express our deepest appreciation to our wives, Brook and Beth, and our families, who showed extraordinary patience with, and support for, our book writing.

Index I-1
1.5 Evolutionary Foundations
Changes in the Hereditary Instructions Allow Evolution
Biomolecules First Arose by Chemical Evolution
RNA or Related Precursors May Have Been the First Genes and Catalysts
Biological Evolution Began More Than Three and a Half Billion Years Ago
The First Cell Probably Used Inorganic Fuels
Eukaryotic Cells Evolved from Simpler Precursors in Several Stages
Molecular Anatomy Reveals Evolutionary Relationships
Functional Genomics Shows the Allocations of Genes to Specific Cellular Processes
Genomic Comparisons Have Increasing Importance in Human Biology and Medicine

I STRUCTURE AND CATALYSIS

2 Water

2.1 Weak Interactions in Aqueous Systems
Hydrogen Bonding Gives Water Its Unusual Properties
Water Forms Hydrogen Bonds with Polar Solutes
Water Interacts Electrostatically with Charged Solutes
Entropy Increases as Crystalline Substances Dissolve
Nonpolar Gases Are Poorly Soluble in Water
Nonpolar Compounds Force Energetically Unfavorable Changes in the Structure of Water
van der Waals Interactions Are Weak Interatomic Attractions
Weak Interactions Are Crucial to Macromolecular Structure and Function
Solute s Affect the Colligative Properties of Aqueous Solutions

2.2 Ionization of Water, Weak Acids, and Weak Bases
Pure Water Is Slightly Ionized
The Ionization of Water Is Expressed by an Equilibrium Constant
The pH Scale Designates the H+ and OH—Concentrations
Weak Acids and Bases Have Characteristic Acid Dissociation Constants
Titration Curves Reveal the pk a of Weak Acids

2.3 Buffering against pH Changes in Biological Systems
Buffers Are Mixtures of Weak Acids and Their Conjugate Bases
The Henderson-Hasselbalch Equation Relates pH, pk a, and Buffer Concentration
Weak Acids or Bases Buffer Cells and Tissues against pH Changes
Untreated Diabetes Produces Life-Threatening Acidosis

Box 2-1 Medicine: On Being One's Own Rabbit
(Don't Try This at Home!)

2.4 Water as a Reactant

2.5 The Fitness of the Aqueous Environment for Living Organisms

3 Amino Acids, Peptides, and Proteins

3.1 Amino Acids
Amino Acids Share Common Structural Features
The Amino Acid Residues in Proteins Are L Stereoisomers
Amino Acids Can Be Classified by R Group

Box 3-1 Methods: Absorption of Light by Molecules:
The Lambert-Beer Law
Uncommon Amino Acids Also Have Important Functions
Amino Acids Can Act as Acids and Bases
Amino Acids Have Characteristic Titration Curves
Titration Curves Predict the Electric Charge of Amino Acids
Amino Acids Differ in Their Acid-Base Properties

3.2 Peptides and Proteins
Peptides Are Chains of Amino Acids
Peptides Can Be Distinguished by Their Ionization Behavior
Biologically Active Peptides and Polypeptides Occur in a Vast Range of Sizes and Compositions
Some Proteins Contain Chemical Groups Other Than Amino Acids

3.3 Working with Proteins
Proteins Can Be Separated and Purified
Proteins Can Be Separated and Characterized by Electrophoresis
Unseparated Proteins Can Be Quantified

3.4 The Structure of Proteins: Primary Structure
The Function of a Protein Depends on Its Amino Acid Sequence
The Amino Acid Sequences of Millions of Proteins Have Been Determined
Short Polypeptides Are Sequenced with Automated Procedures
Large Proteins Must Be Sequenced in Smaller Segments
Amino Acid Sequences Can Also Be Deduced by Other Methods

Box 3–2 Methods: Investigating Proteins with Mass Spectrometry
Small Peptides and Proteins Can Be Chemically Synthesized
Amino Acid Sequences Provide Important Biochemical Information
Protein Sequences Can Elucidate the History of Life on Earth

Box 3–3 Consensus Sequences and Sequence Logos
4 The Three-Dimensional Structure of Proteins

4.1 Overview of Protein Structure
- A Protein's Conformation Is Stabilized Largely by Weak Interactions
- The Peptide Bond Is Rigid and Planar

4.2 Protein Secondary Structure
- The α Helix Is a Common Protein Secondary Structure

Box 4–1 Methods: Knowing the Right Hand from the Left
- Amino Acid Sequence Affects Stability of the α Helix
- The β Conformation Organizes Polypeptide Chains into Sheets
- β Turns Are Common in Proteins
- Common Secondary Structures Have Characteristic Dihedral Angles
- Common Secondary Structures Can Be Assessed by Circular Dichroism

4.3 Protein Tertiary and Quaternary Structures
- Fibrous Proteins Are Adapted for a Structural Function

Box 4–2 Permanent Waving Is Biochemical Engineering

Box 4–3 Medicine: Why Sailors, Explorers, and College Students Should Eat Their Fresh Fruits and Vegetables

Box 4–4 The Protein Data Bank
- Structural Diversity Reflects Functional Diversity in Globular Proteins
- Myoglobin Provided Early Clues about the Complexity of Globular Protein Structure
- Globular Proteins Have a Variety of Tertiary Structures

Box 4–5 Methods: Methods for Determining the Three-Dimensional Structure of a Protein
- Protein Motifs Are the Basis for Protein Structural Classification
- Protein Quaternary Structures Range from Simple Diners to Large Complexes

4.4 Protein Denaturation and Folding
- Loss of Protein Structure Results in Loss of Function
- Amino Acid Sequence Determines Tertiary Structure
- Polypeptides Fold Rapidly by a Stepwise Process
- Some Proteins Undergo Assisted Folding
- Defects in Protein Folding May Be the Molecular Basis for a Wide Range of Human Genetic Disorders

Box 4–6 Medicine: Death by Misfolding: The Prion Diseases

5 Protein Function

5.1 Reversible Binding of a Protein to a Ligand: Oxygen-Binding Proteins
- Oxygen Can Bind to a Heme Prosthetic Group
- Myoglobin Has a Single Binding Site for Oxygen
- Protein-Ligand Interactions Can Be Described Quantitatively

Protein Structure Affects How Ligands Bind
Hemoglobin Transports Oxygen in Blood
Hemoglobin Subunits Are Structurally Similar to Myoglobin
Hemoglobin Undergoes a Structural Change on Binding Oxygen
Hemoglobin Binds Oxygen Cooperatively
Cooperative Ligand Binding Can Be Described Quantitatively

Box 5–1 Medicine: Carbon Monoxide: A Stealthy Killer
- Two Models Suggest Mechanisms for Cooperative Binding
- Hemoglobin Also Transports H⁺ and CO₂
- Oxygen Binding to Hemoglobin Is Regulated by 2,3-Bisphosphoglycerate
- Sickle-Cell Anemia Is a Molecular Disease of Hemoglobin

5.2 Complementary Interactions between Proteins and Ligands: The Immune System and Immunoglobulins
- The Immune Response Features a Specialized Array of Cells and Proteins
- Antibodies Have Two Identical Antigen-Binding Sites
- Antibodies Bind Tightly and Specifically to Antigen
- The Antibody-Antigen Interaction Is the Basis for a Variety of Important Analytical Procedures

5.3 Protein Interactions Modulated by Chemical Energy: Actin, Myosin, and Molecular Motors
- The Major Proteins of Muscle Are Myosin and Actin
- Additional Proteins Organize the Thin and Thick Filaments into Ordered Structures
- Myosin Thick Filaments Slide along Actin Thin Filaments

6 Enzymes

6.1 An Introduction to Enzymes
- Most Enzymes Are Proteins
- Enzymes Are Classified by the Reactions They Catalyze

6.2 How Enzymes Work
- Enzymes Affect Reaction Rates, Not Equilibria
- Reaction Rates and Equilibria Have Precise Thermodynamic Definitions
- A Few Principles Explain the Catalytic Power and Specificity of Enzymes
- Weak Interactions between Enzyme and Substrate Are Optimized in the Transition State
- Binding Energy Contributes to Reaction Specificity and Catalysis
- Specific Catalytic Groups Contribute to Catalysis

6.3 Enzyme Kinetics as an Approach to Understanding Mechanism
- Substrate Concentration Affects the Rate of Enzyme-Catalyzed Reactions
- The Relationship between Substrate Concentration and Reaction Rate Can Be Expressed Quantitatively
Contents

Box 6–1 Transformations of the Michaelis-Menten Equation:
The Double-Reciprocal Plot
Kinetic Parameters Are Used to Compare Enzyme Activities
Many Enzymes Catalyze Reactions with Two or More Substrates
Pre–Steady State Kinetics Can Provide Evidence for Specific Reaction Steps
Enzymes Are Subject to Reversible or Irreversible Inhibition

Box 6–2 Kinetic Tests for Determining Inhibition Mechanisms
Enzyme Activity Depends on pH

6.4 Examples of Enzymatic Reactions
The Chymotrypsin Mechanism Involves Acylation and Deacylation of a Ser Residue

Box 6–3 Evidence for Enzyme–Transition State Complementarity
Hexokinase Undergoes Induced Fit on Substrate Binding
The Enolase Reaction Mechanism Requires Metal Ions
Lysozyme Uses Two Successive Nucleophilic Displacement Reactions
An Understanding of Enzyme Mechanism Drives Important Advances in Medicine

6.5 Regulatory Enzymes
Allosteric Enzymes Undergo Conformational Changes in Response to Modulator Binding
In Many Pathways, Regulated Steps Are Catalyzed by Allosteric Enzymes
The Kinetic Properties of Allosteric Enzymes Diverge from Michaelis-Menten Behavior
Some Enzymes Are Regulated by Reversible Covalent Modification
Phosphoryl Groups Affect the Structure and Catalytic Activity of Enzymes
Multiple Phosphorylations Allow Exquisite Regulatory Control
Some Enzymes and Other Proteins Are Regulated by Proteolytic Cleavage of an Enzyme Precursor
Some Regulatory Enzymes Use Several Regulatory Mechanisms

7 Carbohydrates and Glycobiology

7.1 Monosaccharides and Disaccharides
The Two Families of Monosaccharides Are Aldoses and Ketoses
Monosaccharides Have Asymmetric Centers
The Common Monosaccharides Have Cyclic Structures
Organisms Contain a Variety of Hexose Derivatives
Monosaccharides Are Reducing Agents

Box 7–1 Medicine: Blood Glucose Measurements in the Diagnosis and Treatment of Diabetes
Disaccharides Contain a Glycosidic Bond

7.2 Polysaccharides
Some Homopolysaccharides Are Stored Forms of Fuel
Some Homopolysaccharides Serve Structural Roles
Steric Factors and Hydrogen Bonding Influence Homopolysaccharide Folding
Bacterial and Algal Cell Walls Contain Structural Heteropolysaccharides
Glycosaminoglycans Are Heteropolysaccharides of the Extracellular Matrix

7.3 Glycoconjugates: Proteoglycans, Glycoproteins, and Glycolipids
Proteoglycans Are Glycosaminoglycan-Containing Macromolecules of the Cell Surface and Extracellular Matrix
Glycoproteins Have Covalently Attached Oligosaccharides
Glycolipids and Lipopolysaccharides Are Membrane Components

7.4 Carbohydrates as Informational Molecules: The Sugar Code
Lectins Are Proteins That Read the Sugar Code and Mediate Many Biological Processes
Lectin-Carbohydrate Interactions Are Highly Specific and Often Polyvalent

7.5 Working with Carbohydrates

8 Nucleotides and Nucleic Acids

8.1 Some Basics
Nucleotides and Nucleic Acids Have Characteristic Bases and Pentoses
Phosphodiester Bonds Link Successive Nucleotides in Nucleic Acids
The Properties of Nucleotide Bases Affect the Three-Dimensional Structure of Nucleic Acids

8.2 Nucleic Acid Structure
DNA Is a Double Helix that Stores Genetic Information
DNA Can Occur in Different Three-Dimensional Forms
Certain DNA Sequences Adopt Unusual Structures
Messenger RNAs Code for Polypeptide Chains
Many RNAs Have More Complex Three-Dimensional Structures

8.3 Nucleic Acid Chemistry
Double-Helical DNA and RNA Can Be Denatured
Nucleic Acids from Different Species Can Form Hybrids
Nucleotides and Nucleic Acids Undergo Nonenzymatic Transformations
Some Bases of DNA Are Methylated
The Sequences of Long DNA Strands Can Be Determined
The Chemical Synthesis of DNA Has Been Automated
8.4 Other Functions of Nucleotides
Nucleotides Carry Chemical Energy in Cells
Adenine Nucleotides Are Components of Many Enzyme Cofactors
Some Nucleotides Are Regulatory Molecules

9 DNA-Based Information Technologies
9.1 DNA Cloning: The Basics
Restriction Endonucleases and DNA Ligase Yield Recombinant DNA
Cloning Vectors Allow Amplification of Inserted DNA Segments
Specific DNA Sequences Are Detectable by Hybridization
Expression of Cloned Genes Produces Large Quantities of Protein
Alterations in Cloned Genes Produce Modified Proteins
Terminal Tags Provide Binding Sites for Affinity Purification

9.2 From Genes to Genomes
DNA Libraries Provide Specialized Catalogs of Genetic Information
The Polymerase Chain Reaction Amplifies Specific DNA Sequences
Genome Sequences Provide the Ultimate Genetic Libraries

Box 9–1 A Potent Weapon in Forensic Medicine

9.3 From Genomes to Proteomes
Sequence or Structural Relationships Provide Information on Protein Function
Cellular Expression Patterns Can Reveal the Cellular Function of a Gene
Detection of Protein-Protein Interactions Helps to Define Cellular and Molecular Function

9.4 Genome Alterations and New Products of Biotechnology
A Bacterial Plant Parasite Aids Cloning in Plants
Manipulation of Animal Cell Genomes Provides Information on Chromosome Structure and Gene Expression

Box 9–2 Medicine: The Human Genome and Human Gene Therapy
New Technologies Promise to Expedite the Discovery of New Pharmaceuticals
Recombinant DNA Technology Yields New Products and Challenges

10 Lipids
10.1 Storage Lipids
Fatty Acids Are Hydrocarbon Derivatives
Triacylglycerols Are Fatty Acid Esters of Glycerol
Triacylglycerols Provide Stored Energy and Insulation

Box 10–1 Sperm Whales: Fatheads of the Deep
Partial Hydrogenation of Cooking Oils Produces Trans Fatty Acids
Waxes Serve as Energy Stores and Water Repellents

10.2 Structural Lipids in Membranes
Glycerophospholipids Are Derivatives of Phosphatidic Acid
Some Glycerophospholipids Have Ether-Linked Fatty Acids
Chloroplasts Contain Galactolipids and Sulfolipids
Archaea Contain Unique Membrane Lipids
Sphingolipids Are Derivatives of Sphingosine
Sphingolipids at Cell Surfaces Are Sites of Biological Recognition
Phospholipids and Sphingolipids Are Degraded in Lysosomes
Sterols Have Four Fused Carbon Rings

Box 10–2 Medicine: Abnormal Accumulations of Membrane Lipids: Some Inherited Human Diseases
10.3 Lipids as Signals, Cofactors, and Pigments
Phosphatidylinositol and Sphingosine Derivatives Act as Intracellular Signals
Eicosanoids Carry Messages to Nearby Cells
Steroid Hormones Carry Messages between Tissues
Vascular Plants Produce Thousands of Volatile Signals
Vitamins A and D Are Hormone Precursors
Vitamins E and K and the Lipid Quinones Are Oxidation-Reduction Cofactors
Dolichols Activate Sugar Precursors for Biosynthesis
Many Natural Pigments Are Lipidic Conjugated Dienes

10.4 Working with Lipids
Lipid Extraction Requires Organic Solvents
Adsorption Chromatography Separates Lipids of Different Polarity
Gas-Liquid Chromatography Resolves Mixtures of Volatile Lipid Derivatives
Specific Hydrolysis Aids in Determination of Lipid Structure
Mass Spectrometry Reveals Complete Lipid Structure
Lipidomics Seeks to Catalog All Lipids and Their Functions

11 Biological Membranes and Transport
11.1 The Composition and Architecture of Membranes
Each Type of Membrane Has Characteristic Lipids and Proteins
All Biological Membranes Share Some Fundamental Properties
A Lipid Bilayer Is the Basic Structural Element of Membranes
Three Types of Membrane Proteins Differ in Their Association with the Membrane
Many Membrane Proteins Span the Lipid Bilayer
Integral Proteins Are Held in the Membrane by Hydrophobic Interactions with Lipids
The Topology of an Integral Membrane Protein Can Sometimes Be Predicted from Its Sequence
Covalently Attached Lipids Anchor Some Membrane Proteins

11.2 Membrane Dynamics
Acyl Groups in the Bilayer Interior Are Ordered to Varying Degrees
Transbilayer Movement of Lipids Requires Catalysis
Lipids and Proteins Diffuse Laterally in the Bilayer
Sphingolipids and Cholesterol Cluster Together in Membrane Rafts

Box 11-1 Methods: Atomic Force Microscopy to Visualize Membrane Proteins
Membrane Curvature and Fusion Are Central to Many Biological Processes
Integral Proteins of the Plasma Membrane Are Involved in Surface Adhesion, Signaling, and Other Cellular Processes

11.3 Solute Transport across Membranes
Passive Transport Is Facilitated by Membrane Proteins
Transporters Can Be Grouped into Superfamilies Based on Their Structures
The Glucose Transporter of Erythrocytes Mediates Passive Transport
The Chloride-Bicarbonate Exchanger Catalyzes Electroneutral Cotransport of Anions across the Plasma Membrane

Box 11-2 Medicine: Defective Glucose and Water Transport in Two Forms of Diabetes
Active Transport Results in Solute Movement against a Concentration or Electrochemical Gradient
P-Type ATPases Undergo Phosphorylation during Their Catalytic Cycles
P-Type ATPases Are Reversible, ATP-Driven Proton Pumps
ABC Transporters Use ATP to Drive the Active Transport of a Wide Variety of Substrates
Ion Gradients Provide the Energy for Secondary Active Transport

Box 11-3 Medicine: A Defective Ion Channel in Cystic Fibrosis
Aquaporins Form Hydrophilic Transmembrane Channels for the Passage of Water
Ion-Selective Channels Allow Rapid Movement of Ions across Membranes
Ion-Channel Function Is Measured Electrically
The Structure of a K⁺ Channel Reveals the Basis for Its Specificity
Gated Ion Channels Are Central in Neuronal Function
Defective Ion Channels Can Have Severe Physiological Consequences

12 Biosignaling

12.1 General Features of Signal Transduction
Box 12-1 Methods: Scatchard Analysis Quantifies the Receptor-Ligand Interaction
Fermentations Are Used to Produce Some Common Foods and Industrial Chemicals 550

14.4 Gluconeogenesis 551
Conversion of Pyruvate to Phosphoenolpyruvate Requires Two Exergonic Reactions 553
Conversion of Fructose 1,6-Bisphosphate to Fructose 6-Phosphate Is the Second Bypass 556
Conversion of Glucose 6-Phosphate to Glucose Is the Third Bypass 556
Gluconeogenesis Is Energetically Expensive, but Essential 556
Citric Acid Cycle Intermediates and Some Amino Acids Are Glucogenic 557
Mammals Cannot Convert Fatty Acids to Glucose 557
Glycolysis and Gluconeogenesis Are Reciprocally Regulated 557

14.5 Pentose Phosphate Pathway of Glucose Oxidation 558
Box 14-4 Medicine: Why Pythagoras Wouldn’t Eat Falafel: Glucose 6-Phosphate Dehydrogenase Deficiency 559
The Oxidative Phase Produces Pentose Phosphates and NADPH 559
The Nonoxidative Phase Recycles Pentose Phosphates to Glucose 6-Phosphate 560
Wernicke-Korsakoff Syndrome Is Exacerbated by a Defect in Transketolase 563
Glucose 6-Phosphate Is Partitioned between Glycolysis and the Pentose Phosphate Pathway 563

15 Principles of Metabolic Regulation 569

15.1 Regulation of Metabolic Pathways 570
Cells and Organisms Maintain a Dynamic Steady State 571
Both the Amount and the Catalytic Activity of an Enzyme Can Be Regulated 571
Reactions Far from Equilibrium in Cells Are Common Points of Regulation 574
Adenine Nucleotides Play Special Roles in Metabolic Regulation 575

15.2 Analysis of Metabolic Control 577
The Contribution of Each Enzyme to Flux through a Pathway Is Experimentally Measurable 578
The Control Coefficient Quantifies the Effect of a Change in Enzyme Activity on Metabolite Flux through a Pathway 578
Box 15-1 Methods: Metabolic Control Analysis: Quantitative Aspects 579
The Elasticity Coefficient Is Related to an Enzyme’s Responsiveness to Changes in Metabolite or Regulator Concentrations 580
The Response Coefficient Expresses the Effect of an Outside Controller on Flux through a Pathway 581
Metabolic Control Analysis Has Been Applied to Carbohydrate Metabolism, with Surprising Results 581
Metabolic Control Analysis Suggests a General Method for Increasing Flux through a Pathway 582

15.3 Coordinated Regulation of Glycolysis and Gluconeogenesis 582
Hexokinase Isozymes of Muscle and Liver Are Affected Differently by Their Product, Glucose 6-Phosphate 583
Box 15–2 Isozymes: Different Proteins That Catalyze the Same Reaction 584
Hexokinase IV (Glucokinase) and Glucose 6-Phosphatase Are Transcriptionally Regulated 585
Phosphofructokinase-1 and Fructose 1,6-Bisphosphatase Are Reciprocally Regulated 585
Fructose 2,6-Bisphosphate Is a Potent Allosteric Regulator of PFK-1 and FBPase-1 587
Xylose 5-Phosphate Is a Key Regulator of Carbohydrate and Fat Metabolism 588
The Glycolytic Enzyme Pyruvate Kinase Is Allosterically Inhibited by ATP 588
The Gluconeogenic Conversion of Pyruvate to Phosphoenol Pyruvate Is Under Multiple Types of Regulation 590
Transcriptional Regulation of Glycolysis and Gluconeogenesis Changes the Number of Enzyme Molecules 590
Box 15–3 Medicine: Genetic Mutations That Lead to Rare Forms of Diabetes 593

15.4 The Metabolism of Glycogen in Animals 594
Glycogen Breakdown Is Catalyzed by Glycogen Phosphorylase 595
Glucose 1-Phosphate Can Enter Glycolysis or, in Liver, Replenish Blood Glucose 596
The Sugar Nucleotide UDP-Glucose Donates Glucose for Glycogen Synthesis 596
Box 15–4 Carl and Gerty Cori: Pioneers in Glycogen Metabolism and Disease 598
Glycogenin Primes the Initial Sugar Residues in Glycogen 601

15.5 Coordinated Regulation of Glycogen Synthesis and Breakdown 602
Glycogen Phosphorylase Is Regulated Allosterically and Hormonally 603
Glycogen Synthase Is Also Regulated by Phosphorylation and Dephosphorylation 605
Glycogen Synthase Kinase 3 Mediates Some of the Actions of Insulin 606
Phosphoprotein Phosphatase 1 Is Central to Glycogen Metabolism 606
Allosteric and Hormonal Signals Coordinate Carbohydrate Metabolism Globally 606
Carbohydrate and Lipid Metabolism Are Integrated by Hormonal and Allosteric Mechanisms 608

16 The Citric Acid Cycle 615

16.1 Production of Acetyl-CoA (Activated Acetate) 616
Pyruvate Is Oxidized to Acetyl-CoA and CO2 616
The Pyruvate Dehydrogenase Complex Requires Five Coenzymes 617
The Pyruvate Dehydrogenase Complex Consists of Three Distinct Enzymes
In Substrate Channeling, Intermediates Never Leave the Enzyme Surface

16.2 Reactions of the Citric Acid Cycle
The Citric Acid Cycle Has Eight Steps
Box 16–1 Moonlighting Enzymes: Proteins with More Than One Job
Box 16–2 Synthases and Synthetases; Ligases and Lyases; Kinases, Phosphatases, and Phosphorylases: Yes, the Names Are Confusing!
Box 16–3 Citrate: A Symmetric Molecule That Reacts Asymmetrically
The Energy of Oxidations in the Cycle Is Efficiently Conserved
Why Is the Oxidation of Acetate So Complicated? Citric Acid Cycle Components Are Important
Anaplerotic Reactions Replenish Citric Acid Cycle Intermediates
Box 16–4 Citrate Synthase, Soda Pop, and the World Food Supply
Biotin in Pyruvate Carboxylase Carries CO₂ Groups

16.3 Regulation of the Citric Acid Cycle
Production of Acetyl-CoA by the Pyruvate Dehydrogenase Complex Is Regulated by Allosteric and Covalent Mechanisms
The Citric Acid Cycle Is Regulated at Its Three Exergonic Steps
Substrate Channeling through Multi-enzyme Complexes May Occur in the Citric Acid Cycle
Some Mutations in Enzymes of the Citric Acid Cycle Lead to Cancer

16.4 The Glyoxylate Cycle
The Glyoxylate Cycle Produces Four-Carbon Compounds from Acetate
The Citric Acid and Glyoxylate Cycles Are Coordinate Regulated

17 Fatty Acid Catabolism

17.1 Digestion, Mobilization, and Transport of Fats
Dietary Fats Are Absorbed in the Small Intestine
Hormones Trigger Mobilization of Stored Triacylglycerols
Fatty Acids Are Activated and Transferred into Mitochondria

17.2 Oxidation of Fatty Acids
The β-Oxidation of Saturated Fatty Acids Has Four Basic Steps
The Four β-Oxidation Steps Are Repeated to Yield Acetyl-CoA and ATP
Box 17–1 Fat Bears Carry Out β-Oxidation in Their Sleep
Acetyl-CoA Can Be Further Oxidized in the Citric Acid Cycle
Oxidation of Unsaturated Fatty Acids Requires Two Additional Reactions
Complete Oxidation of Odd-Number Fatty Acids Requires Three Extra Reactions

Box 17–2 Coenzyme B₁₂: A Radical Solution to a Perplexing Problem
Fatty Acid Oxidation Is Tightly Regulated
Transcription Factors Turn on the Synthesis of Proteins for Lipid Catabolism
Genetic Defects in Fatty Acyl-CoA Dehydrogenases Cause Serious Disease
Peroxisomes Also Carry Out β-Oxidation
Plant Peroxisomes and Glyoxysomes Use Acetyl-CoA from β-Oxidation as a Biosynthetic Precursor
The β-Oxidation Enzymes of Different Organelles Have Diverged during Evolution
The ω-Oxidation of Fatty Acids Occurs in the Endoplasmic Reticulum
Phytanic Acid Undergoes ω-Oxidation in Peroxisomes

17.3 Ketone Bodies
Ketone Bodies, Formed in the Liver, Are Exported to Other Organs as Fuel
Ketone Bodies Are Overproduced in Diabetes and during Starvation

18 Amino Acid Oxidation and the Production of Urea

18.1 Metabolic Fates of Amino Groups
Dietary Protein Is Enzymatically Degraded to Amino Acids
Pyridoxal Phosphate Participates in the Transfer of α-Amino Groups to α-Ketoglutarate
Glutamate Releases Its Amino Group As Ammonia in the Liver

Box 18–1 Medicine: Assays for Tissue Damage
Glutamine Transports Ammonia in the Bloodstream
Alanine Transports Ammonia from Skeletal Muscles to the Liver
Ammonia Is Toxic to Animals

18.2 Nitrogen Excretion and the Urea Cycle
Urea Is Produced from Ammonia in Five Enzymatic Steps
The Citric Acid and Urea Cycles Can Be Linked
The Activity of the Urea Cycle Is Regulated at Two Levels
Pathway Interconnections Reduce the Energetic Cost of Urea Synthesis
Genetic Defects in the Urea Cycle Can Be Life-Threatening

18.3 Pathways of Amino Acid Degradation
Some Amino Acids Are Converted to Glucose, Others to Ketone Bodies
Several Enzyme Cofactors Play Important Roles in Amino Acid Catabolism
Six Amino Acids Are Degraded to Pyruvate
Seven Amino Acids Are Degraded to Acetyl-CoA
Phenylalanine Catabolism Is Genetically Defective in Some People 696
Five Amino Acids Are Converted to α-Ketoglutarate 698
Four Amino Acids Are Converted to Succinyl-CoA 699
Box 18–2 Medicine: Scientific Sleuths Solve a Murder Mystery 700
Branched-Chain Amino Acids Are Not Degraded in the Liver 701
Asparagine and Aspartate Are Degraded to Oxaloacetate 701

19 Oxidative Phosphorylation and Photophosphorylation 707

OXIDATIVE PHOSPHORYLATION

19.1 Electron-Transfer Reactions in Mitochondria 708
Electrons Are Funneled to Universal Electron Acceptors 709
Electrons Pass through a Series of Membrane-Bound Carriers 710
Electron Carriers Function in Multienzyme Complexes 712
Mitochondrial Complexes May Associate in Respirasomes 718
The Energy of Electron Transfer Is Efficiently Conserved in a Proton Gradient 718
Reactive Oxygen Species Are Generated during Oxidative Phosphorylation 720
Plant Mitochondria Have Alternative Mechanisms for Oxidizing NADH 721

Box 19–1 Hot, Stinking Plants and Alternative Respiratory Pathways 722

19.2 ATP Synthesis 723
ATP Synthase Has Two Functional Domains, F₀ and F₁ 725
ATP Is Stabilized Relative to ADP on the Surface of F₁ 725
The Proton Gradient Drives the Release of ATP from the Enzyme Surface 726
Each β Subunit of ATP Synthase Can Assume Three Different Conformations 726
Rotational Catalysis Is Key to the Binding-Change Mechanism for ATP Synthesis 728
Chemiosmotic Coupling Allows Nonintegral Stoichiometries of O₂ Consumption and ATP Synthesis 729
The Proton-Motive Force Energizes Active Transport 730
Shuttle Systems Indirectly Convey Cytosolic NADH into Mitochondria for Oxidation 731

19.3 Regulation of Oxidative Phosphorylation 732
Oxidative Phosphorylation Is Regulated by Cellular Energy Needs 733
An Inhibitory Protein Prevents ATP Hydrolysis during Hypoxia 733
Hypoxia Leads to ROS Production and Several Adaptive Responses 733

ATP-Producing Pathways Are Coordinate Regulated 734

19.4 Mitochondria in Thermogenesis, Steroid Synthesis, and Apoptosis 735
Uncoupled Mitochondria in Brown Adipose Tissue Produce Heat 736
Mitochondrial P-450 Oxygenases Catalyze Steroid Hydroxylations 736
Mitochondria Are Central to the Initiation of Apoptosis 737

19.5 Mitochondrial Genes: Their Origin and the Effects of Mutations 738
Mitochondria Evolved from Endosymbiotic Bacteria 739
Mutations in Mitochondrial DNA Accumulate throughout the Life of the Organism 739
Some Mutations in Mitochondrial Genomes Cause Disease 740
Diabetes Can Result from Defects in the Mitochondria of Pancreatic β Cells 741

PHOTOSYNTHESIS: HARVESTING LIGHT ENERGY

19.6 General Features of Photophosphorylation 742
Photosynthesis in Plants Takes Place in Chloroplasts 743
Light Drives Electron Flow in Chloroplasts 743

19.7 Light Absorption 744
Chlorophylls Absorb Light Energy for Photosynthesis 745
Accessory Pigments Extend the Range of Light Absorption 747
Chlorophyll Funnels the Absorbed Energy to Reaction Centers by Exciton Transfer 747

19.8 The Central Photochemical Event: Light-Driven Electron Flow 749
Bacteria Have One of Two Types of Single Photochemical Reaction Center 749
Kinetic and Thermodynamic Factors Prevent the Dissipation of Energy by Internal Conversion 751
In Plants, Two Reaction Centers Act in Tandem 752
Antenna Chlorophylls Are Tightly Integrated with Electron Carriers 754
The Cytochrome b₆f Complex Links Photosystems II and I 755
Cyclic Electron Flow between PSⅠ and the Cytochrome b₆f Complex Increases the Production of ATP Relative to NADPH 756
State Transitions Change the Distribution of LHCII between the Two Photosystems 756
Water Is Split by the Oxygen-Evolving Complex 756

19.9 ATP Synthesis by Photophosphorylation 759
A Proton Gradient Couples Electron Flow and Photophosphorylation 759
The Approximate Stoichiometry of Photophosphorylation Has Been Established 760
The ATP Synthase of Chloroplasts Is Like That of Mitochondria 760
19.10 The Evolution of Oxygenic Photosynthesis
Chloroplasts Evolved from Ancient Photosynthetic Bacteria
In *Halobacterium*, a Single Protein Absorbs Light and Pumps Protons to Drive ATP Synthesis

20 Carbohydrate Biosynthesis in Plants and Bacteria

20.1 Photosynthetic Carbohydrate Synthesis
Plastids Are Organelles Unique to Plant Cells and Algae
Carbon Dioxide Assimilation Occurs in Three Stages
Synthesis of Each Triose Phosphate from CO₂ Requires Six NADPH and Nine ATP
A Transport System Exports Triose Phosphates from the Chloroplast and Imports Phosphate
Four Enzymes of the Calvin Cycle Are Indirectly Activated by Light

20.2 Photorespiration and the C₄ and CAM Pathways
Photorespiration Results from Rubisco's Oxygenase Activity
The Salvage of Phosphoglycolate Is Costly
In C₄ Plants, CO₂ Fixation and Rubisco Activity Are Spatially Separated
In CAM Plants, CO₂ Capture and Rubisco Action Are Temporally Separated

20.3 Biosynthesis of Starch and Sucrose
ADP-Glucose Is the Substrate for Starch Synthesis in Plant Plastids and for Glycogen Synthesis in Bacteria
UDP-Glucose Is the Substrate for Sucrose Synthesis in the Cytosol of Leaf Cells
Conversion of Triose Phosphates to Sucrose and Starch Is Tightly Regulated

20.4 Synthesis of Cell Wall Polysaccharides:
Plant Cellulose and Bacterial Peptidoglycan
Cellulose Is Synthesized by Supramolecular Structures in the Plasma Membrane
Lipid-Linked Oligosaccharides Are Precursors for Bacterial Cell Wall Synthesis

20.5 Integration of Carbohydrate Metabolism in the Plant Cell
Glucoseoneogenesis Converts Fats and Proteins to Glucose in Germinating Seeds
Pools of Common Intermediates Link Pathways in Different Organelles

21 Lipid Biosynthesis

21.1 Biosynthesis of Fatty Acids and Eicosanoids
Malonyl-CoA Is Formed from Acetyl-CoA and Bicarbonate
Fatty Acid Synthesis Proceeds in a Repeating Reaction Sequence

21.2 Biosynthesis of Triacylglycerols
Triacylglycerols and Glycerophospholipids Are Synthesized from the Same Precursors
Triacylglycerol Biosynthesis in Animals Is Regulated by Hormones
Adipose Tissue Generates Glycerol 3-Phosphate by Glyceroneogenesis
Thiazolidinediones Treat Type 2 Diabetes by Increasing Glyceroneogenesis

21.3 Biosynthesis of Membrane Phospholipids
Cells Have Two Strategies for Attaching Phospholipid Head Groups
Phospholipid Synthesis in *E. coli* Employs CDP-Diacylglycerol
Eukaryotes Synthesize Anionic Phospholipids from CDP-Diacylglycerol
Eukaryotic Pathways to Phosphatidylserine, Phosphatidylethanolamine, and Phosphatidylcholine Are Interrelated
Plasmalogen Synthesis Requires Formation of an Ether-Linked Fatty Alcohol
Sphingolipid and Glycerophospholipid Synthesis Share Precursors and Some Mechanisms
Polar Lipids Are Targeted to Specific Cellular Membranes

21.4 Biosynthesis of Cholesterol, Steroids, and Isoprenoids
Cholesterol Is Made from Acetyl-CoA in Four Stages
Cholesterol Has Several Fates
Cholesterol and Other Lipids Are Carried on Plasma Lipoproteins

Box 21–1 Medicine: ApoE Alleles Predict Incidence of Alzheimer's Disease
Cholesterol Esters Enter Cells by Receptor-Mediated Endocytosis
Cholesterol Biosynthesis Is Regulated at Several Levels

Box 21–2 Medicine: The Lipid Hypothesis and the Development of Statins
The Mammalian Fatty Acid Synthase Has Multiple Active Sites
Fatty Acid Synthase Receives the Acetyl and Malonyl Groups
The Fatty Acid Synthase Reactions Are Repeated to Form Palmitate
Fatty Acid Synthesis Occurs in the Cytosol of Many Organisms but in the Chloroplasts of Plants
Acetate Is Shuttled out of Mitochondria as Citrate
Fatty Acid Biosynthesis Is Tightly Regulated
Long-Chain Saturated Fatty Acids Are Synthesized from Palmitate
Desaturation of Fatty Acids Requires a Mixed-Function Oxidase

Eicosanoids Are Formed from 20-Carbon Polyunsaturated Fatty Acids

21.5 Biosynthesis of Cholesterol, Steroids, and Isoprenoids
Cholesterol Is Made from Acetyl-CoA in Four Stages
Cholesterol Has Several Fates
Cholesterol and Other Lipids Are Carried on Plasma Lipoproteins

Box 21–2 Medicine: ApoE Alleles Predict Incidence of Alzheimer's Disease
Cholesterol Esters Enter Cells by Receptor-Mediated Endocytosis
Cholesterol Biosynthesis Is Regulated at Several Levels

Box 21–3 Medicine: The Lipid Hypothesis and the Development of Statins
Steroid Hormones Are Formed by Side-Chain Cleavage and Oxidation of Cholesterol. Intermediates in Cholesterol Biosynthesis Have Many Alternative Fates.

22 Biosynthesis of Amino Acids, Nucleotides, and Related Molecules

22.1 Overview of Nitrogen Metabolism

22.2 Biosynthesis of Amino Acids

22.3 Molecules Derived from Amino Acids

Box 22–3 Medicine: Curing African Sleeping Sickness with a Biochemical Trojan Horse Arginine Is the Precursor for Biological Synthesis of Nitric Oxide.

22.4 Biosynthesis and Degradation of Nucleotides

23 Hormonal Regulation and Integration of Mammalian Metabolism

23.1 Hormones: Diverse Structures for Diverse Functions

23.2 Tissue-Specific Metabolism: The Division of Labor

23.3 Hormonal Regulation of Fuel Metabolism

23.4 Obesity and the Regulation of Body Mass
Adipose Tissue Has Important Endocrine Functions. Leptin Stimulates Production of Anorexigenic Peptide Hormones. Leptin Triggers a Signaling Cascade That Regulates Gene Expression. The Leptin System May Have Evolved to Regulate the Starvation Response.
Insulin Acts in the Arcuate Nucleus to Regulate Eating and Energy Conservation

Adiponectin Acts through AMPK to Increase Insulin Sensitivity

Diet Regulates the Expression of Genes Central to Maintaining Body Mass

Short-Term Eating Behavior Is Influenced by Ghrelin and PYY3-36

23.5 Obesity, the Metabolic Syndrome, and Type 2 Diabetes

In Type 2 Diabetes the Tissues Become Insensitive to Insulin

Type 2 Diabetes Is Managed with Diet, Exercise, and Medication

III INFORMATION PATHWAYS

24 Genes and Chromosomes

24.1 Chromosomal Elements

Genes Are Segments of DNA That Code for Polypeptide Chains and RNAs

DNA Molecules Are Much Longer Than the Cellular or Viral Packages That Contain Them

Eukaryotic Genes and Chromosomes Are Very Complex

24.2 DNA Supercoiling

Most Cellular DNA Is Underwound

DNA Underwinding Is Defined by Topological Linking Number

Topoisomerases Catalyze Changes in the Linking Number of DNA

Box 24–1 Medicine: Curing Disease by Inhibiting Topoisomerases

DNA Compaction Requires a Special Form of Supercoiling

24.3 The Structure of Chromosomes

Chromatin Consists of DNA and Proteins

Histones Are Small, Basic Proteins

Nucleosomes Are the Fundamental Organizational Units of Chromatin

Box 24–2 Medicine: Epigenetics, Nucleosome Structure, and Histone Variants

Nucleosomes Are Packed into Successively Higher-Order Structures

Condensed Chromosome Structures Are Maintained by SMC Proteins

Bacterial DNA Is Also Highly Organized

25 DNA Metabolism

25.1 DNA Replication

DNA Replication Follows a Set of Fundamental Rules

DNA Is Degraded by Nucleases

DNA Is Synthesized by DNA Polymerases

Replication Is Very Accurate

E. coli Has at Least Five DNA Polymerases

DNA Replication Requires Many Enzymes and Protein Factors

Replication of the E. coli Chromosome Proceeds in Stages

Replication in Eukaryotic Cells Is Both Similar and More Complex

Viral DNA Polymerases Provide Targets for Antiviral Therapy

25.2 DNA Repair

Mutations Are Linked to Cancer

All Cells Have Multiple DNA Repair Systems

The Interaction of Replication Forks with DNA Damage Can Lead to Error-Prone Translesion DNA Synthesis

Box 25–1 Medicine: DNA Repair and Cancer

25.3 DNA Recombination

Homologous Genetic Recombination Has Several Functions

Recombination during Meiosis Is Initiated with Double-Strand Breaks

Recombination Requires a Host of Enzymes and Other Proteins

All Aspects of DNA Metabolism Come Together to Repair Stalled Replication Forks

Site-Specific Recombination Results in Precise DNA Rearrangements

Complete Chromosome Replication Can Require Site-Specific Recombination

Transposable Genetic Elements Move from One Location to Another

Immunoglobulin Genes Assemble by Recombination

26 RNA Metabolism

26.1 DNA-Dependent Synthesis of RNA

RNA Is Synthesized by RNA Polymerases

RNA Synthesis Begins at Promoters

Box 26–1 Methods: RNA Polymerase Leaves Its Footprint on a Promoter

Transcription Is Regulated at Several Levels

Specific Sequences Signal Termination of RNA Synthesis

Eukaryotic Cells Have Three Kinds of Nuclear RNA Polymerases

RNA Polymerase II Requires Many Other Protein Factors for Its Activity

DNA-Dependent RNA Polymerase Undergoes Selective Inhibition

26.2 RNA Processing

Eukaryotic mRNAs Are Capped at the 5’ End

Both Introns and Exons Are Transcribed from DNA into RNA

RNA Catalyzes the Splicing of Introns

Eukaryotic mRNAs Have a Distinctive 3’ End Structure

A Gene Can Give Rise to Multiple Products by Differential RNA Processing
Ribosomal RNAs and tRNAs Also Undergo Processing
Special-Function RNAs Undergo Several Types of Processing
RNA Enzymes Are the Catalysts of Some Events in RNA Metabolism
Cellular mRNAs Are Degraded at Different Rates
Polynucleotide Phosphorylase Makes Random RNA-like Polymers

26.3 RNA-Dependent Synthesis of RNA and DNA
Reverse Transcriptase Produces DNA from Viral RNA
Some Retroviruses Cause Cancer and AIDS
Many Transposons, Retroviruses, and Introns May Have a Common Evolutionary Origin

Box 26-2 Medicine: Fighting AIDS with Inhibitors of HIV Reverse Transcriptase
Telomerase Is a Specialized Reverse Transcriptase
Some Viral RNAs Are Replicated by RNA-Dependent RNA Polymerase
RNA Synthesis Offers Important Clues to Biochemical Evolution

Box 26-3 Methods: The SELEX Method for Generating RNA Polymers with New Functions
Box 26-4 An Expanding RNA Universe Filled with TUF RNAs

27 Protein Metabolism

27.1 The Genetic Code
The Genetic Code Was Cracked Using Artificial mRNA Templates

Box 27-1 Exceptions That Prove the Rule: Natural Variations in the Genetic Code
Wobble Allows Some tRNAs to Recognize More than One Codon
Translational Frameshifting and RNA Editing Affect How the Code Is Read

27.2 Protein Synthesis
Protein Biosynthesis Takes Place in Five Stages
The Ribosome Is a Complex Supramolecular Machine

Box 27-2 From an RNA World to a Protein World
Transfer RNAs Have Characteristic Structural Features
Stage 1: Aminoacyl-tRNA Synthetases Attach the Correct Amino Acids to Their tRNAs

Box 27-3 Natural and Unnatural Expansion of the Genetic Code
Stage 2: A Specific Amino Acid Initiates Protein Synthesis
Stage 3: Peptide Bonds Are Formed in the Elongation Stage

Box 27-4 Induced Variation in the Genetic Code: Nonsense Suppression
Stage 4: Termination of Polypeptide Synthesis Requires a Special Signal

Stage 5: Newly Synthesized Polypeptide Chains Undergo Folding and Processing
Protein Synthesis Is Inhibited by Many Antibiotics and Toxins

27.3 Protein Targeting and Degradation
Positranslational Modification of Many Eukaryotic Proteins Begins in the Endoplasmic Reticulum
Glycosylation Plays a Key Role in Protein Targeting
Signal Sequences for Nuclear Transport Are Not Cleaved
Bacteria Also Use Signal Sequences for Protein Targeting
Cells Import Proteins by Receptor-Mediated Endocytosis
Protein Degradation Is Mediated by Specialized Systems in All Cells

28 Regulation of Gene Expression

28.1 Principles of Gene Regulation
RNA Polymerase Binds to DNA at Promoters
Transcription Initiation Is Regulated by Proteins That Bind to or near Promoters
Many Bacterial Genes Are Clustered and Regulated in Operons
The lac Operon Is Subject to Negative Regulation
Regulatory Proteins Have Discrete DNA-Binding Domains
Regulatory Proteins Also Have Protein-Protein Interaction Domains

28.2 Regulation of Gene Expression in Bacteria
The lac Operon Undergoes Positive Regulation
Many Genes for Amino Acid Biosynthetic Enzymes Are Regulated by Transcription Attenuation
Induction of the SOS Response Requires Destruction of Repressor Proteins
Synthesis of Ribosomal Proteins Is Coordinated with rRNA Synthesis
The Function of Some mRNAs Is Regulated by Small RNAs in Cis or in Trans
Some Genes Are Regulated by Genetic Recombination

28.3 Regulation of Gene Expression in Eukaryotes
Transcriptionally Active Chromatin Is Structurally Distinct from Inactive Chromatin
Chromatin Is Remodeled by Acetylation and Nucleosomal Displacement/Repositioning
Many Eukaryotic Promoters Are Positively Regulated
DNA-Binding Activators and Coactivators Facilitate Assembly of the General Transcription Factors
The Genes of Galactose Metabolism in Yeast Are Subject to Both Positive and Negative Regulation
Transcription Activators Have a Modular Structure
With the cell, biology discovered its atom... To characterize life, it was henceforth essential to study the cell and analyze its structure: to single out the common denominators, necessary for the life of every cell; alternatively, to identify differences associated with the performance of special functions.

—François Jacob, La logique du vivant: une histoire de l'hérédité (The Logic of Life: A History of Heredity), 1970

The Foundations of Biochemistry

1.1 Cellular Foundations 2
1.2 Chemical Foundations 11
1.3 Physical Foundations 19
1.4 Genetic Foundations 27
1.5 Evolutionary Foundations 29

About fifteen billion years ago, the universe arose as a cataclysmic eruption of hot, energy-rich subatomic particles. Within seconds, the simplest elements (hydrogen and helium) were formed. As the universe expanded and cooled, material condensed under the influence of gravity to form stars. Some stars became enormous and then exploded as supernovae, releasing the energy needed to fuse simpler atomic nuclei into the more complex elements. Thus were produced, over billions of years, Earth itself and the chemical elements found on Earth today. About four billion years ago, life arose—simple microorganisms with the ability to extract energy from chemical compounds and, later, from sunlight, which they used to make a vast array of more complex biomolecules from the simple elements and compounds on the Earth’s surface.

Biochemistry asks how the remarkable properties of living organisms arise from the thousands of different molecules. When these molecules are isolated and examined individually, they conform to all the physical and chemical laws that describe the behavior of inanimate matter—as do all the processes occurring in living organisms. The study of biochemistry shows how the collections of inanimate molecules that constitute living organisms interact to maintain and perpetuate life animated solely by the physical and chemical laws that govern the nonliving universe.

Yet organisms possess extraordinary attributes, properties that distinguish them from other collections of matter. What are these distinguishing features of living organisms?

A high degree of chemical complexity and microscopic organization. Thousands of different molecules make up a cell’s intricate internal structures (Fig. 1–1a). These include very long polymers, each with its characteristic sequence of subunits, its unique three-dimensional structure, and its highly specific selection of binding partners in the cell.

Systems for extracting, transforming, and using energy from the environment (Fig. 1–1b), enabling organisms to build and maintain their intricate structures and to do mechanical, chemical, osmotic, and electrical work. This counteracts the tendency of all matter to decay toward a more disordered state, to come to equilibrium with its surroundings.

Defined functions for each of an organism’s components and regulated interactions among them. This is true not only of macroscopic structures, such as leaves and stems or hearts and lungs, but also of microscopic intracellular structures and individual chemical compounds. The interplay among the chemical components of a living organism is dynamic; changes in one component cause coordinating or compensating changes in another, with the whole ensemble displaying a character beyond that of its individual parts. The collection of molecules carries out a program, the end result of which is reproduction of the program and self-perpetuation of that collection of molecules—in short, life.

Mechanisms for sensing and responding to alterations in their surroundings, constantly adjusting to these changes by adapting their internal chemistry or their location in the environment.

A capacity for precise self-replication and self-assembly (Fig. 1–1c). A single bacterial cell
placed in a sterile nutrient medium can give rise to a billion identical “daughter” cells in 24 hours. Each cell contains thousands of different molecules, some extremely complex; yet each bacterium is a faithful copy of the original, its construction directed entirely from information contained in the genetic material of the original cell.

**A capacity to change over time by gradual evolution.** Organisms change their inherited life strategies, in very small steps, to survive in new circumstances. The result of eons of evolution is an enormous diversity of life forms, superficially very different (Fig. 1–2) but fundamentally related through their shared ancestry. This fundamental unity of living organisms is reflected at the molecular level in the similarity of gene sequences and protein structures.

Despite these common properties, and the fundamental unity of life they reveal, it is difficult to make generalizations about living organisms. Earth has an enormous diversity of organisms. The range of habitats, from hot springs to Arctic tundra, from animal intestines to college dormitories, is matched by a correspondingly wide range of specific biochemical adaptations, achieved within a common chemical framework. For the sake of clarity, in this book we sometimes risk certain generalizations, which, though not perfect, remain useful; we also frequently point out the exceptions to these generalizations, which can prove illuminating.

Biochemistry describes in molecular terms the structures, mechanisms, and chemical processes shared by all organisms and provides organizing principles that underlie life in all its diverse forms, principles we refer to collectively as the molecular logic of life. Although biochemistry provides important insights and practical applications in medicine, agriculture, nutrition, and industry, its ultimate concern is with the wonder of life itself.

In this introductory chapter we give an overview of the cellular, chemical, physical, and genetic backgrounds to biochemistry and the overarching principle of evolution—the development over generations of the properties of living cells. As you read through the book, you may find it helpful to refer back to this chapter at intervals to refresh your memory of this background material.

### 1.1 Cellular Foundations

The unity and diversity of organisms become apparent even at the cellular level. The smallest organisms consist of single cells and are microscopic. Larger, multicellular organisms contain many different types of cells, which vary in size, shape, and specialized function. Despite

**FIGURE 1–2** Diverse living organisms share common chemical features. Birds, beasts, plants, and soil microorganisms share with humans the same basic structural units (cells) and the same kinds of macromolecules (DNA, RNA, proteins) made up of the same kinds of monomeric subunits (nucleotides, amino acids). They utilize the same pathways for synthesis of cellular components, share the same genetic code, and derive from the same evolutionary ancestors. Shown here is a detail from “The Garden of Eden,” by Jan van Kessel the Younger (1626–1679).
these obvious differences, all cells of the simplest and most complex organisms share certain fundamental properties, which can be seen at the biochemical level.

**Cells Are the Structural and Functional Units of All Living Organisms**

Cells of all kinds share certain structural features (Fig. 1–3). The **plasma membrane** defines the periphery of the cell, separating its contents from the surroundings. It is composed of lipid and protein molecules that form a thin, tough, pliable, hydrophobic barrier around the cell. The membrane is a barrier to the free passage of inorganic ions and most other charged or polar compounds. Transport proteins in the plasma membrane allow the passage of certain ions and molecules; receptor proteins transmit signals into the cell; and membrane enzymes participate in some reaction pathways. Because the individual lipids and proteins of the plasma membrane are not covalently linked, the entire structure is remarkably flexible, allowing changes in the shape and size of the cell. As a cell grows, newly made lipid and protein molecules are inserted into its plasma membrane; cell division produces two cells, each with its own membrane. This growth and cell division (fission) occurs without loss of membrane integrity.

The internal volume enclosed by the plasma membrane, the **cytoplasm** (Fig. 1–3), is composed of an aqueous solution, the **cytosol**, and a variety of suspended particles with specific functions. The cytosol is a highly concentrated solution containing enzymes and the RNA molecules that encode them; the components (amino acids and nucleotides) from which these macromolecules are assembled; hundreds of small organic molecules called **metabolites**, intermediates in biosynthetic and degradative pathways; **coenzymes**, compounds essential to many enzyme-catalyzed reactions; inorganic ions; and such supramolecular structures as **ribosomes**, the sites of protein synthesis, and **proteasomes**, which degrade proteins no longer needed by the cell.

All cells have, for at least some part of their life, either a **nucleus** or a **nucleoid**, in which the **genome**—the complete set of genes, composed of DNA—is stored and replicated. The nucleoid, in bacteria and archaea, is not separated from the cytoplasm by a membrane; the nucleus, in **eukaryotes**, consists of nuclear material enclosed within a double membrane, the nuclear envelope. Cells with nuclear envelopes make up the large group Eukarya (Greek eu, "true," and karyon, "nucleus"). Microorganisms without nuclear envelopes, formerly grouped together as **prokaryotes** (Greek pro, "before"), are now recognized as comprising two very distinct groups, Bacteria and Archaea, described below.

**Cellular Dimensions Are Limited by Diffusion**

Most cells are microscopic, invisible to the unaided eye. Animal and plant cells are typically 5 to 100 μm in diameter, and many unicellular microorganisms are only 1 to 2 μm long (see the inside back cover for information on units and their abbreviations). What limits the dimensions of a cell? The lower limit is probably set by the minimum number of each type of biomolecule required by the cell. The smallest cells, certain bacteria known as mycoplasmas, are 300 nm in diameter and have a volume of about 10⁻¹⁴ mL. A single bacterial ribosome is about 20 nm in its longest dimension, so a few ribosomes take up a substantial fraction of the volume in a mycoplasmal cell.

The upper limit of cell size is probably set by the rate of diffusion of solute molecules in aqueous systems. For example, a bacterial cell that depends on oxygen-consuming reactions for energy production must obtain molecular oxygen by diffusion from the surrounding medium through its plasma membrane. The cell is so small, and the ratio of its surface area to its volume is so large, that every part of its cytoplasm is easily reached...
FIGURE 1–4 Phylogeny of the three domains of life. Phylogenetic relationships are often illustrated by a “family tree” of this type. The basis for this tree is the similarity in nucleotide sequences of the ribosomal RNAs of each group; the more similar the sequence, the closer the location of the branches, with the distance between branches representing the degree of difference between two sequences. Phylogenetic trees can also be constructed from similarities across species of the amino acid sequences of a single protein. For example, sequences of the protein GroEL (a bacterial protein that assists in protein folding) were compared to generate the tree in Figure 3–32. The tree in Figure 3–33 is a “consensus” tree, which uses several comparisons such as these to make the best estimates of evolutionary relatedness of a group of organisms.

by O₂ diffusing into the cell. With increasing cell size, however, surface-to-volume ratio decreases, until metabolism consumes O₂ faster than diffusion can supply it. Metabolism that requires O₂ thus becomes impossible as cell size increases beyond a certain point, placing a theoretical upper limit on the size of cells.

There Are Three Distinct Domains of Life

All living organisms fall into one of three large groups (domains) that define three branches of evolution from a common progenitor (Fig. 1–4). Two large groups of single-celled microorganisms can be distinguished on genetic and biochemical grounds: Bacteria and Archaea. Bacteria inhabit soils, surface waters, and the tissues of other living or decaying organisms. Many of the Archaea, recognized as a distinct domain by Carl Woese in the 1980s, inhabit extreme environments—salt lakes, hot springs, highly acidic bogs, and the ocean depths. The available evidence suggests that the Archaea and Bacteria diverged early in evolution. All eukaryotic organisms, which make up the third domain, Eukarya,
evolved from the same branch that gave rise to the Archaea; eukaryotes are therefore more closely related to archaea than to bacteria.

Within the domains of Archaea and Bacteria are subgroups distinguished by their habitats. In aerobic habitats with a plentiful supply of oxygen, some resident organisms derive energy from the transfer of electrons from fuel molecules to oxygen. Other environments are anaerobic, virtually devoid of oxygen, and microorganisms adapted to these environments obtain energy by transferring electrons to nitrate (forming N₂), sulfate (forming H₂S), or CO₂ (forming CH₄). Many organisms that have evolved in anaerobic environments are obligate anaerobes: they die when exposed to oxygen. Others are facultative anaerobes, able to live with or without oxygen.

We can classify organisms according to how they obtain the energy and carbon they need for synthesizing cellular material (as summarized in Fig. 1–5). There are two broad categories based on energy sources: phototrophs (Greek trophe, “nourishment”) trap and use sunlight, and chemotrophs derive their energy from oxidation of a chemical fuel. Some chemotrophs, the lithotrophs, oxidize inorganic fuels—HS⁻ to S⁰ (elemental sulfur), S⁰ to SO₄²⁻, NO₂⁻ to NO₃⁻, or Fe²⁺ to Fe³⁺, for example. Organotrophs oxidize a wide array of organic compounds available in their surroundings. Phototrophs and chemotrophs may also be divided into those that can obtain all needed carbon from CO₂ (autotrophs) and those that require organic nutrients (heterotrophs).

Escherichia coli is the Most-Studied Bacterium

Bacterial cells share certain common structural features, but also show group-specific specializations (Fig. 1–6). E. coli is a usually harmless inhabitant of the human intestinal tract. The E. coli cell is about 2 μm long and a little less than 1 μm in diameter. It has a protective outer membrane and an inner plasma membrane that encloses the cytoplasm and the nucleoid. Between the inner and outer membranes is a thin but strong layer of a polymer (peptidoglycan) that gives the cell its shape and rigidity. The plasma membrane and the layers outside it constitute the cell envelope. We should note here that in archaea, rigidity is conferred by a different type of polymer (pseudopeptidoglycan). The plasma membranes of bacteria consist of a thin bilayer of lipid molecules penetrated by proteins. Archaeal membranes have a similar architecture, but the lipids are strikingly different from those of bacteria (see Fig. 10–12).

Ribosomes Bacterial ribosomes are smaller than eukaryotic ribosomes, but serve the same function—protein synthesis from an RNA message.

Nucleoid Contains a single, simple, long circular DNA molecule.

Pili Provide points of adhesion to surface of other cells.

Flagella Propel cell through its surroundings.

Escherichia coli Structure with type of bacteria.

**FIGURE 1–6** Common structural features of bacterial cells. Because of differences in cell envelope structure, some bacteria (gram-positive bacteria) retain Gram's stain (introduced by Hans Christian Gram in 1882), and others (gram-negative bacteria) do not. E. coli is gram-negative. Cyanobacteria are distinguished by their extensive internal membrane system, which is the site of photosynthetic pigments. Although the cell envelopes of archaea and gram-positive bacteria look similar under the electron microscope, the structures of the membrane lipids and the polysaccharides are distinctly different (see Fig. 10–12).
The cytoplasm of *E. coli* contains about 15,000 ribosomes, various numbers (10 to thousands) of copies of each of 1,000 or so different enzymes, perhaps 1,000 organic compounds of molecular weight less than 1,000 (metabolites and cofactors), and a variety of inorganic ions. The nucleoid contains a single, circular molecule of DNA, and the cytoplasm (like that of most bacteria) contains one or more smaller, circular segments of DNA.

(a) Animal cell

(b) Plant cell

**FIGURE 1-7 Eukaryotic cell structure.** Schematic illustrations of two major types of eukaryotic cell: (a) a representative animal cell and (b) a representative plant cell. Plant cells are usually 10 to 100 μm in diameter—larger than animal cells, which typically range from 5 to 30 μm. Structures labeled in red are unique to either animal or plant cells. Eukaryotic microorganisms (such as protists and fungi) have structures similar to those in plant and animal cells, but many also contain specialized organelles not illustrated here.
called **plasmids**. In nature, some plasmids confer resistance to toxins and antibiotics in the environment. In the laboratory, these DNA segments are especially amenable to experimental manipulation and are powerful tools for genetic engineering (see Chapter 9).

Most bacteria (including *E. coli*) exist as individual cells, but cells of some bacterial species (the myxobacteria, for example) show simple social behavior, forming many-celled aggregates.

**Eukaryotic Cells Have a Variety of Membranous Organelles, Which Can Be Isolated for Study**

Typical eukaryotic cells (Fig. 1–7) are much larger than bacteria—commonly 5 to 100 µm in diameter, with cell volumes a thousand to a million times larger than those of bacteria. The distinguishing characteristics of eukaryotes are the nucleus and a variety of membrane-enclosed organelles with specific functions: mitochondria, endoplasmic reticulum, Golgi complexes, peroxisomes, and lysosomes. In addition to these, plant cells also contain vacuoles and chloroplasts (Fig. 1–7). Also present in the cytoplasm of many cells are granules or droplets containing stored nutrients such as starch and fat.

In a major advance in biochemistry, Albert Claude, Christian de Duve, and George Palade developed methods for separating organelles from the cytosol and from each other—an essential step in investigating their structures and functions. In a typical cell fractionation (Fig. 1–8), cells or tissues in solution are gently disrupted by physical shear. This treatment ruptures the plasma membrane but leaves most of the organelles

---

**FIGURE 1–8 Subcellular fractionation of tissue.** A tissue such as liver is first mechanically homogenized to break cells and disperse their contents in an aqueous buffer. The sucrose medium has an osmotic pressure similar to that in organelles, thus balancing diffusion of water into and out of the organelles, which would swell and burst in a solution of lower osmolarity (see Fig. 2–12). (a) The large and small particles in the suspension can be separated by centrifugation at different speeds, or (b) particles of different density can be separated by isopycnic centrifugation. In isopycnic centrifugation, a centrifuge tube is filled with a solution, the density of which increases from top to bottom; a solute such as sucrose is dissolved at different concentrations to produce the density gradient. When a mixture of organelles is layered on top of the density gradient and the tube is centrifuged at high speed, individual organelles sediment until their buoyant density exactly matches that in the gradient. Each layer can be collected separately.
intact. The homogenate is then centrifuged; organelles such as nuclei, mitochondria, and lysosomes differ in size and therefore sediment at different rates.

Differential centrifugation results in a rough fractionation of the cytoplasmic contents, which may be further purified by isopycnic ("same density") centrifugation. In this procedure, organelles of different buoyant densities (the result of different ratios of lipid and protein in each type of organelle) are separated by centrifugation through a column of solvent with graded density. By carefully removing material from each region of the gradient and observing it with a microscope, the biochemist can establish the sedimentation position of each organelle and obtain purified organelles for further study. For example, these methods were used to establish that lysosomes contain degradative enzymes, mitochondria contain oxidative enzymes, and chloroplasts contain photosynthetic pigments. The isolation of an organelle enriched in a certain enzyme is often the first step in the purification of that enzyme.

The Cytoplasm Is Organized by the Cytoskeleton and Is Highly Dynamic

Fluorescence microscopy reveals several types of protein filaments crisscrossing the eukaryotic cell, forming an interlocking three-dimensional meshwork, the cytoskeleton. There are three general types of cytoplasmic filaments—actin filaments, microtubules, and intermediate filaments (Fig. 1–9)—differing in width (from about 6 to 22 nm), composition, and specific function. All types provide structure and organization to the cytoplasm and shape to the cell. Actin filaments and microtubules also help to produce the motion of organelles or of the whole cell.

Each type of cytoskeletal component is composed of simple protein subunits that associate noncovalently to form filaments of uniform thickness. These filaments are not permanent structures; they undergo constant disassembly into their protein subunits and reassembly into filaments. Their locations in cells are not rigidly fixed but may change dramatically with mitosis, cytokinesis, amoeboid motion, or changes in cell shape. The assembly, disassembly, and location of all types of filaments are regulated by other proteins, which serve to link or bundle the filaments or to move cytoplasmic organelles along the filaments.

The picture that emerges from this brief survey of eukaryotic cell structure is of a cell with a meshwork of structural fibers and a complex system of membrane-enclosed compartments (Fig. 1–7). The filaments disassemble and then reassemble elsewhere. Membranous vesicles bud from one organelle and fuse with another. Organelles move through the cytoplasm along protein from the cell center, are stained green; and chromosomes (in the nucleus) are stained blue. (b) A newt lung cell undergoing mitosis. Microtubules (green), attached to structures called kinetochores (yellow) on the condensed chromosomes (blue), pull the chromosomes to opposite poles, or centrosomes (magenta), of the cell. Intermediate filaments, made of keratin (red), maintain the structure of the cell.
filaments, their motion powered by energy-dependent motor proteins. The **endomembrane system** segregates specific metabolic processes and provides surfaces on which certain enzyme-catalyzed reactions occur. **Exocytosis** and **endocytosis**, mechanisms of transport (out of and into cells, respectively) that involve membrane fusion and fission, provide paths between the cytoplasm and surrounding medium, allowing for secretion of substances produced in the cell and uptake of extracellular materials.

**Cells Build Supramolecular Structures**

Macromolecules and their monomeric subunits differ greatly in size (Fig. 1–10). An alanine molecule is less than 0.5 nm long. A molecule of hemoglobin, the oxygen-carrying protein of erythrocytes (red blood cells), consists of nearly 600 amino acid subunits in four long chains, folded into globular shapes and associated in a structure 5.5 nm in diameter. In turn, proteins are much smaller than ribosomes (about 20 nm in diameter), which are in turn much smaller than organelles such as mitochondria,

**FIGURE 1–10** The organic compounds from which most cellular materials are constructed: the ABCs of biochemistry. Shown here are (a) six of the 20 amino acids from which all proteins are built (the side chains are shaded pink); (b) the five nitrogenous bases, two five-carbon sugars, and phosphate ion from which all nucleic acids are built; (c) five components of membrane lipids; and (d) α-glucose, the simple sugar from which most carbohydrates are derived. Note that phosphate is a component of both nucleic acids and membrane lipids.

Level 2:
Macromolecules

Level 1:
Monomeric units

**FIGURE 1-11** Structural hierarchy in the molecular organization of cells. The nucleus of this plant cell is an organelle containing several types of supramolecular complexes, including chromatin. Chromatin typically 1,000 nm in diameter. It is a long jump from simple biomolecules to cellular structures that can be seen with the light microscope. *Figure 1-11* illustrates the structural hierarchy in cellular organization.

The monomeric subunits of proteins, nucleic acids, and polysaccharides are joined by covalent bonds. In supramolecular complexes, however, macromolecules are held together by noncovalent interactions—much weaker, individually, than covalent bonds. Among these noncovalent interactions are hydrogen bonds (between polar groups), ionic interactions (between charged groups), hydrophobic interactions (among nonpolar groups in aqueous solution), and van der Waals interactions (London forces)—all of which have energies much smaller than those of covalent bonds. These noncovalent interactions are described in Chapter 2. The large numbers of weak interactions between macromolecules in supramolecular complexes stabilize these assemblies, producing their unique structures.

In Vitro Studies May Overlook Important Interactions among Molecules

One approach to understanding a biological process is to study purified molecules in vitro (“in glass”—in the test tube), without interference from other molecules present in the intact cell—that is, in vivo (“in the living”). Although this approach has been remarkably revealing, we must keep in mind that the inside of a cell is quite different from the inside of a test tube. The “interfering” components eliminated by purification may be critical to the biological function or regulation of the molecule purified. For example, in vitro studies of pure enzymes are commonly done at very low enzyme concentrations in thoroughly stirred aqueous solutions. In the cell, an enzyme is dissolved or suspended in a gel-like cytosol with thousands of other proteins, some of which bind to that enzyme and influence its activity. Some enzymes are components of multienzyme complexes in which reactants are channeled from one enzyme to another, never entering the bulk solvent. Diffusion is hindered in the gel-like cytosol, and the cytosolic composition varies throughout the cell. In short, a given molecule may behave quite differently in the cell and in vitro. A central challenge of biochemistry is to understand the influences of cellular organization and macromolecular associations on the function of individual enzymes and other biomolecules—to understand function in vivo as well as in vitro.

**SUMMARY 1.1 Cellular Foundations**

- All cells are bounded by a plasma membrane; have a cytosol containing metabolites, coenzymes, inorganic ions, and enzymes; and have a set of genes contained within a nucleoid (bacteria and archaea) or nucleus (eukaryotes).
- Phototrophs use sunlight to do work; chemotrophs oxidize fuels, passing electrons to good electron acceptors: inorganic compounds, organic compounds, or molecular oxygen.
- Bacterial and archaeal cells contain cytosol, a nucleoid, and plasmids. Eukaryotic cells have a nucleus and are multicompartmented, with certain processes segregated in specific organelles; organelles can be separated and studied in isolation.
- Cytoskeletal proteins assemble into long filaments that give cells shape and rigidity and serve as rails along which cellular organelles move throughout the cell.
Supramolecular complexes are held together by noncovalent interactions and form a hierarchy of structures, some visible with the light microscope. When individual molecules are removed from these complexes to be studied in vitro, interactions important in the living cell may be lost.

1.2 Chemical Foundations

Biochemistry aims to explain biological form and function in chemical terms. By the late eighteenth century, chemists had concluded that the composition of living matter is strikingly different from that of the inanimate world. Antoine-Laurent Lavoisier (1743–1794) noted the relative chemical simplicity of the “mineral world” and contrasted it with the complexity of the “plant and animal worlds”; the latter, he knew, were composed of compounds rich in the elements carbon, oxygen, nitrogen, and phosphorus.

During the first half of the twentieth century, parallel biochemical investigations of glucose breakdown in yeast and in animal muscle cells revealed remarkable chemical similarities in these two apparently very different cell types; the breakdown of glucose in yeast and muscle cells involved the same 10 chemical intermediates and the same 10 enzymes. Subsequent studies of many other biochemical processes in many different organisms have confirmed the generality of this observation, neatly summarized in 1954 by Jacques Monod: “What is true of E. coli is true of the elephant.” The current understanding is that all organisms share a common evolutionary origin based in part on this observed universality of chemical intermediates and transformations, often termed “biochemical unity.”

Fewer than 30 of the more than 90 naturally occurring chemical elements are essential to organisms. Most of the elements in living matter have relatively low atomic numbers; only two have atomic numbers above that of selenium, 34 (Fig. 1-12). The four most abundant elements in living organisms, in terms of percentage of total number of atoms, are hydrogen, oxygen, nitrogen, and carbon, which together make up more than 99% of the mass of most cells. They are the lightest elements capable of efficiently forming one, two, three, and four bonds, respectively; in general, the lightest elements form the strongest bonds. The trace elements (Fig. 1-12) represent a minuscule fraction of the weight of the human body, but all are essential to life, usually because they are essential to the function of specific proteins, including many enzymes. The oxygen-transporting capacity of the hemoglobin molecule, for example, is absolutely dependent on four iron ions that make up only 0.3% of its mass.

Biomolecules Are Compounds of Carbon with a Variety of Functional Groups

The chemistry of living organisms is organized around carbon, which accounts for more than half the dry weight of cells. Carbon can form single bonds with hydrogen atoms, and both single and double bonds with oxygen and nitrogen atoms (Fig. 1-13). Of greatest significance in biology is the ability of carbon atoms to form
FIGURE 1–14 Geometry of carbon bonding. (a) Carbon atoms have a characteristic tetrahedral arrangement of their four single bonds. (b) Carbon–carbon single bonds have freedom of rotation, as shown for the compound ethane (CH$_3$–CH$_3$). (c) Double bonds are shorter and do not allow free rotation. The two doubly bonded carbons and the atoms designated A, B, X, and Y all lie in the same rigid plane.

FIGURE 1–15 Some common functional groups of biomolecules. In this figure and throughout the book, we use R to represent “any substituent.” It may be as simple as a hydrogen atom, but typically it is a carbon-containing group. When two or more substituents are shown in a molecule, we designate them R$^1$, R$^2$, and so forth.
very stable single bonds with up to four other carbon atoms. Two carbon atoms also can share two (or three) electron pairs, thus forming double (or triple) bonds.

The four single bonds that can be formed by a carbon atom project from the nucleus to the four apices of a tetrahedron (Fig. 1-14), with an angle of about 109.5° between any two bonds and an average bond length of 0.154 nm. There is free rotation around each single bond, unless very large or highly charged groups are attached to both carbon atoms, in which case rotation may be restricted. A double bond is shorter (about 0.134 nm) and rigid and allows only limited rotation about its axis.

Covalently linked carbon atoms in biomolecules can form linear chains, branched chains, and cyclic structures. It seems likely that the bonding versatility of carbon, with itself and with other elements, was a major factor in the selection of carbon compounds for the molecular machinery of cells during the origin and evolution of living organisms. No other chemical element can form molecules of such widely different sizes, shapes, and composition.

Most biomolecules can be regarded as derivatives of hydrocarbons, with hydrogen atoms replaced by a variety of functional groups that confer specific chemical properties on the molecule, forming various families of organic compounds. Typical of these are alcohols, which have one or more hydroxyl groups; amines, with amino groups; aldehydes and ketones, with carbonyl groups; and carboxylic acids, with carboxyl groups (Fig. 1-15). Many biomolecules are polyfunctional, containing two or more types of functional groups (Fig. 1-16), each with its own chemical characteristics and reactions. The chemical “personality” of a compound is determined by the chemistry of its functional groups and their disposition in three-dimensional space.

Cells Contain a Universal Set of Small Molecules

Dissolved in the aqueous phase (cytosol) of all cells is a collection of perhaps a thousand different small organic molecules ($M_r \sim 100$ to $\sim 500$), the central metabolites in the major pathways occurring in nearly every cell—the metabolites and pathways that have been conserved throughout the course of evolution. (See Box 1-1 for an explanation of the various ways of referring to molecular weight.) This collection of molecules includes the common amino acids, nucleotides, sugars and their phosphorylated derivatives, and mono-, di-, and tricarboxylic acids. The molecules are polar or charged, water soluble, and present in micromolar to millimolar concentrations. They are trapped in the cell because the plasma membrane is impermeable to them—although specific membrane transporters can catalyze the movement of some molecules into and out of the cell or between compartments in eukaryotic cells. The universal occurrence of the same set of compounds in living cells reflects the evolutionary conservation of metabolic pathways that developed in the earliest cells.

There are other small biomolecules, specific to certain types of cells or organisms. For example, vascular plants contain, in addition to the universal set, small molecules called secondary metabolites, which play roles specific to plant life. These metabolites include compounds that give plants their characteristic

![Acetyl-coenzyme A](image)

**FIGURE 1-16** Several common functional groups in a single biomolecule. Acetyl-coenzyme A (often abbreviated as acetyl-CoA) is a carrier of acetyl groups in some enzymatic reactions. The functional groups are screened in the structural formula. As we will see in Chapter 2, several of these functional groups can exist in protonated or unprotonated forms, depending on the pH. In the space-filling model, N is blue, C is black, P is orange, O is red, and H is white. The yellow atom at the left is the sulfur of the critical thioester bond between the acetyl moiety and coenzyme A.
There are two common (and equivalent) ways to describe molecular mass; both are used in this text. The first is molecular weight, or relative molecular mass, denoted \( M_r \). The molecular weight of a substance is defined as the ratio of the mass of a molecule of that substance to one-twelfth the mass of carbon-12 \(^{12}\text{C} \). Since \( M_r \) is a ratio, it is dimensionless—it has no associated units. The second is molecular mass, denoted \( m \). This is simply the mass of one molecule, or the molar mass divided by Avogadro’s number. The molecular mass, \( m \), is expressed in daltons (abbreviated Da). One dalton is equivalent to one-twelfth the mass of carbon-12; a kilodalton (kDa) is 1,000 daltons; a megadalton (MDa) is 1 million daltons.

Consider, for example, a molecule with a mass 1,000 times that of water. We can say of this molecule either \( M_r = 18,000 \) or \( m = 18,000 \) daltons. We can also describe it as an “18 kDa molecule.” However, the expression \( M_r = 18,000 \) daltons is incorrect.

Another convenient unit for describing the mass of a single atom or molecule is the atomic mass unit (formerly amu, now commonly denoted u). One atomic mass unit (1 u) is defined as one-twelfth the mass of an atom of carbon-12. Since the experimentally measured mass of an atom of carbon-12 is \( 1.9926 \times 10^{-23} \text{ g} \), 1 u = \( 1.6606 \times 10^{-24} \text{ g} \). The atomic mass unit is convenient for describing the mass of a peak observed by mass spectrometry (see Box 3–2).

Scent, and compounds such as morphine, quinine, nicotine, and caffeine that are valued for their physiological effects on humans but used for other purposes by plants.

The entire collection of small molecules in a given cell has been called that cell’s metabolome, in parallel with the term “genome” (defined earlier and expanded on in Section 1.5).

**Macromolecules Are the Major Constituents of Cells**

Many biological molecules are macromolecules, polymers with molecular weights above ~5,000 that are assembled from relatively simple precursors. Shorter polymers are called oligomers (Greek oligos, “few”). Proteins, nucleic acids, and polysaccharides are macromolecules composed of monomers with molecular weights of 500 or less. Synthesis of macromolecules is a major energy-consuming activity of cells. Macromolecules themselves may be further assembled into supramolecular complexes, forming functional units such as ribosomes. Table 1–1 shows the major classes of biomolecules in an E. coli cell.

**Proteins**, long polymers of amino acids, constitute the largest fraction (besides water) of a cell. Some proteins have catalytic activity and function as enzymes; others serve as structural elements, signal receptors, or transporters that carry specific substances into or out of cells. Proteins are perhaps the most versatile of all biomolecules; a catalog of their many functions would be very long. The sum of all the proteins functioning in a given cell is the cell’s proteome. The nucleic acids, DNA and RNA, are polymers of nucleotides. They store and transmit genetic information, and some RNA molecules have structural and catalytic roles in supramolecular complexes. The polysaccharides, polymers of simple sugars such as glucose, have three major functions: as energy-rich fuel stores, as rigid structural components of cell walls (in plants and bacteria), and as extracellular recognition elements that bind to proteins on other cells. Shorter polymers of sugars (oligosaccharides) attached to proteins or lipids at the cell surface serve as specific cellular signals. The lipids, water-insoluble hydrocarbon derivatives, serve as structural components of membranes, energy-rich fuel stores, pigments, and intracellular signals.

Three-Dimensional Structure Is Described by Configuration and Conformation

The covalent bonds and functional groups of a biomolecule are, of course, central to its function, but so also is the arrangement of the molecule’s constituent atoms in three-dimensional space—its stereochemistry. A carbon-containing compound commonly exists as stereoisomers, molecules with the same chemical bonds but different configuration, the fixed spatial arrangement of atoms. Interactions between biomolecules are invariably stereospecific, requiring specific configurations in the interacting molecules.

Figure 1-17 shows three ways to illustrate the stereochemistry, or configuration, of simple molecules. The perspective diagram specifies stereochemistry unambiguously, but bond angles and center-to-center bond lengths are better represented with ball-and-stick models. In space-filling models, the radius of each “atom” is proportional to its van der Waals radius, and the contours of the model define the space occupied by the molecule (the volume of space from which atoms of other molecules are excluded).

Configuration is conferred by the presence of either (1) double bonds, around which there is no freedom of rotation, or (2) chiral centers, around which substituent groups are arranged in a specific orientation. The identifying characteristic of stereoisomers is that they cannot be interconverted without temporarily breaking one or more covalent bonds. Figure 1-18a shows the configurations of maleic acid and its isomer, fumaric acid. These compounds are geometric isomers, or cis-trans isomers; they differ in the arrangement of their substituent groups with respect to the nonrotating double bond (Latin cis, “on this side”—groups on the same side of the double bond; trans, “across”—groups on opposite sides). Maleic acid (maleate at the neutral pH of cytoplasm) is the cis isomer and fumaric acid (fumarate) the

FIGURE 1–19 Molecular asymmetry: chiral and achiral molecules. (a) When a carbon atom has four different substituent groups (A, B, X, Y), they can be arranged in two ways that represent nonsuperposable mirror images of each other (enantiomers). This asymmetric carbon atom is called a chiral atom or chiral center. (b) When a tetrahedral carbon has only three dissimilar groups (i.e., the same group occurs twice), only one configuration is possible and the molecule is symmetric, or achiral. In this case the molecule is superposable on its mirror image: the molecule on the left can be rotated counterclockwise (when looking down the vertical bond from A to C) to create the molecule in the mirror.

trans isomer; each is a well-defined compound that can be separated from the other, and each has its own unique chemical properties. A binding site (on an enzyme, for example) that is complementary to one of these molecules would not be complementary to the other, which explains why the two compounds have distinct biological roles despite their similar chemistry.

In the second type of stereoisomer, four different substituents bonded to a tetrahedral carbon atom may be arranged in two different ways in space—that is, have two configurations (Fig. 1–19)—yielding two stereoisomers with similar or identical chemical properties but differing in certain physical and biological properties. A carbon atom with four different substituents is said to be asymmetric, and asymmetric carbons are called chiral centers (Greek chiros, “hand”; some stereoisomers are related structurally as the right hand is to the left). A molecule with only one chiral carbon can have two stereoisomers; when two or more (n) chiral carbons are present, there can be 2^n stereoisomers. Stereoisomers that are mirror images of each other are called enantiomers (Fig. 1–19). Pairs of stereoisomers that are not mirror images of each other are called diastereomers (Fig. 1–20).

As Louis Pasteur first observed in 1848 (Box 1–2), enantiomers have nearly identical chemical properties but differ in a characteristic physical property: their interaction with plane-polarized light. In separate solutions,
Louis Pasteur encountered the phenomenon of optical activity in 1843, during his investigation of the crystalline sediment that accumulated in wine casks (a form of tartraric acid called paratartaric acid—also called racemic acid, from Latin racemus, “bunch of grapes”). He used fine forceps to separate two types of crystals identical in shape but mirror images of each other. Both types proved to have all the chemical properties of tartaric acid, but in solution one type rotated plane-polarized light to the left (levorotatory), the other to the right (dextrorotatory). Pasteur later described the experiment and its interpretation:

In isomeric bodies, the elements and the proportions in which they are combined are the same, only the arrangement of the atoms is different . . . We know, on the one hand, that the molecular arrangements of the two tartaric acids are asymmetric, and, on the other hand, that these arrangements are absolutely identical, excepting that they exhibit asymmetry in opposite directions. Are the atoms of the dextro acid grouped in the form of a right-handed spiral, or are they placed at the apex of an irregular tetrahedron, or are they disposed according to this or that asymmetric arrangement? We do not know.*

Now we do know. X-ray crystallographic studies in 1951 confirmed that the levorotatory and dextrorotatory forms of tartaric acid are mirror images of each other at the molecular level and established the absolute configuration of each (Fig. 1). The same approach has been used to demonstrate that although the amino acid alanine has two stereoisomeric forms (designated D and L), alanine in proteins exists exclusively in one form (the L isomer; see Chapter 3).

**KEY CONVENTION:** Given the importance of stereochemistry in reactions between biomolecules (see below), biochemists must name and represent the structure of each biomolecule so that its stereochemistry is unambiguous. For compounds with more than one chiral center, the most useful system of nomenclature is the RS system. In this system, each group attached to a chiral carbon is assigned a priority. The priorities of some common substituents are

\[-\text{OCH}_3 > -\text{OH} > -\text{NH}_2 > -\text{COOH} > -\text{CHO} > -\text{CH}_2\text{OH} > -\text{CH}_3 > -\text{H}\]

For naming in the RS system, the chiral atom is viewed with the group of lowest priority (4 in the following diagram) pointing away from the viewer. If the priority of the other three groups (1 to 3) decreases in clockwise order, the configuration is (R) (Latin rectus, “right”); if counterclockwise, the configuration is (S) (Latin sinister; “left”). In this way each chiral carbon is designated either (R) or (S), and the inclusion of these designations in the name of the compound provides an unambiguous description of the stereochemistry at each chiral center.

![Figure 1](image-url) Pasteur separated crystals of two stereoisomers of tartaric acid and showed that solutions of the separated forms rotated plane-polarized light to the same extent but in opposite directions. These dextrorotatory and levorotatory forms were later shown to be the (R,R) and (S,S) isomers represented here. The RS system of nomenclature is explained in the text.

Distinct from configuration is molecular conformation, the spatial arrangement of substituent groups that, without breaking any bonds, are free to assume different positions in space because of the freedom of rotation about single bonds. In the simple hydrocarbon ethane, for example, there is nearly complete freedom of rotation around the C—C bond. Many different, interconvertible conformations of ethane are possible, depending on the degree of rotation (Fig. 1–21). Two conformations are of special interest: the staggered, which is more stable than all others and thus predominates, and the eclipsed, which is least stable. We cannot isolate either of these conformational forms, because they are freely interconvertible. However, when one or more of the hydrogen atoms on each carbon is replaced by a functional group that is either very large or electrically charged, freedom of rotation around the C—C bond is hindered. This limits the number of stable conformations of the ethane derivative.

Interactions between Biomolecules Are Stereospecific
When biomolecules interact, the “fit” between them must be stereochemically correct. The three-dimensional structure of biomolecules large and small—the combination of configuration and conformation—is of the utmost importance in their biological interactions: reactant with its enzyme, hormone with its receptor on a cell surface, antigen with its specific antibody, for example (Fig. 1–22). The study of biomolecular stereochemistry, with precise physical methods, is an important part of modern research on cell structure and biochemical function.

In living organisms, chiral molecules are usually present in only one of their chiral forms. For example, the amino acids in proteins occur only as their L isomers; glucose occurs only as its D isomer. (The conventions for naming stereoisomers of the amino acids are described in Chapter 8; those for sugars, in Chapter 7; the RS system, described above, is the most useful for some biomolecules.) In contrast, when a compound with an asymmetric carbon atom is chemically synthesized in the laboratory, the reaction usually produces all possible chiral forms: a mixture of the D and L forms, for example. Living cells produce only one chiral form of a biomolecule because the enzymes that synthesize that molecule are also chiral.

Stereospecificity, the ability to distinguish between stereoisomers, is a property of enzymes and other proteins and a characteristic feature of the molecular logic of living cells. If the binding site on a protein is complementary to one isomer of a chiral compound, it will not be complementary to the other isomer, for the same reason that a left glove does not fit a right hand. Some striking examples of the ability of biological systems to distinguish stereoisomers are shown in Figure 1–23.

The common classes of chemical reactions encountered in biochemistry are described in Chapter 13, as an introduction to the reactions of metabolism.

**SUMMARY 1.2 Chemical Foundations**

- Because of its bonding versatility, carbon can produce a broad array of carbon—carbon skeletons with a variety of functional groups; these groups give biomolecules their biological and chemical personalities.

**FIGURE 1–21 Conformations.** Many conformations of ethane are possible because of freedom of rotation around the C—C bond. In the ball-and-stick model, when the front carbon atom (as viewed by the reader) with its three attached hydrogens is rotated relative to the rear carbon atom, the potential energy of the molecule rises to a maximum in the fully eclipsed conformation (torsion angle 0°, 120°, etc.), then falls to a minimum in the fully staggered conformation (torsion angle 60°, 180°, etc.). Because the energy differences are small enough to allow rapid interconversion of the two forms (millions of times per second), the eclipsed and staggered forms cannot be separately isolated.

**FIGURE 1–22 Complementary fit between a macromolecule and a small molecule.** A segment of RNA from a regulatory region, known as TAR, of the human immunodeficiency virus genome (gray) with a bound argininamide molecule (colored); the argininamide is used to represent an amino acid residue of a protein that binds to the TAR region. Argininamide fits into a pocket on the RNA surface and is held in this orientation by several noncovalent interactions with the RNA. This representation of the RNA molecule is produced with software that can calculate the shape of the outer surface of a macromolecule, defined either by the van der Waals radii of all the atoms in the molecule or by the “solvent exclusion volume,” the volume a water molecule cannot penetrate.
A nearly universal set of several hundred small molecules is found in living cells; the interconversions of these molecules in the central metabolic pathways have been conserved in evolution.

Proteins and nucleic acids are linear polymers of simple monomeric subunits; their sequences contain the information that gives each molecule its three-dimensional structure and its biological functions.

Molecular configuration can be changed only by breaking covalent bonds. For a carbon atom with four different substituents (a chiral carbon), the substituent groups can be arranged in two different ways, generating stereoisomers with distinct properties. Only one stereoisomer is biologically active. Molecular conformation is the position of atoms in space that can be changed by rotation about single bonds, without breaking covalent bonds.

Interactions between biological molecules are almost invariably stereospecific: they require a precise complementary match between the interacting molecules.

1.3 Physical Foundations

Living cells and organisms must perform work to stay alive and to reproduce themselves. The synthetic reactions that occur within cells, like the synthetic processes in any factory, require the input of energy. Energy is also consumed in the motion of a bacterium or an Olympic sprinter, in the flashing of a firefly or the electrical discharge of an eel. And the storage and expression of information require energy, without which structures rich in information inevitably become disordered and meaningless.

In the course of evolution, cells have developed highly efficient mechanisms for coupling the energy obtained from sunlight or fuels to the many energy-consuming processes they must carry out. One goal of biochemistry is to understand, in quantitative and chemical terms, the means by which energy is extracted, channeled, and consumed in living cells. We can consider cellular energy conversions—like all other energy conversions—in the context of the laws of thermodynamics.
Living Organisms Exist in a Dynamic Steady State, Never at Equilibrium with Their Surroundings

The molecules and ions contained within a living organism differ in kind and in concentration from those in the organism's surroundings. A paramecium in a pond, a shark in the ocean, a bacterium in the soil, an apple tree in an orchard—all are different in composition from their surroundings and, once they have reached maturity, maintain a more or less constant composition in the face of constantly changing surroundings.

Although the characteristic composition of an organism changes little through time, the population of molecules within the organism is far from static. Small molecules, macromolecules, and supramolecular complexes are continuously synthesized and broken down in chemical reactions that involve a constant flux of mass and energy through the system. The hemoglobin molecules carrying oxygen from your lungs to your brain at this moment were synthesized within the past month; by next month they will have been degraded and entirely replaced by new hemoglobin molecules. The glucose you ingested with your most recent meal is now circulating in your bloodstream; before the day is over these particular glucose molecules will have been converted into something else—carbon dioxide or fat, perhaps—and will have been replaced with a fresh supply of glucose, so that your blood glucose concentration is more or less constant over the whole day. The amounts of hemoglobin and glucose in the blood remain nearly constant because the rate of synthesis or intake of each just balances the rate of its breakdown, consumption, or conversion into some other product. The constancy of concentration is the result of a dynamic steady state, a steady state that is far from equilibrium. Maintaining this steady state requires the constant investment of energy; when a cell can no longer generate energy, it dies and begins to decay toward equilibrium with its surroundings. We consider below exactly what is meant by "steady state" and "equilibrium."

Organisms Transform Energy and Matter from Their Surroundings

For chemical reactions occurring in solution, we can define a system as all the constituent reactants and products, the solvent that contains them, and the immediate atmosphere—in short, everything within a defined region of space. The system and its surroundings together constitute the universe. If the system exchanges neither matter nor energy with its surroundings, it is said to be isolated. If the system exchanges energy but not matter with its surroundings, it is a closed system; if it exchanges both energy and matter with its surroundings, it is an open system.

A living organism is an open system; it exchanges both matter and energy with its surroundings. Organisms derive energy from their surroundings in two ways: (1) they take up chemical fuels (such as glucose) from the environment and extract energy by oxidizing them (see Box 1-3, Case 2); or (2) they absorb energy from sunlight.

The first law of thermodynamics describes the principle of the conservation of energy: in any physical or chemical change, the total amount of energy in the universe remains constant, although the form of the energy may change. Cells are consummate transducers of energy, capable of interconverting chemical, electromagnetic, mechanical, and osmotic energy with great efficiency (Fig. 1–24).

![Figure 1-24: Some energy interconversions in living organisms.](image-url)

During metabolic energy transductions, the randomness of the system plus surroundings (expressed quantitatively as entropy) increases as the potential energy of complex nutrient molecules decreases. (a) Living organisms extract energy from their surroundings; (b) convert some of it into useful forms of energy to produce work; (c) return some energy to the surroundings as heat; and (d) release end-product molecules that are less well organized than the starting fuel, increasing the entropy of the universe. One effect of all these transformations is (e) increased order (decreased randomness) in the system in the form of complex macromolecules. We return to a quantitative treatment of entropy in Chapter 13.
The term "entropy," which literally means "a change within," was first used in 1851 by Rudolf Clausius, one of the formulators of the second law of thermodynamics. A rigorous quantitative definition of entropy involves statistical and probability considerations. However, its nature can be illustrated qualitatively by three simple examples, each demonstrating one aspect of entropy.

The key descriptors of entropy are randomness and disorder, manifested in different ways.

**Case 1: The Teakettle and the Randomization of Heat**

We know that steam generated from boiling water can do useful work. But suppose we turn off the burner under a teakettle full of water at 100 °C (the "system") in the kitchen (the "surroundings") and allow the teakettle to cool. As it cools, no work is done, but heat passes from the teakettle to the surroundings, raising the temperature of the surroundings (the kitchen) by an infinitesimally small amount until complete equilibrium is attained. At this point all parts of the teakettle and the kitchen are at precisely the same temperature. The free energy that was once concentrated in the teakettle of hot water at 100 °C, potentially capable of doing work, has disappeared. Its equivalent in heat energy is still present in the teakettle + kitchen (i.e., the "universe") but has become completely randomized throughout. This energy is no longer available to do work because there is no temperature differential within the kitchen. Moreover, the increase in entropy of the kitchen (the surroundings) is irreversible. We know from everyday experience that heat never spontaneously passes back from the kitchen into the teakettle to raise the temperature of the water to 100 °C again.

**Case 2: The Oxidation of Glucose**

Entropy is a state not only of energy but of matter. Aerobic (heterotrophic) organisms extract free energy from glucose obtained from their surroundings by oxidizing the glucose with O₂, also obtained from the surroundings. The end products of this oxidative metabolism, CO₂ and H₂O, are returned to the surroundings. In this process the surroundings undergo an increase in entropy, whereas the organism itself remains in a steady state and undergoes no change in its internal order. Although some entropy arises from the dissipation of heat, entropy also arises from another kind of disorder, illustrated by the equation for the oxidation of glucose:

\[ C_6H_{12}O_6 + 6O_2 \rightarrow 6CO_2 + 6H_2O \]

We can represent this schematically as

In this form the 125 letters contain little or no information, but they are very rich in entropy. Such considerations have led to the conclusion that information is a form of energy; information has been called "negative entropy." In fact, the branch of mathematics called information theory, which is basic to the programming logic of computers, is closely related to thermodynamic theory. Living organisms are highly ordered, nonrandom structures, immensely rich in information and thus entropy-poor.
The Flow of Electrons Provides Energy for Organisms

Nearly all living organisms derive their energy, directly or indirectly, from the radiant energy of sunlight. The light-driven splitting of water during photosynthesis releases its electrons for the reduction of CO₂ and the release of O₂ into the atmosphere:

\[
\text{light} \quad 6\text{CO}_2 + 6\text{H}_2\text{O} \rightarrow \text{C}_6\text{H}_{12}\text{O}_6 + 6\text{O}_2 \\
\text{(light-driven reduction of CO}_2\text{)}
\]

Nonphotosynthetic cells and organisms obtain the energy they need by oxidizing the energy-rich products of photosynthesis, then passing the electrons thus acquired to atmospheric O₂ to form water, CO₂, and other end products, which are recycled in the environment:

\[
\text{C}_6\text{H}_{12}\text{O}_6 + \text{O}_2 \rightarrow 6\text{CO}_2 + 6\text{H}_2\text{O} + \text{energy} \\
\text{(energy-yielding oxidation of glucose)}
\]

Thus autotrophs and heterotrophs participate in global cycles of O₂ and CO₂, driven ultimately by sunlight, making these two large groups of organisms interdependent. Virtually all energy transductions in cells can be traced to this flow of electrons from one molecule to another, in a “downhill” flow from higher to lower electrochemical potential; as such, this is formally analogous to the flow of electrons in a battery-driven electric circuit. All these reactions involved in electron flow are oxidation-reduction reactions: one reactant is oxidized (loses electrons) as another is reduced (gains electrons).

Creating and Maintaining Order Requires Work and Energy

As we've noted, DNA, RNA, and proteins are informational macromolecules; the precise sequence of their monomeric subunits contains information, just as the letters in this sentence do. In addition to using chemical energy to form the covalent bonds between these subunits, the cell must invest energy to order the subunits in their correct sequence. It is extremely improbable that amino acids in a mixture would spontaneously condense into a single type of protein, with a unique sequence. This would represent increased order in a population of molecules; but according to the second law of thermodynamics, the tendency in nature is toward ever-greater disorder in the universe: the total entropy of the universe is continually increasing. To bring about the synthesis of macromolecules from their monomeric units, free energy must be supplied to the system (in this case, the cell).

**KEY CONVENTION:** The randomness or disorder of the components of a chemical system is expressed as entropy, \( S \) (Box 1–3). Any change in randomness of the system is expressed as entropy change, \( \Delta S \), which by convention has a positive value when randomness increases. J. Willard Gibbs, who developed the theory of energy changes during chemical reactions, showed that the free-energy content, \( G \), of any closed system can be defined in terms of three quantities: enthalpy, \( H \), reflecting the number and kinds of bonds; entropy, \( S \); and the absolute temperature, \( T \) (in Kelvin). The definition of free energy is \( G = H - TS \). When a chemical reaction occurs at constant temperature, the free-energy change, \( \Delta G \), is determined by the enthalpy change, \( \Delta H \), reflecting the kinds and numbers of chemical bonds and noncovalent interactions broken and formed, and the entropy change, \( \Delta S \), describing the change in the system’s randomness:

\[
\Delta G = \Delta H - T\Delta S
\]

where, by definition, \( \Delta H \) is negative for a reaction that releases heat, and \( \Delta S \) is positive for a reaction that increases the system’s randomness.

A process tends to occur spontaneously only if \( \Delta G \) is negative (if free energy is released in the process). Yet cell function depends largely on molecules, such as proteins and nucleic acids, for which the free energy of formation is positive: the molecules are less stable and more highly ordered than a mixture of their monomeric components. To carry out these thermodynamically unfavorable, energy-requiring (endergonic) reactions, cells couple them to other reactions that liberate free energy (exergonic reactions), so that the overall process is exergonic: the sum of the free-energy changes is negative.

The usual source of free energy in coupled biological reactions is the energy released by breakage of phosphoanhydride bonds such as those in adenosine triphosphate (ATP; Fig. 1–25) and guanosine triphosphate (GTP). Here, each \( \text{P} \) represents a phosphoryl group:

\[
\text{Amino acids} \rightarrow \text{protein} \quad \Delta G_1 \text{ is positive (endergonic)} \\
\text{ATP} \rightarrow \text{AMP} + \text{P} = \text{P} \quad \Delta G_2 \text{ is negative (exergonic)} \\
\text{or ATP} \rightarrow \text{ADP} + \text{P}
\]

When these reactions are coupled, the sum of \( \Delta G_1 \) and \( \Delta G_2 \) is negative—the overall process is exergonic. By this coupling strategy, cells are able to synthesize and maintain the information-rich polymers essential to life.

Energy Coupling Links Reactions in Biology

The central issue in bioenergetics (the study of energy transformations in living systems) is the means by which energy from fuel metabolism or light capture is coupled to a cell’s energy-requiring reactions. In thinking about
energy coupling, it is useful to consider a simple mechanical example, as shown in Figure 1–26a. An object at the top of an inclined plane has a certain amount of potential energy as a result of its elevation. It tends to slide down the plane, losing its potential energy of position as it approaches the ground. When an appropriate string-and-pulley device couples the falling object to another, smaller object, the spontaneous downward motion of the larger can lift the smaller, accomplishing a certain amount of work. The amount of energy available to do work is the free-energy change, ΔG; this is always somewhat less than the theoretical amount of energy released, because some energy is dissipated as the heat of friction. The greater the elevation of the larger object, the greater the energy released (ΔG) as the object slides downward and the greater the amount of work that can be accomplished. The larger object can lift the smaller only because, at the outset, the larger object was far from its equilibrium position: it had at some earlier point been elevated above the ground, in a process that itself required the input of energy.

How does this apply in chemical reactions? In closed systems, chemical reactions proceed spontaneously until equilibrium is reached. When a system is at equilibrium, the rate of product formation exactly equals the rate at which product is converted to reactant. Thus there is no net change in the concentration of reactants and products. The energy change as the system moves from its initial state to equilibrium, with no changes in temperature or pressure, is given by the free-energy change, ΔG. The magnitude of ΔG depends on the particular chemical reaction and on how far from equilibrium is reached. When a system is:

![Figure 1-26](image_url)

**FIGURE 1–26 Energy coupling in mechanical and chemical processes.**

(a) The downward motion of an object releases potential energy that can do mechanical work. The potential energy made available by spontaneous downward motion, an exergonic process (pink), can be coupled to the endergonic upward movement of another object (blue).

(b) In reaction 1, the formation of glucose 6-phosphate from glucose and inorganic phosphate (P\(_i\)) yields a product of higher energy than the two reactants. For this endergonic reaction, ΔG is positive. In reaction 2, the exergonic breakdown of adenosine triphosphate (ATP) has a large, negative free-energy change (ΔG\(_2\)). The third reaction is the sum of reactions 1 and 2, and the free-energy change, ΔG\(_3\), is the arithmetic sum of ΔG\(_1\) and ΔG\(_2\). Because ΔG\(_3\) is negative, the overall reaction is exergonic and proceeds spontaneously.
equilibrium the system is initially. Each compound involved in a chemical reaction contains a certain amount of potential energy, related to the kind and number of its bonds. In reactions that occur spontaneously, the products have less free energy than the reactants, thus the reaction releases free energy, which is then available to do work. Such reactions are exergonic; the decline in free energy from reactants to products is expressed as a negative value. Endergonic reactions require an input of energy, and their $\Delta G$ values are positive. As in mechanical processes, only part of the energy released in exergonic chemical reactions can be used to accomplish work. In living systems some energy is dissipated as heat or lost to increasing entropy.

In biological organisms, just as in the mechanical example in Figure 1-26a, an exergonic reaction can be coupled to an endergonic reaction to drive otherwise unfavorable reactions. Figure 1-26b (a type of graph called a reaction coordinate diagram) illustrates this principle for the conversion of glucose to glucose 6-phosphate, the first step in the pathway for oxidation of glucose. The simplest way to produce glucose 6-phosphate would be:

\[
\text{Reaction 1: } \text{Glucose} + \text{P}_i \rightarrow \text{glucose 6-phosphate}
\]

(exergonic; $\Delta G_1$ is positive)

(Here, $\text{P}_i$ is an abbreviation for inorganic phosphate, $\text{HPO}_4^{2-}$; Don’t be concerned about the structure of these compounds now; we describe them in detail later in the book.) This reaction does not occur spontaneously; $\Delta G_1$ is positive. A second, very exergonic reaction can occur in all cells:

\[
\text{Reaction 2: } \text{ATP} \rightarrow \text{ADP} + \text{P}_i
\]

(exergonic; $\Delta G_2$ is negative)

These two chemical reactions share a common intermediate, $\text{P}_i$, which is consumed in reaction 1 and produced in reaction 2. The two reactions can therefore be coupled in the form of a third reaction, which we can write as the sum of reactions 1 and 2, with the common intermediate, $\text{P}_i$, omitted from both sides of the equation:

\[
\text{Reaction 3: } \text{Glucose} + \text{ATP} \rightarrow \text{glucose 6-phosphate} + \text{ADP}
\]

Because more energy is released in reaction 2 than is consumed in reaction 1, the free-energy change for reaction 3, $\Delta G_3$, is negative, and the synthesis of glucose 6-phosphate can therefore occur by reaction 3.

The coupling of exergonic and endergonic reactions through a shared intermediate is central to the energy exchanges in living systems. As we shall see, reactions that break down ATP (such as reaction 2 in Fig. 1-26b) release energy that drives many endergonic processes in cells. ATP breakdown in cells is exergonic because all living cells maintain a concentration of ATP far above its equilibrium concentration. It is this disequilibrium that allows ATP to serve as the major carrier of chemical energy in all cells.

$K_{eq}$ and $\Delta G^\circ$ Are Measures of a Reaction’s Tendency to Proceed Spontaneously

The tendency of a chemical reaction to go to completion can be expressed as an equilibrium constant. For the reaction in which $a$ moles of A react with $b$ moles of B to give $c$ moles of C and $d$ moles of D,

\[
aA + bB \rightarrow cC + dD
\]

the equilibrium constant, $K_{eq}$, is given by

\[
K_{eq} = \frac{[\text{C}]^c [\text{D}]^d}{[\text{A}]^a [\text{B}]^b}
\]

where $[\text{A}]_{eq}$ is the concentration of A, $[\text{B}]_{eq}$ the concentration of B, and so on, when the system has reached equilibrium. A large value of $K_{eq}$ means the reaction tends to proceed until the reactants are almost completely converted into the products.

Gibbs showed that $\Delta G$ (the actual free-energy change) for any chemical reaction is a function of the standard free-energy change, $\Delta G^\circ$—a constant that is characteristic of each specific reaction—and a term that expresses the initial concentrations of reactants and products:

\[
\Delta G = \Delta G^\circ + RT \ln \frac{[\text{C}]^c [\text{D}]^d}{[\text{A}]^a [\text{B}]^b}
\]

where $[\text{A}]_i$ is the initial concentration of A, and so forth; $R$ is the gas constant; and $T$ is the absolute temperature. $\Delta G$ is a measure of the distance of a system from its equilibrium position. When a reaction has reached equilibrium, no driving force remains and it can do no work: $\Delta G = 0$. For this special case, $[\text{A}]_i = [\text{A}]_{eq}$, and so on, for all reactants and products, and

\[
\frac{[\text{C}]^c [\text{D}]^d}{[\text{A}]^a [\text{B}]^b} = \frac{[\text{C}]_{eq}^c [\text{D}]_{eq}^d}{[\text{A}]_{eq}^a [\text{B}]_{eq}^b}
\]

Substituting 0 for $\Delta G$ and $K_{eq}$ for $\frac{[\text{C}]^c [\text{D}]^d}{[\text{A}]^a [\text{B}]^b}$ in Equation 1–1, we obtain the relationship

\[
\Delta G^\circ = -RT \ln K_{eq}
\]

from which we see that $\Delta G^\circ$ is simply a second way (besides $K_{eq}$) of expressing the driving force on a reaction. Because $K_{eq}$ is experimentally measurable, we have a way of determining $\Delta G^\circ$, the thermodynamic constant characteristic of each reaction.

The units of $\Delta G^\circ$ and $\Delta G$ are joules per mole (or calories per mole). When $K_{eq} >> 1$, $\Delta G^\circ$ is large and negative; when $K_{eq} << 1$, $\Delta G^\circ$ is large and positive. From a table of experimentally determined values of either $K_{eq}$ or $\Delta G^\circ$, we can see at a glance which reactions tend to go to completion and which do not.

One caution about the interpretation of $\Delta G^\circ$: thermodynamic constants such as this show where the final equilibrium for a reaction lies but tell us nothing about how fast that equilibrium will be achieved. The rates of
reactions are governed by the parameters of kinetics, a topic we consider in detail in Chapter 6.

**Enzymes Promote Sequences of Chemical Reactions**

All biological macromolecules are much less thermodynamically stable than their monomeric subunits, yet they are kinetically stable: their uncatalyzed breakdown occurs so slowly (over years rather than seconds) that, on a time scale that matters for the organism, these molecules are stable. Virtually every chemical reaction in a cell occurs at a significant rate only because of the presence of enzymes—biocatalysts that, like all other catalysts, greatly enhance the rate of specific chemical reactions without being consumed in the process.

The path from reactant(s) to product(s) almost invariably involves an energy barrier, called the activation barrier (Fig. 1–27), that must be surmounted for any reaction to proceed. The breaking of existing bonds and formation of new ones generally requires, first, a distortion of the existing bonds to create a transition state of higher free energy than either reactant or product. The highest point in the reaction coordinate diagram represents the transition state, and the difference in energy between the reactant in its ground state and in its transition state is the activation energy, \( \Delta G^* \). An enzyme catalyzes a reaction by providing a more comfortable fit for the transition state: a surface that complements the transition state in stereochemistry, polarity, and charge. The binding of enzyme to the transition state is exergonic, and the energy released by this binding reduces the activation energy for the reaction and greatly increases the reaction rate.

A further contribution to catalysis occurs when two or more reactants bind to the enzyme’s surface close to each other and with stereospecific orientations that favor the reaction. This increases by orders of magnitude the probability of productive collisions between reactants. As a result of these factors and several others, discussed in Chapter 6, enzyme-catalyzed reactions commonly proceed at rates greater than \( 10^{12} \) times faster than the uncatalyzed reactions. (That is a million million times faster!)

Cellular catalysts are, with a few notable exceptions, proteins. (Some RNA molecules have enzymatic activity, as discussed in Chapters 26 and 27.) Again with a few exceptions, each enzyme catalyzes a specific reaction, and each reaction in a cell is catalyzed by a different enzyme. Thousands of different enzymes are therefore required by each cell. The multiplicity of enzymes, their specificity (the ability to discriminate between reactants), and their susceptibility to regulation give cells the capacity to lower activation barriers selectively. This selectivity is crucial for the effective regulation of cellular processes. By allowing specific reactions to proceed at significant rates at particular times, enzymes determine how matter and energy are channeled into cellular activities.

The thousands of enzyme-catalyzed chemical reactions in cells are functionally organized into many sequences of consecutive reactions, called pathways, in which the product of one reaction becomes the reactant in the next. Some pathways degrade organic nutrients into simple end products in order to extract chemical energy and convert it into a form useful to the cell; together these degradative, free-energy-yielding reactions are designated catabolism. The energy released by catabolic reactions drives the synthesis of ATP. As a result, the cellular concentration of ATP is far above its equilibrium concentration, so that \( \Delta G \) for ATP breakdown is large and negative. Similarly, metabolism results in the production of the reduced electron carriers NADH and NADPH, both of which can donate electrons in processes that generate ATP or drive reductive steps in biosynthetic pathways.

Other pathways start with small precursor molecules and convert them to progressively larger and more complex molecules, including proteins and nucleic acids. Such synthetic pathways, which invariably require the input of energy, are collectively designated anabolism. The overall network of enzyme-catalyzed pathways constitutes cellular metabolism. ATP (and the energetically equivalent nucleoside triphosphates cytidine triphosphate (CTP), uridine triphosphate (UTP), and guanosine triphosphate (GTP)) is the connecting link between the catabolic and anabolic components of this network (shown schematically in Fig. 1–28). The pathways of enzyme-catalyzed reactions that act on the main constituents of cells—proteins, fats, sugars, and nucleic acids—are virtually identical in all living organisms.
Metabolism is Regulated to Achieve Balance and Economy

Not only do living cells simultaneously synthesize thousands of different kinds of carbohydrate, fat, protein, and nucleic acid molecules and their simpler subunits, but they do so in the precise proportions required by the cell under any given circumstance. For example, during rapid cell growth the precursors of proteins and nucleic acids must be made in large quantities, whereas in non-growing cells the requirement for these precursors is much reduced. Key enzymes in each metabolic pathway are regulated so that each type of precursor molecule is produced in a quantity appropriate to the current requirements of the cell.

Consider the pathway in *E. coli* that leads to the synthesis of the amino acid isoleucine, a constituent of proteins. The pathway has five steps catalyzed by five different enzymes (A through F represent the intermediates in the pathway):

\[
\text{Threonine} \rightarrow \text{B} \rightarrow \text{C} \rightarrow \text{D} \rightarrow \text{E} \rightarrow \text{F} \rightarrow \text{Isoleucine}
\]

If a cell begins to produce more isoleucine than it needs for protein synthesis, the unused isoleucine accumulates and the increased concentration inhibits the catalytic activity of the first enzyme in the pathway, immediately slowing the production of isoleucine. Such feedback inhibition keeps the production and utilization of each metabolic intermediate in balance. (Throughout the book, we will use \( \otimes \) to indicate inhibition of an enzymatic reaction.)

Although the concept of discrete pathways is an important tool for organizing our understanding of metabolism, it is an oversimplification. There are thousands of metabolic intermediates in a cell, many of which are part of more than one pathway. Metabolism would be better represented as a web of interconnected and independent pathways. A change in the concentration of any one metabolite would start a ripple effect, influencing the flow of materials through other pathways. The task of understanding these complex interactions among intermediates and pathways in quantitative terms is daunting, but the new emphasis on systems biology, discussed in Chapter 15, has begun to offer important insights into the overall regulation of metabolism.

Cells also regulate the synthesis of their own catalysts, the enzymes, in response to increased or diminished need for a metabolic product; this is the substance of Chapter 28. The expression of genes (the translation from information in DNA to active protein in the cell) and synthesis of enzymes are other layers of metabolic control in the cell. All layers must be taken into account when describing the overall control of cellular metabolism.

**SUMMARY 1.3 Physical Foundations**

- Living cells are open systems, exchanging matter and energy with their surroundings, extracting and channeling energy to maintain themselves in a dynamic steady state distant from equilibrium. Energy is obtained from sunlight or fuels by converting the energy from electron flow into the chemical bonds of ATP.
- The tendency for a chemical reaction to proceed toward equilibrium can be expressed as the
free-energy change, $\Delta G$, which has two components: enthalpy change, $\Delta H$, and entropy change, $\Delta S$. These variables are related by the equation $\Delta G = \Delta H - T \Delta S$.

- When $\Delta G$ of a reaction is negative, the reaction is exergonic and tends to go toward completion; when $\Delta G$ is positive, the reaction is endergonic and tends to go in the reverse direction. When two reactions can be summed to yield a third reaction, the $\Delta G$ for this overall reaction is the sum of the $\Delta G$s of the two separate reactions.

- The reactions converting ATP to P$_i$ and ADP or to AMP and PP$_i$ are highly exergonic (large negative $\Delta G$). Many endergonic cellular reactions are driven by coupling them, through a common intermediate, to these highly exergonic reactions.

- The standard free-energy change for a reaction, $\Delta G^\circ$, is a physical constant that is related to the equilibrium constant by the equation $\Delta G^\circ = -RT \ln K_{eq}$.

- Most cellular reactions proceed at useful rates only because enzymes are present to catalyze them. Enzymes act in part by stabilizing the transition state, reducing the activation energy, $\Delta G^+$, and increasing the reaction rate by many orders of magnitude. The catalytic activity of enzymes in cells is regulated.

- Metabolism is the sum of many interconnected reaction sequences that interconvert cellular metabolites. Each sequence is regulated to provide what the cell needs at a given time and to expend energy only when necessary.

### 1.4 Genetic Foundations

Perhaps the most remarkable property of living cells and organisms is their ability to reproduce themselves for countless generations with nearly perfect fidelity. This continuity of inherited traits implies constancy, over millions of years, in the structure of the molecules that contain the genetic information. Very few historical records of civilization, even those etched in copper or carved in stone (Fig. 1–29), have survived for a thousand years. But there is good evidence that the genetic instructions in living organisms have remained nearly unchanged over very much longer periods; many bacteria have nearly the same size, shape, and internal structure and contain the same kinds of precursor molecules and enzymes as bacteria that lived nearly four billion years ago. This continuity of structure and composition is the result of continuity in the structure of the genetic material.

Among the seminal discoveries in biology in the twentieth century were the chemical nature and the three-dimensional structure of the genetic material, deoxyribonucleic acid, DNA. The sequence of the monomeric subunits, the nucleotides (strictly, deoxyribonucleotides, as discussed below), in this linear polymer encodes the instructions for forming all other cellular components and provides a template for the production of identical DNA molecules to be distributed to progeny when a cell divides. The perpetuation of a biological species requires that its genetic information be maintained in a stable form, expressed accurately in the form of gene products, and reproduced with a minimum of errors. Effective storage, expression, and reproduction of the genetic message define individual species, distinguish them from one another, and assure their continuity over successive generations.

**Genetic Continuity Is Vested in Single DNA Molecules**

DNA is a long, thin, organic polymer, the rare molecule that is constructed on the atomic scale in one dimension (width) and the human scale in another (length: a molecule of DNA can be many centimeters long). A human sperm or egg, carrying the accumulated hereditary information of billions of years of evolution, transmits this inheritance in the form of DNA molecules, in which the linear sequence of covalently linked nucleotide subunits encodes the genetic message.

Usually when we describe the properties of a chemical species, we describe the average behavior of a very large number of identical molecules. While it is difficult...
to predict the behavior of any single molecule in a collection of, say, a picomole (about $6 \times 10^{11}$ molecules) of a compound, the average behavior of the molecules is predictable because so many molecules enter into the average. Cellular DNA is a remarkable exception. The DNA that is the entire genetic material of *E. coli* is a single molecule containing 4.64 million nucleotide pairs. That single molecule must be replicated perfectly in every detail if an *E. coli* cell is to give rise to identical progeny by cell division; there is no room for averaging in this process! The same is true for all cells. A human sperm brings to the egg that it fertilizes just one molecule of DNA in each of its 23 different chromosomes, to combine with just one DNA molecule in each corresponding chromosome in the egg. The result of this union is very highly predictable: an embryo with all of its ~25,000 genes, constructed of 3 billion nucleotide pairs, intact. An amazing chemical feat!

**WORKED EXAMPLE 1-1 Fidelity of DNA Replication**

Calculate the number of times the DNA of a modern *E. coli* cell has been copied accurately since its earliest bacterial precursor cell arose about 3.5 billion years ago. Assume for simplicity that over this time period *E. coli* has undergone, on average, one cell division every 12 hours (this is an overestimate for modern bacteria, but probably an underestimate for ancient bacteria).

**Solution:**

$$
(1 \text{ generation}/12 \text{ hr})(24 \text{ hr/d})(365 \text{ d/yr})(3.5 \times 10^9 \text{ yr}) = 2.6 \times 10^{12} \text{ generations}.
$$

A single page of this book contains about 5,000 characters, so the entire book contains about 5 million characters. The chromosome of *E. coli* also contains about 5 million characters (base pairs). If you made a hand-written copy of this book and then passed on the copy to a classmate to copy by hand, and this copy were then copied by a third classmate, and so on, how closely would each successive copy of the book resemble the original? Now, imagine the textbook that would result from hand-copying this one a few trillion times!

**The Structure of DNA Allows for Its Replication and Repair with Near-Perfect Fidelity**

The capacity of living cells to preserve their genetic material and to duplicate it for the next generation results from the structural complementarity between the two strands of the DNA molecule (Fig. 1–30). The basic unit of DNA is a linear polymer of four different monomeric subunits, deoxyribonucleotides, arranged in a precise linear sequence. It is this linear sequence that encodes the genetic information. Two of these polymeric strands are twisted about each other to form the DNA double helix, in which each deoxyribonucleotide in one strand pairs specifically with a complementary deoxyribonucleotide in the opposite strand. Before a cell divides, the two DNA strands separate and each serves as a template for the synthesis of a new, complementary strand, generating two identical double-helical molecules, one for each daughter cell. If, at any time, one strand is damaged, continuity of information is assured by the information present in the other strand, which can act as a template for repair of the damage.

**FIGURE 1–30 Complementarity between the two strands of DNA.**

DNA is a linear polymer of covalently joined deoxyribonucleotides, of four types: deoxyadenylate (A), deoxyguanylate (G), deoxycytidylate (C), and deoxythymidylate (T). Each nucleotide, with its unique three-dimensional structure, can associate very specifically but noncovalently with one other nucleotide in the complementary chain: A always associates with T, and G with C. Thus, in the double-stranded DNA molecule, the entire sequence of nucleotides in one strand is complementary to the sequence in the other. The two strands, held together by hydrogen bonds (represented here by vertical light blue lines) between each pair of complementary nucleotides, twist about each other to form the DNA double helix. In DNA replication, the two strands (blue) separate and two new strands (pink) are synthesized, each with a sequence complementary to one of the original strands. The result is two double-helical molecules, each identical to the original DNA.
The Linear Sequence in DNA Encodes Proteins with Three-Dimensional Structures

The information in DNA is encoded in its linear (one-dimensional) sequence of deoxyribonucleotide subunits, but the expression of this information results in a three-dimensional cell. This change from one to three dimensions occurs in two phases. A linear sequence of deoxyribonucleotides in DNA codes (through an intermediary, RNA) for the production of a protein with a corresponding linear sequence of amino acids (Fig. 1–31). The protein folds into a particular three-dimensional shape, determined by its amino acid sequence and stabilized primarily by noncovalent interactions. Although the final shape of the folded protein is dictated by its amino acid sequence, the folding is aided by "molecular chaperones" (see Fig. 4–29). The precise three-dimensional structure, or native conformation, of the protein is crucial to its function.

Once in its native conformation, a protein may associate noncovalently with other macromolecules (other proteins, nucleic acids, or lipids) to form supramolecular complexes such as chromosomes, ribosomes, and membranes. The individual molecules of these complexes have specific, high-affinity binding sites for each other, and within the cell they spontaneously self-assemble into functional complexes.

Although protein sequences carry all necessary information for achieving their native conformation, accurate folding and self-assembly also require the right cellular environment—pH, ionic strength, metal ion concentrations, and so forth. Thus the DNA sequence alone is not enough to dictate the formation of a cell.

SUMMARY 1.4 Genetic Foundations

- Genetic information is encoded in the linear sequence of four types of deoxyribonucleotides in DNA.
- The double-helical DNA molecule contains an internal template for its own replication and repair.
- The linear sequence of amino acids in a protein, which is encoded in the DNA of the gene for that protein, produces a protein's unique three-dimensional structure—a process also dependent on environmental conditions.
- Individual macromolecules with specific affinity for other macromolecules self-assemble into supramolecular complexes.

1.5 Evolutionary Foundations

Nothing in biology makes sense except in the light of evolution.

—Theodosius Dobzhansky, The American Biology Teacher, March 1973

Great progress in biochemistry and molecular biology in recent decades has amply confirmed the validity of Dobzhansky's striking generalization. The remarkable similarity of metabolic pathways and gene sequences across the phyla argues strongly that all modern organisms are derived from a common evolutionary progenitor by a series of small changes (mutations), each of which conferred a selective advantage to some organism in some ecological niche.

Changes in the Hereditary Instructions Allow Evolution

Despite the near-perfect fidelity of genetic replication, infrequent, unrepaired mistakes in the DNA replication process lead to changes in the nucleotide sequence of DNA, producing a genetic mutation (Fig. 1–32) and changing the instructions for a cellular component. Incorrectly repaired damage to one of the DNA strands has the same effect. Mutations in the DNA handed down to offspring—that is, mutations carried in the reproductive cells—may be harmful or even lethal to the new organism or cell; they may, for example, cause the synthesis of a defective enzyme that is not able to catalyze an essential metabolic reaction. Occasionally,
however, a mutation better equips an organism or cell to survive in its environment. The mutant enzyme might have acquired a slightly different specificity, for example, so that it is now able to use some compound that the cell was previously unable to metabolize. If a population of cells were to find itself in an environment where that compound was the only or the most abundant available source of fuel, the mutant cell would have a selective advantage over the other, unmutated (wild-type) cells in the population. The mutant cell and its progeny would survive and prosper in the new environment, whereas wild-type cells would starve and be eliminated. This is what Darwin meant by “survival of the fittest under selective pressure”—the process of natural selection.

Occasionally, a second copy of a whole gene is introduced into the chromosome as a result of defective replication of the chromosome. The second copy is superfluous, and mutations in this gene will not be deleterious; it becomes a means by which the cell may evolve, by producing a new gene with a new function while retaining the original gene and gene function. Seen in this light, the DNA molecules of modern organisms are historical documents, records of the long journey from the earliest cells to modern organisms. The historical accounts in DNA are not complete, however; in the course of evolution, many mutations must have been erased or written over. But DNA molecules are the best source of biological history that we have. The frequency of errors in DNA replication represents a balance between too many errors, which would yield nonviable daughter cells, and too few, which would prevent the genetic variation that allows survival of mutant cells in new ecological niches.

Several billion years of adaptive selection have refined cellular systems to take maximum advantage of the chemical and physical properties of available raw materials. Chance genetic variations in individuals in a population, combined with natural selection, have resulted in the evolution of today’s enormous variety of organisms, each adapted to its particular ecological niche.

Biomolecules First Arose by Chemical Evolution

In our account thus far we have passed over the first chapter of the story of evolution: the appearance of the first living cell. Apart from their occurrence in living organisms, organic compounds, including the basic biomolecules such as amino acids and carbohydrates, are found in only trace amounts in the Earth’s crust, the sea, and the atmosphere. How did the first living organisms acquire their characteristic organic building blocks? According to one hypothesis, these compounds were created by the effects of powerful atmospheric forces—ultraviolet irradiation, lightning, or volcanic eruptions—on the gases in the prebiotic Earth’s atmosphere, and on inorganic solutes in superheated thermal vents deep in the ocean.

This hypothesis was tested in a classic experiment on the abiotic (nonbiological) origin of organic biomolecules carried out in 1953 by Stanley Miller in the laboratory of Harold Urey. Miller subjected gaseous mixtures
such as those presumed to exist on the prebiotic Earth, including NH₃, CH₄, H₂O, and H₂, to electrical sparks produced across a pair of electrodes (to simulate lightning) for periods of a week or more, then analyzed the contents of the closed reaction vessel (Fig. 1–33). The gas phase of the resulting mixture contained CO and CO₂, as well as the starting materials. The water phase contained a variety of organic compounds, including some amino acids, hydroxy acids, aldehydes, and hydrogen cyanide (HCN). This experiment established the possibility of abiotic production of biomolecules in relatively short times under relatively mild conditions.

More refined laboratory experiments have provided good evidence that many of the chemical components of living cells, including polypeptides and RNA-like molecules, can form under these conditions. Polymers of RNA can act as catalysts in biologically significant reactions (see Chapters 26 and 27), and RNA probably played a crucial role in prebiotic evolution, both as catalyst and as information repository.

### RNA or Related Precursors May Have Been the First Genes and Catalysts

In modern organisms, nucleic acids encode the genetic information that specifies the structure of enzymes, and enzymes catalyze the replication and repair of nucleic acids. The mutual dependence of these two classes of biomolecules brings up the perplexing question: which came first, DNA or protein?

The answer may be that they appeared about the same time, and RNA preceded them both. The discovery that RNA molecules can act as catalysts in their own formation suggests that RNA or a similar molecule may have been the first gene and the first catalyst. According to this scenario (Fig. 1–34), one of the earliest stages of biological evolution was the chance formation, in the primordial soup, of an RNA molecule that could catalyze the formation of other RNA molecules of the same sequence—a self-replicating, self-perpetuating RNA. The concentration of a self-replicating RNA molecule would increase exponentially, as one molecule formed two, two formed four, and so on. The fidelity of self-replication was presumably less than perfect, so the process would generate variants of the RNA, some of which might be even better able to self-replicate. In the competition for nucleotides, the most efficient of the self-replicating sequences would win, and less efficient replicators would fade from the population.

**FIGURE 1–34** A possible “RNA world” scenario.
The division of function between DNA (genetic information storage) and protein (catalysis) was, according to the “RNA world” hypothesis, a later development. New variants of self-replicating RNA molecules developed, with the additional ability to catalyze the condensation of amino acids into peptides. Occasionally, the peptide(s) thus formed would reinforce the self-replicating ability of the RNA, and the pair—RNA molecule and helping peptide—could undergo further modifications in sequence, generating increasingly efficient self-replicating systems. The remarkable discovery that, in the protein-synthesizing machinery of modern cells (ribosomes), RNA molecules, not proteins, catalyze the formation of peptide bonds is consistent with the RNA world hypothesis.

Some time after the evolution of this primitive protein-synthesizing system, there was a further development: DNA molecules with sequences complementary to the self-replicating RNA molecules took over the function of conserving the “genetic” information, and RNA molecules evolved to play roles in protein synthesis. (We explain in Chapter 8 why DNA is a more stable molecule than RNA and thus a better repository of inheritable information.) Proteins proved to be versatile catalysts and, over time, took over most of that function. Lipidlike compounds in the primordial soup formed relatively impermeable layers around self-replicating collections of molecules. The concentration of proteins and nucleic acids within these lipid enclosures favored the molecular interactions required in self-replication.

Biological Evolution Began More Than Three and a Half Billion Years Ago

Earth was formed about 4.6 billion years ago, and the first evidence of life dates to more than 3.5 billion years ago. In 1996, scientists working in Greenland found chemical evidence of life (“fossil molecules”) from as far back as 3.85 billion years ago, forms of carbon embedded in rock that seem to have a distinctly biological origin. Somewhere on Earth during its first billion years the first simple organism arose, capable of replicating its own structure from a template (RNA?) that was the first genetic material. Because the terrestrial atmosphere at the dawn of life was nearly devoid of oxygen, and because there were few microorganisms to scavenge organic compounds formed by natural processes, these compounds were relatively stable. Given this stability and eons of time, the improbable became inevitable: the organic compounds were incorporated into evolving cells to produce increasingly effective self-reproducing catalysts. The process of biological evolution had begun.

The First Cell Probably Used Inorganic Fuels

The earliest cells arose in a reducing atmosphere (there was no oxygen) and probably obtained energy from inorganic fuels, such as ferrous sulfide and ferrous carbonate, both abundant on the early Earth. For example, the reaction

\[
\text{FeS + H}_2\text{S} \rightarrow \text{FeS}_2 + \text{H}_2
\]

yields enough energy to drive the synthesis of ATP or similar compounds. The organic compounds they required may have arisen by the nonbiological actions of lightning or of heat from volcanoes or thermal vents in the sea on components of the early atmosphere: \(\text{CO}_2, \text{CO}, \text{N}_2, \text{NH}_3, \text{CH}_4, \) and such. An alternative source of organic compounds has been proposed: extraterrestrial space. In 2006, the Stardust space mission brought back tiny particles of dust from the tail of a comet; the dust contained a variety of organic compounds.

Early unicellular organisms gradually acquired the ability to derive energy from compounds in their environment and to use that energy to synthesize more of their own precursor molecules, thereby becoming less dependent on outside sources. A very significant evolutionary event was the development of pigments capable of capturing the energy of light from the sun, which could be used to reduce, or “fix,” \(\text{CO}_2\) to form more complex, organic compounds. The original electron donor for these photosynthetic processes was probably \(\text{H}_2\text{S}\), yielding elemental sulfur or sulfate (\(\text{SO}_4^{2-}\)) as the by-product; later cells developed the enzymatic capacity to use \(\text{H}_2\text{O}\) as the electron donor in photosynthetic reactions, eliminating \(\text{O}_2\) as waste. Cyanobacteria are the modern descendants of these early photosynthetic oxygen-producers.

Because the atmosphere of Earth in the earliest stages of biological evolution was nearly devoid of oxygen, the earliest cells were anaerobic. Under these conditions, chemotrophs could oxidize organic compounds to \(\text{CO}_2\) by passing electrons not to \(\text{O}_2\) but to acceptors such as \(\text{SO}_4^{2-}\), in this case yielding \(\text{H}_2\text{S}\) as the product. With the rise of \(\text{O}_2\)-producing photosynthetic bacteria, the atmosphere became progressively richer in oxygen—a powerful oxidant and deadly poison to anaerobes. Responding to the evolutionary pressure of what Lynn Margulis and Dorion Sagan have called the “oxygen holocaust,” some lineages of microorganisms gave rise to aerobes that obtained energy by passing electrons from fuel molecules to oxygen. Because the transfer of electrons from organic molecules to \(\text{O}_2\) releases a great deal of energy, aerobic organisms had an energetic advantage over their anaerobic counterparts when both competed in an environment containing oxygen. This advantage translated into the predominance of aerobic organisms in \(\text{O}_2\)-rich environments.

Modern bacteria and archaea inhabit almost every ecological niche in the biosphere, and there are organisms capable of using virtually every type of organic compound as a source of carbon and energy. Photosynthetic microbes in both fresh and marine waters trap solar energy and use it to generate carbohydrates and all other
cell constituents, which are in turn used as food by other forms of life. The process of evolution continues—and, in rapidly reproducing bacterial cells, on a time scale that allows us to witness it in the laboratory. One approach toward producing a "protocell" in the laboratory involves determining the minimum number of genes necessary for life by examining the genomes of simple bacteria. The smallest known genome for a free-living bacterium is that of Mycobacterium genitalium, which comprises 580,000 base pairs encoding 483 genes.

**Eukaryotic Cells Evolved from Simpler Precursors in Several Stages**

Starting about 1.5 billion years ago, the fossil record begins to show evidence of larger and more complex organisms, probably the earliest eukaryotic cells (Fig. 1–35). Details of the evolutionary path from non-nucleated to nucleated cells cannot be deduced from the fossil record alone, but morphological and biochemical comparisons of modern organisms have suggested a sequence of events consistent with the fossil evidence.

Three major changes must have occurred. First, as cells acquired more DNA, the mechanisms required to fold it compactly into discrete complexes with specific proteins and to divide it equally between daughter cells at cell division became more elaborate. Specialized proteins were required to stabilize folded DNA and to pull the resulting DNA-protein complexes (chromosomes) apart during cell division. Second, as cells became larger, a system of intracellular membranes developed, including a double membrane surrounding the DNA. This membrane segregated the nuclear process of RNA synthesis on a DNA template from the cytoplasmic process of protein synthesis on ribosomes. Finally, early eukaryotic cells, which were incapable of photosynthesis or aerobic metabolism, enveloped aerobic bacteria or photosynthetic bacteria to form endosymbiotic associations that eventually became permanent (Fig. 1–36). Some aerobic bacteria evolved into the mitochondria of modern eukaryotes, and some photosynthetic cyanobacteria became the plastids, such as the chloroplasts of green algae, the likely ancestors of modern plant cells.

At some later stage of evolution, unicellular organisms found it advantageous to cluster together, thereby acquiring greater motility, efficiency, or reproductive success than their free-living single-celled competitors. Further evolution of such clustered organisms led to permanent associations among individual cells and eventually to specialization within the colony—to cellular differentiation.

The advantages of cellular specialization led to the evolution of increasingly complex and highly differentiated organisms, in which some cells carried out the sensory functions, others the digestive, photosynthetic, or reproductive functions, and so forth. Many modern multicellular organisms contain hundreds of different cell types, each specialized for a function that supports the entire organism. Fundamental mechanisms that evolved early have been further refined and embellished through evolution. The same basic structures and mechanisms that underlie the beating motion of cilia in Paramecium and of flagella in Chlamydomonas are employed by the highly differentiated vertebrate sperm cell, for example.

**Molecular Anatomy Reveals Evolutionary Relationships**

Biochemists now have an enormously rich, ever increasing treasury of information on the molecular anatomy of cells that they can use to analyze evolutionary relationships and refine evolutionary theory. The sequence of the genome, the complete genetic endowment of an organism, has been determined for hundreds of bacteria and more than 40 archaea and for growing numbers of eukaryotic microorganisms, including Saccharomyces cerevisiae and Plasmodium sp.; plants, including Arabidopsis thaliana and rice; and multicellular animals, including Caenorhabditis elegans (a roundworm),
Anaerobic metabolism is inefficient because fuel is not completely oxidized.

Bacterium is engulfed by ancestral eukaryote, and multiplies within it.

Some bacterial genes move to the nucleus, and the bacterial endosymbionts become mitochondria.

Symbiotic system can now carry out aerobic catabolism. Nonphotosynthetic eukaryote

Bacterium

Mitochondrion

Nonphotosynthetic eukaryote

Photosynthetic eukaryote

Engulfed cyanobacterium becomes an endosymbiont and multiplies; new cell can make ATP using energy from sunlight.

Photosynthetic cyanobacterium

Light energy is used to synthesize biomolecules from CO₂.

Photosynthetic eukaryote

In time, some cyanobacterial genes move to the nucleus, and endosymbionts become plastids (chloroplasts).

Two homologous genes (or proteins) found in different species are said to be orthologous, and their protein products are orthologs. Orthologs are commonly found to have the same function in both organisms, and when a newly sequenced gene in one species is found to be strongly orthologous with a gene in another, this gene is presumed to encode a protein with the same function in both species. By this means, the function of gene products can be deduced from the genomic sequence, without any biochemical characterization of the gene product. An annotated genome includes, in addition to the DNA sequence itself, a description of the likely function of each gene product, deduced from comparisons with other genomic sequences and established protein functions. Sometimes, by identifying the pathways (sets of enzymes) encoded in a genome, we can deduce from the genomic sequence alone the organism's metabolic capabilities.

The sequence differences between homologous genes may be taken as a rough measure of the degree to which the two species have diverged during evolution—of how long ago their common evolutionary precursor gave rise to two lines with different evolutionary fates. The larger the number of sequence differences, the earlier the divergence in evolutionary history. One can construct a phylogeny (family tree) in which the evolutionary distance between any two species is represented by their proximity on the tree (Fig. 1–4 is an example).
In the course of evolution, new structures, processes, or regulatory mechanisms are acquired, reflections of the changing genomes of the evolving organisms. The genome of a simple eukaryote such as yeast should have genes related to formation of the nuclear membrane, genes not present in bacteria or archaea. The genome of an insect should contain genes that encode proteins involved in specifying insects' characteristic segmented body plan, genes not present in yeast. The genomes of all vertebrate animals should share genes that specify the development of a spinal column, and those of mammals should have unique genes necessary for the development of the placenta, a characteristic of mammals—and so on. Comparisons of the whole genomes of species in each phylum are leading to the identification of genes critical to fundamental evolutionary changes in body plan and development.

**Functional Genomics Shows the Allocations of Genes to Specific Cellular Processes**

When the sequence of a genome is fully determined and each gene is assigned a function, molecular geneticists can group genes according to the processes (DNA synthesis, protein synthesis, generation of ATP, and so forth) in which they function and thus find what fraction of the genome is allocated to each of a cell's activities. The largest category of genes in *E. coli, A. thaliana,* and *H. sapiens* consists of genes of (as yet) unknown function, which make up more than 40% of the genes in each species. The transporters that move ions and small molecules across plasma membranes take up a significant proportion of the genes in all three species, more in the bacterium and plant than in the mammal (10% of the ~4,400 genes of *E. coli, ~8% of the ~32,000 genes of *A. thaliana,* and ~4% of the ~29,000 genes of *H. sapiens*). Genes that encode the proteins and RNA required for protein synthesis make up 3% to 4% of the *E. coli* genome, but in the more complex cells of *A. thaliana,* more genes are needed for targeting proteins to their final location in the cell than are needed to synthesize those proteins (about 6% and 2% of the genome, respectively). In general, the more complex the organism, the greater the proportion of its genome that encodes genes involved in the regulation of cellular processes and the smaller the proportion dedicated to the basic processes themselves, such as ATP generation and protein synthesis.

**Genomic Comparisons Have Increasing Importance in Human Biology and Medicine**

The genomes of chimpanzees and humans are 99.9% identical, yet the differences between the
two species are vast. The relatively few differences in genetic endowment must explain the possession of language by humans, the extraordinary athleticism of chimpanzees, and myriad other differences. Genomic comparison is allowing researchers to identify candidate genes linked to divergences in the developmental programs of humans and the other primates and to the emergence of complex functions such as language. The picture will become clearer only as more primate genomes become available for comparison with the human genome.

Similarly, the differences in genetic endowment among humans are vanishingly small compared with the differences between humans and chimpanzees, yet these differences account for the variety among us—including differences in health and in susceptibility to chronic diseases. We have much to learn about the variability in sequence among humans, and the availability of genomic information will almost certainly transform medical diagnosis and treatment. We may expect that for some genetic diseases, palliatives will be replaced by cures; and that for disease susceptibilities associated with particular genetic markers, forewarning and perhaps increased preventive measures will prevail. Today's "medical history" may be replaced by a "medical forecast."

SUMMARY 1.5 Evolutionary Foundations

- Occasional inheritable mutations yield organisms that are better suited for survival in an ecological niche and progeny that are preferentially selected. This process of mutation and selection is the basis for the Darwinian evolution that led from the first cell to all modern organisms and explains the fundamental similarity of all living organisms.

- Life originated about 3.5 billion years ago, most likely with the formation of a membrane-enclosed compartment containing a self-replicating RNA molecule. The components for the first cell may have been produced near thermal vents at the bottom of the sea or by the action of lightning and high temperature on simple atmospheric molecules such as CO₂ and NH₃.

- The catalytic and genetic roles played by the early RNA genome were, over time, taken over by proteins and DNA, respectively.

- Eukaryotic cells acquired the capacity for photosynthesis and oxidative phosphorylation from endosymbiotic bacteria. In multicellular organisms, differentiated cell types specialize in one or more of the functions essential to the organism's survival.

- Knowledge of the complete genomic nucleotide sequences of organisms from different branches of the phylogenetic tree provides insights into evolution and offers great opportunities in human medicine.

Key Terms

All terms are defined in the glossary.

- metabolite
- nucleus
- genome
- eukaryote
- prokaryote
- bacteria
- archaea
- cytoskeleton
- stereoisomers
- configuration
- chiral center
- conformation
- entropy

Further Reading

General

A distinguished historian of biochemistry traces the development of this science and discusses its impact on medicine, pharmacy, and agriculture.

A highly readable and authoritative account of the rise of biochemistry and molecular biology in the twentieth century.

The importance of applying chemical tools to biological problems, described by an eminent practitioner.

An exploration of the philosophical implications of biological knowledge.

Short, beautifully written discussion of the emergence of complex organisms from simple beginnings.

A short discussion of the minimal definition of life, on Earth and elsewhere.

Cellular Foundations

An excellent introductory textbook of cell biology.

A superb text, useful for this and later chapters.

A collection of almost 100 articles on all aspects of prebiotic and early biological evolution; probably the single best source on molecular evolution.

A collection of stimulating reviews on a wide range of topics related to the RNA world scenario.

Brief review of developments in studies of the origin of life: primitive atmospheres, submarine vents, autotrophic versus heterotrophic origin, the RNA and pre-RNA worlds, and the time required for life to arise.

The arguments for dividing all living creatures into five kingdoms: Monera, Prototista, Fungi, Animalia, Plantae. (Compare Woese et al., 1990, below.)

Description of all major groups of organisms, beautifully illustrated with electron micrographs and drawings.

A history of the development of science, with special emphasis on Darwinian evolution, by an eminent Darwin scholar.

Summary of laboratory experiments on chemical evolution, by the person who did the original Miller-Urey experiment.

Short, clear review.

Development of current thinking about cellular evolution by one of the seminal thinkers in the field.

The arguments for dividing all living creatures into three domains. (Compare Margulis, 1996, above.)

### Problems

Some problems related to the contents of the chapter follow. (In solving end-of-chapter problems, you may wish to refer to the tables on the inside of the back cover.) Each problem has a title for easy reference and discussion. For all numerical problems, keep in mind that answers should be expressed with the correct number of significant figures. Brief solutions are provided in Appendix B; expanded solutions are published in the *Absolute Ultimate Study Guide to Accompany Principles of Biochemistry*.

#### 1. The Size of Cells and Their Components

(a) If you were to magnify a cell 10,000 fold (typical of the magnification achieved using an electron microscope), how big would it appear? Assume you are viewing a “typical” eukaryotic cell with a cellular diameter of 50 μm.
(b) If this cell were a muscle cell (myocyte), how many molecules of actin could it hold? (Assume the cell is spherical and no other cellular components are present; actin molecules are spherical, with a diameter of 3.6 nm. The volume of a sphere is \( \frac{4}{3} \pi r^3 \).)

(c) If this were a liver cell (hepatocyte) of the same dimensions, how many mitochondria could it hold? (Assume the cell is spherical; no other cellular components are present; and the mitochondria are spherical, with a diameter of 1.5 \( \mu \)m.)

(d) Glucose is the major energy-yielding nutrient for most cells. Assuming a cellular concentration of 1 nm (that is, 1 millimole/L), calculate how many molecules of glucose would be present in our hypothetical (and spherical) eukaryotic cell. (Avogadro's number, the number of molecules in 1 mol of a nonionized substance, is \( 6.02 \times 10^{23} \).)

(e) Hexokinase is an important enzyme in the metabolism of glucose. If the concentration of hexokinase in our eukaryotic cell is 20 \( \mu \)M, how many glucose molecules are present per hexokinase molecule?

2. Components of \( E. coli \) \( E. coli \) cells are rod-shaped, about 2 \( \mu \)m long and 0.8 \( \mu \)m in diameter. The volume of a cylinder is \( \pi r^2h \), where \( h \) is the height of the cylinder.

(a) If the average density of \( E. coli \) (mostly water) is \( 1.1 \times 10^3 \) g/L, what is the mass of a single cell?

(b) \( E. coli \) has a protective cell envelope 10 \( \mu \)m thick. What percentage of the total volume of the bacterium does the cell envelope occupy?

(c) \( E. coli \) is capable of growing and multiplying rapidly because it contains some 15,000 spherical ribosomes (diameter 18 nm), which carry out protein synthesis. What percentage of the cell volume do the ribosomes occupy?

3. Genetic Information in \( E. coli \) DNA The genetic information contained in DNA consists of a linear sequence of coding units, known as codons. Each codon is a specific sequence of three deoxyribonucleotides (three deoxyribonucleotide pairs in double-stranded DNA), and each codon codes for a single amino acid unit in a protein. The molecular weight of an \( E. coli \) DNA molecule is about 3.1 \( \times 10^6 \) g/mol. The average molecular weight of a nucleotide pair is 660 g/mol, and each nucleotide pair contributes 0.34 nm to the length of DNA.

(a) Calculate the length of an \( E. coli \) DNA molecule. Compare the length of the DNA molecule with the cell dimensions (see Problem 2). How does the DNA molecule fit into the cell?

(b) Assume that the average protein in \( E. coli \) consists of a chain of 400 amino acids. What is the maximum number of proteins that can be coded by an \( E. coli \) DNA molecule?

4. The High Rate of Bacterial Metabolism Bacterial cells have a much higher rate of metabolism than animal cells. Under ideal conditions some bacteria double in size and divide every 20 min, whereas most animal cells under rapid growth conditions require 24 hours. The high rate of bacterial metabolism requires a high ratio of surface area to cell volume.

(a) Why does surface-to-volume ratio affect the maximum rate of metabolism?

(b) Calculate the surface-to-volume ratio for the spherical bacterium \( Neisseria gonorrhoeae \) (diameter 0.5 \( \mu \)m), responsible for the disease gonorrhea. Compare it with the surface-to-volume ratio for a globular amoeba, a large eukaryotic cell (diameter 150 \( \mu \)m). The surface area of a sphere is \( 4\pi r^2 \).

5. Fast Axonal Transport Neurons have long thin processes called axons, structures specialized for conducting signals throughout the organism's nervous system. Some axonal processes can be as long as 2 m—for example, the axons that originate in your spinal cord and terminate in the muscles of your toes. Small membrane-enclosed vesicles carrying materials essential to axonal function move along microtubules of the cytoskeleton, from the cell body to the tips of the axons. If the average velocity of a vesicle is 1 \( \mu \)m/s, how long does it take a vesicle to move from a cell body in the spinal cord to the axonal tip in the toes?

6. Is Synthetic Vitamin C as Good as the Natural Vitamin? A claim put forth by some purveyors of health foods is that vitamins obtained from natural sources are more healthful than those obtained by chemical synthesis. For example, pure L-ascorbic acid (vitamin C) extracted from rose hips is better than pure L-ascorbic acid manufactured in a chemical plant. Are the vitamins from the two sources different? Can the body distinguish a vitamin's source?

7. Identification of Functional Groups Figures 1-15 and 1-16 show some common functional groups of biomolecules. Because the properties and biological activities of biomolecules are largely determined by their functional groups, it is important to be able to identify them. In each of the compounds below, circle and identify by name each functional group.

8. Drug Activity and Stereochemistry The quantitative differences in biological activity between the two enantiomers of a compound are sometimes quite large. For example, the \( \alpha \) isomer of the drug isoproterenol, used to treat
mild asthma, is 50 to 80 times more effective as a bronchodilator than the L isomer. Identify the chiral center in isoproterenol. Why do the two enantiomers have such radically different bioactivity?

9. Separating Biomolecules In studying a particular biomolecule (a protein, nucleic acid, carbohydrate, or lipid) in the laboratory, the biochemist first needs to separate it from other biomolecules in the sample—that is, to purify it. Specific purification techniques are described later in the text. However, by looking at the monomeric subunits of a biomolecule, you should have some ideas about the characteristics of the molecule that would allow you to separate it from other molecules. For example, how would you separate (a) amino acids from fatty acids and (b) nucleotides from glucose?

10. Silicon-Based Life? Silicon is in the same group of the periodic table as carbon and, like carbon, can form up to four single bonds. Many science fiction stories have been based on the premise of silicon-based life. Is this realistic? What characteristics of silicon make it less well adapted than carbon as the central organizing element for life? To answer this question, consider what you have learned about carbon's bonding versatility, and refer to a beginning inorganic chemistry textbook for silicon's bonding properties.

11. Drug Action and Shape of Molecules Some years ago two drug companies marketed a drug under the trade names Dexedrine and Benzedrine. The structure of the drug is shown below.

The physical properties (C, H, and N analysis, melting point, solubility, etc.) of Dexedrine and Benzedrine were identical. The recommended oral dosage of Dexedrine (which is still available) was 5 mg/day, but the recommended dosage of Benzedrine (no longer available) was twice that. Apparently it required considerably more Benzedrine than Dexedrine to yield the same physiological response. Explain this apparent contradiction.

12. Components of Complex Biomolecules Figure 1–10 shows the major components of complex biomolecules. For each of the three important biomolecules below (shown in their ionized forms at physiological pH), identify the constituents.

(a) Guanosine triphosphate (GTP), an energy-rich nucleotide that serves as a precursor to RNA:

(b) Methionine enkephalin, the brain's own opiate:

(c) Phosphatidylcholine, a component of many membranes:

13. Determination of the Structure of a Biomolecule An unknown substance, X, was isolated from rabbit muscle. Its structure was determined from the following observations and experiments. Qualitative analysis showed that X was composed entirely of C, H, and O. A weighed sample of X was completely oxidized, and the H₂O and CO₂ produced were measured; this quantitative analysis revealed that X contained 40.00% C, 6.710% H, and 53.29% O by weight. The molecular mass of X, determined by mass spectrometry, was 90.00 u (atomic mass units; see Box 1–1). Infrared spectroscopy showed that X contained one double bond. X dissolved readily in water to give an acidic solution; the solution demonstrated optical activity when tested in a polarimeter.

(a) Determine the empirical and molecular formula of X.
(b) Draw the possible structures of X that fit the molecular formula and contain one double bond. Consider only linear or branched structures and disregard cyclic structures. Note that oxygen makes very poor bonds to itself.
(c) What is the structural significance of the observed optical activity? Which structures in (b) are consistent with the observation?
(d) What is the structural significance of the observation that a solution of X was acidic? Which structures in (b) are consistent with the observation?
(e) What is the structure of X? Is more than one structure consistent with all the data?

14. Sweet-Tasting Molecules Many compounds taste sweet to humans. Sweet taste results when a molecule binds to the sweet receptor, one type of taste receptor, on the surface of certain tongue cells. The stronger the binding, the lower the concentration required to saturate the receptor and the sweeter a given concentration of that substance tastes. The standard free-energy change, ΔG°, of the binding reaction
between a sweet molecule and a sweet receptor can be measured in kilojoules or kilocalories per mole.

Sweet taste can be quantified in units of “molar relative sweetness” (MRS), a measure that compares the sweetness of a substance to the sweetness of sucrose. For example, saccharin has an MRS of 161; this means that saccharin is 161 times sweeter than sucrose. In practical terms, this is measured by asking human subjects to compare the sweetness of solutions containing different concentrations of each compound. Sucrose and saccharin taste equally sweet when sucrose is at a concentration 161 times higher than that of saccharin.

(a) What is the relationship between MRS and the $\Delta G^\circ$ of the binding reaction? Specifically, would a more negative $\Delta G^\circ$ correspond to a higher or lower MRS? Explain your reasoning.

Shown below are the structures of 10 compounds, all of which taste sweet to humans. The MRS and $\Delta G^\circ$ for binding to the sweet receptor are given for each substance.

(b) Why is it useful to have a computer model to predict the sweetness of molecules, instead of a human- or animal-based taste assay?

In earlier work, Schallenberger and Acree (1967) had suggested that all sweet molecules include an “AH-B” structural group, in which “A and B are electronegative atoms separated by a distance of greater than 2.5 Å [0.25 nm] but less than 4 Å [0.4 nm], H is a hydrogen atom attached to one of the electronegative atoms by a covalent bond” (p. 481).

(c) Given that the length of a “typical” single bond is about 0.15 nm, identify the AH-B group(s) in each of the molecules shown above.

(d) Based on your findings from (c), give two objections to the statement that “molecules containing an AH-B structure will taste sweet.”

(e) For the two of the molecules shown above, the AH-B model can be used to explain the difference in MRS and $\Delta G^\circ$. Which two molecules are these, and how would you use them to support the AH-B model?

(f) Several of the molecules have closely related structures but very different MRS and $\Delta G^\circ$ values. Give two such examples, and use these to argue that the AH-B model is unable to explain the observed differences in sweetness.

In their computer-modeling study, Morini and coauthors used the three-dimensional structure of the sweet receptor and a molecular dynamics modeling program called GRAMM to predict the $\Delta G^\circ$ of binding of sweet molecules to the sweet receptor. First, they “trained” their model—that is, they refined the parameters so that the $\Delta G^\circ$ values predicted by the model matched the known $\Delta G^\circ$ values for one set of sweet molecules (the “training set”). They then “tested” the model by asking it to predict the $\Delta G^\circ$ values for a new set of molecules (the “test set”).

(g) Why did Morini and colleagues need to test their model against a different set of molecules from the set it was trained on?

(h) The researchers found that the predicted $\Delta G^\circ$ values for the test set differed from the actual values by, on average, 1.3 kcal/mol. Using the values given with the structures above, estimate the resulting error in MRS values.

References

Biochemistry is nothing less than the chemistry of life, and, yes, life can be investigated, analyzed, and understood. To begin, every student of biochemistry needs both a language and some fundamentals; these are provided in Part I.

The chapters of Part I are devoted to the structure and function of the major classes of cellular constituents: water (Chapter 2), amino acids and proteins (Chapters 3 through 6), sugars and polysaccharides (Chapter 7), nucleotides and nucleic acids (Chapter 8), fatty acids and lipids (Chapter 10), and, finally, membranes and membrane signaling proteins (Chapters 11 and 12). We supplement this discourse on molecules with information about the technologies used to study them. Techniques sections are woven in throughout the text, and one chapter (Chapter 9) is devoted entirely to biotechnologies associated with cloning, genomics, and proteomics.

We begin, in Chapter 2, with water, because its properties affect the structure and function of all other cellular constituents. For each class of organic molecules, we first consider the covalent chemistry of the monomeric units (amino acids, monosaccharides, nucleotides, and fatty acids) and then describe the structure of the macromolecules and supramolecular complexes derived from them. An overarching theme is that the polymeric macromolecules in living systems, though large, are highly ordered chemical entities, with specific sequences of monomeric subunits giving rise to discrete structures and functions. This fundamental theme can be broken down into three interrelated principles: (1) the unique structure of each macromolecule determines its function; (2) noncovalent interactions play a critical role in the structure and thus the function of macromolecules; and (3) the monomeric subunits in polymeric macromolecules occur in specific sequences, representing a form of information on which the ordered living state depends.

The relationship between structure and function is especially evident in proteins, which exhibit an extraordinary diversity of functions. One particular polymeric sequence of amino acids produces a strong, fibrous structure found in hair and wool; another produces a protein that transports oxygen in the blood; a
third binds other proteins and catalyzes the cleavage of the bonds between their amino acids. Similarly, the special functions of polysaccharides, nucleic acids, and lipids can be understood as resulting directly from their chemical structure, with their characteristic monomeric subunits precisely linked to form functional polymers. Sugars linked together become energy stores, structural fibers, and points of specific molecular recognition; nucleotides strung together in DNA or RNA provide the blueprint for an entire organism; and aggregated lipids form membranes. Chapter 12 unifies the discussion of biomolecule function, describing how specific signaling systems regulate the activities of biomolecules—within a cell, within an organ, and among organs—to keep an organism in homeostasis.

As we move from monomeric units to larger and larger polymers, the chemical focus shifts from covalent bonds to noncovalent interactions. Covalent bonds, at the monomeric and macromolecular level, place constraints on the shapes assumed by large biomolecules. It is the numerous noncovalent interactions, however, that dictate the stable, native conformations of large molecules while permitting the flexibility necessary for their biological function. As we shall see, noncovalent interactions are essential to the catalytic power of enzymes, the critical interaction of complementary base pairs in nucleic acids, and the arrangement and properties of lipids in membranes. The principle that sequences of monomeric subunits are rich in information emerges most fully in the discussion of nucleic acids (Chapter 8). However, proteins and some short polymers of sugars (oligosaccharides) are also information-rich molecules. The amino acid sequence is a form of information that directs the folding of the protein into its unique three-dimensional structure, and ultimately determines the function of the protein. Some oligosaccharides also have unique sequences and three-dimensional structures that are recognized by other macromolecules.

Each class of molecules has a similar structural hierarchy: subunits of fixed structure are connected by bonds of limited flexibility to form macromolecules with three-dimensional structures determined by noncovalent interactions. These macromolecules then interact to form the supramolecular structures and organelles that allow a cell to carry out its many metabolic functions. Together, the molecules described in Part I are the stuff of life.
Water

2.1 Weak Interactions in Aqueous Systems  43
2.2 Ionization of Water, Weak Acids, and Weak Bases  54
2.3 Buffering against pH Changes in Biological Systems  59
2.4 Water as a Reactant  65
2.5 The Fitness of the Aqueous Environment for Living Organisms  65

2.1 Weak Interactions in Aqueous Systems

Hydrogen bonds between water molecules provide the cohesive forces that make water a liquid at room temperature and favor the extreme ordering of molecules that is typical of crystalline water (ice). Polar biomolecules dissolve readily in water because they can replace water-water interactions with more energetically favorable water-solute interactions. In contrast, nonpolar biomolecules interfere with water-water interactions but are unable to form water-solute interactions—consequently, nonpolar molecules are poorly soluble in water. In aqueous solutions, nonpolar molecules tend to cluster together. Hydrogen bonds and ionic, hydrophobic (Greek, “water-fearing”), and van der Waals interactions are individually weak, but collectively they have a very significant influence on the three-dimensional structures of proteins, nucleic acids, polysaccharides, and membrane lipids.

Hydrogen Bonding Gives Water Its Unusual Properties

Water has a higher melting point, boiling point, and heat of vaporization than most other common solvents (Table 2–1). These unusual properties are a consequence of attractions between adjacent water molecules that give liquid water great internal cohesion. A look at the electron structure of the H₂O molecule reveals the cause of these intermolecular attractions.

Each hydrogen atom of a water molecule shares an electron pair with the central oxygen atom. The geometry of the molecule is dictated by the shapes of the outer electron orbitals of the oxygen atom, which are similar to the sp³ bonding orbitals of carbon (see Fig. 1–14). These orbitals describe a rough tetrahedron, with a hydrogen atom at each of two corners and unshared electron pairs at the other two corners (Fig. 2–1a). The H—O—H bond angle is 104.5°, slightly less than the 109.5° of a perfect tetrahedron because of crowding by the nonbonding orbitals of the oxygen atom.

The oxygen nucleus attracts electrons more strongly than does the hydrogen nucleus (a proton); that is, oxygen is more electronegative. This means that the shared
electrons are more often in the vicinity of the oxygen atom than of the hydrogen. The result of this unequal electron sharing is two electric dipoles in the water molecule, one along each of the \( \text{H} - \text{O} \) bonds; each hydrogen bears a partial positive charge (\( \delta^+ \)), and the oxygen atom bears a partial negative charge equal in magnitude to the sum of the two partial positives (\( 2\delta^- \)). As a result, there is an electrostatic attraction between the oxygen atom of one water molecule and the hydrogen of another (Fig. 2-1b), called a hydrogen bond. Throughout this book, we represent hydrogen bonds with three parallel blue lines, as in Figure 2-1b.

Hydrogen bonds are relatively weak. Those in liquid water have a bond dissociation energy (the energy required to break a bond) of about 23 kJ/mol, compared with 470 kJ/mol for the covalent \( \text{O} - \text{H} \) bond in water or 348 kJ/mol for a covalent \( \text{C} - \text{C} \) bond. The hydrogen bond is about 10% covalent, due to overlaps in the bonding orbitals, and about 90% electrostatic. At room temperature, the thermal energy of an aqueous solution (the kinetic energy of motion of the individual atoms and molecules) is of the same order of magnitude as that required to break hydrogen bonds. When water is heated, the increase in temperature reflects the faster motion of individual water molecules. At any given time, most of the molecules in liquid water are hydrogen bonded, but the lifetime of each hydrogen bond is just 1 to 20 picoseconds (1 ps : 10\(^{-12}\) s); when one hydrogen bond breaks, another hydrogen bond forms, with the same partner or a new one, within 0.1 ps. The apt phrase “flickering clusters” has been applied to the short-lived groups of water molecules interlinked by hydrogen bonds in liquid water. The sum of all the hydrogen bonds between \( \text{H}_2\text{O} \) molecules confers great internal cohesion on liquid water. Extended networks of hydrogen-bonded water molecules also form bridges between solutes (proteins and nucleic acids, for example) that allow the larger molecules to interact with each other over distances of several nanometers without physically touching.

The nearly tetrahedral arrangement of the orbitals about the oxygen atom (Fig. 2-1a) allows each water molecule to form hydrogen bonds with as many as four neighboring water molecules. In liquid water at room temperature and atmospheric pressure, however, water molecules are disorganized and in continuous motion, so that each molecule forms hydrogen bonds with an average of only 3.4 other molecules. In ice, on the other hand, each water molecule is fixed in space and forms hydrogen bonds with a full complement of four other water molecules to yield a regular lattice structure (Fig. 2-2). Breaking a sufficient proportion of hydrogen bonds to destabilize the crystal lattice of ice requires much thermal energy, which accounts for the relatively high melting

\[ \text{Hydrogen acceptor} \]
\[ \text{Hydrogen donor} \]

FIGURE 2-3 Common hydrogen bonds in biological systems. The hydrogen acceptor is usually oxygen or nitrogen; the hydrogen donor is another electronegative atom.

to carbon atoms do not participate in hydrogen bonding, because carbon is only slightly more electronegative than hydrogen and thus the C—H bond is only very weakly polar. The distinction explains why butanol (\( \text{CH}_3(\text{CH}_2)_2\text{CH}_2\text{OH} \)) has a relatively high boiling point of 117 °C, whereas butane (\( \text{CH}_3(\text{CH}_2)_2\text{CH}_3 \)) has a boiling point of only −0.5 °C. Butanol has a polar hydroxyl group and thus can form intermolecular hydrogen bonds. Uncharged but polar biomolecules such as sugars dissolve readily in water because of the stabilizing effect of hydrogen bonds between the hydroxyl groups or carbonyl oxygen of the sugar and the polar water molecules. Alcohols, aldehydes, ketones, and compounds containing N—H bonds all form hydrogen bonds with water molecules (Fig. 2-4) and tend to be soluble in water.

Between peptide groups in polypeptides

Water Forms Hydrogen Bonds with Polar Solutes

Hydrogen bonds are not unique to water. They readily form between an electronegative atom (the hydrogen acceptor, usually oxygen or nitrogen) and a hydrogen atom covalently bonded to another electronegative atom (the hydrogen donor) in the same or another molecule (Fig. 2–3). Hydrogen atoms covalently bonded

FIGURE 2-4 Some biologically important hydrogen bonds.

point of water (Table 2–1). When ice melts or water evaporates, heat is taken up by the system:

\[
\begin{align*}
\text{H}_2\text{O} \text{ (solid)} & \rightarrow \text{H}_2\text{O} \text{ (liquid)} & \Delta H &= +5.9 \text{ kJ/mol} \\
\text{H}_2\text{O} \text{ (liquid)} & \rightarrow \text{H}_2\text{O} \text{ (gas)} & \Delta H &= +44.0 \text{ kJ/mol}
\end{align*}
\]

During melting or evaporation, the entropy of the aqueous system increases as more highly ordered arrays of water molecules relax into the less orderly hydrogen-bonded arrays in liquid water or into the wholly disordered gaseous state. At room temperature, both the melting of ice and the evaporation of water occur spontaneously; the tendency of the water molecules to associate through hydrogen bonds is outweighed by the energetic push toward randomness. Recall that the free-energy change (\( \Delta G \)) must have a negative value for a process to occur spontaneously: \( \Delta G = \Delta H - T \Delta S \), where \( \Delta G \) represents the driving force, \( \Delta H \) the enthalpy change from making and breaking bonds, and \( \Delta S \) the change in randomness. Because \( \Delta H \) is positive for melting and evaporation, it is clearly the increase in entropy (\( \Delta S \)) that makes \( \Delta G \) negative and drives these changes.

Thymine

Adenine
FIGURE 2-5 Directionality of the hydrogen bond. The attraction between the partial electric charges (see Fig. 2-1) is greatest when the three atoms involved in the bond (in this case O, H, and O) lie in a straight line. When the hydrogen-bonded moieties are structurally constrained (when they are parts of a single protein molecule, for example), this ideal geometry may not be possible and the resulting hydrogen bond is weaker.

Hydrogen bonds are strongest when the bonded molecules are oriented to maximize electrostatic interaction, which occurs when the hydrogen atom and the two atoms that share it are in a straight line—that is, when the acceptor atom is in line with the covalent bond between the donor atom and H (Fig. 2-5), putting the positive charge of the hydrogen ion directly between the two partial negative charges. Hydrogen bonds are thus highly directional and capable of holding two hydrogen-bonded molecules or groups in a specific geometric arrangement. As we shall see later, this property of hydrogen bonds confers very precise three-dimensional structures on protein and nucleic acid molecules, which have many intramolecular hydrogen bonds.

Water Interacts Electrostatically with Charged Solutes

Water is a polar solvent. It readily dissolves most biomolecules, which are generally charged or polar compounds (Table 2-2); compounds that dissolve easily in water are hydrophilic (Greek, “water-loving”). In contrast, nonpolar solvents such as chloroform and benzene are poor solvents for polar biomolecules but easily dissolve those that are hydrophobic—nonpolar molecules such as lipids and waxes.

Water dissolves salts such as NaCl by hydrating and stabilizing the Na+ and Cl− ions, weakening the electrostatic interactions between them and thus counteracting their tendency to associate in a crystalline lattice (Fig. 2-6). The same factors apply to charged biomolecules, compounds with functional groups such as ionized carboxylic acids (−COO−), protonated amines (−NH3+), and phosphate esters or anhydrides. Water readily dissolves such compounds by replacing solute-solute hydrogen bonds with solute-water hydrogen bonds, thus screening the electrostatic interactions between solute molecules.

Water is effective in screening the electrostatic interactions between dissolved ions because it has a high dielectric constant, a physical property that reflects the number of dipoles in a solvent. The strength, or force (F), of ionic interactions in a solution depends on the magnitude of the charges (Q), the distance between the charged groups (r), and the dielectric constant (ε, which is dimensionless) of the solvent in which the interactions occur:

\[ F = \frac{Q_1 Q_2}{\varepsilon r^2} \]

For water at 25 °C, ε is 78.5, and for the very nonpolar solvent benzene, ε is 4.6. Thus, ionic interactions between dissolved ions are much stronger in less polar environments. The dependence on \( r^2 \) is such that ionic attractions or repulsions operate only over short distances—in the range of 10 to 40 nm (depending on the electrolyte concentration) when the solvent is water.
Entropy Increases as Crystalline Substances Dissolve

As a salt such as NaCl dissolves, the Na⁺ and Cl⁻ ions leaving the crystal lattice acquire far greater freedom of motion (Fig. 2-6). The resulting increase in entropy (randomness) of the system is largely responsible for the ease of dissolving salts such as NaCl in water. In thermodynamic terms, formation of the solution occurs with a favorable free-energy change: \( \Delta G = \Delta H - T \Delta S \), where \( \Delta H \) has a small positive value and \( T \Delta S \) a large positive value; thus \( \Delta G \) is negative.

Nonpolar Gases Are Poorly Soluble in Water

The molecules of the biologically important gases CO₂, O₂, and N₂ are nonpolar. In O₂ and N₂, electrons are shared equally by both atoms. In CO₂, each C=O bond is polar, but the two dipoles are oppositely directed and cancel each other (Table 2-3). The movement of molecules from the disordered gas phase into aqueous solution constrains their motion and the motion of water molecules and therefore represents a decrease in entropy. The nonpolar nature of these gases and the decrease in entropy when they enter solution combine to make them very poorly soluble in water (Table 2-3). Some organisms have water-soluble “carrier proteins” (hemoglobin and myoglobin, for example) that facilitate the transport of O₂. Carbon dioxide forms carbonic acid (H₂CO₃) in aqueous solution and is transported as the HCO₃⁻ (bicarbonate) ion, either free—bicarbonate is very soluble in water (~100 g/L at 25 °C)—or bound to hemoglobin. Three other gases, NH₃, NO, and H₂S, also have biological roles in some organisms; these gases are polar, dissolve readily in water, and ionize in aqueous solution.

Nonpolar Compounds Force Energetically Unfavorable Changes in the Structure of Water

When water is mixed with benzene or hexane, two phases form; neither liquid is soluble in the other. Nonpolar compounds such as benzene and hexane are hydrophobic—they are unable to undergo energetically favorable interactions with water molecules, and they interfere with the hydrogen bonding among water.

†Note that polar molecules dissolve far better even at low temperatures than do nonpolar molecules at relatively high temperatures.
molecules. All molecules or ions in aqueous solution interfere with the hydrogen bonding of some water molecules in their immediate vicinity, but polar or charged solutes (such as NaCl) compensate for lost water-water hydrogen bonds by forming new solute-water interactions. The net change in enthalpy ($\Delta H$) for dissolving these solutes is generally small. Hydrophobic solutes, however, offer no such compensation, and their addition to water may therefore result in a small gain of enthalpy; the breaking of hydrogen bonds between water molecules takes up energy from the system, requiring the input of energy from the surroundings. In addition to requiring this input of energy, dissolving hydrophobic compounds in water produces a measurable decrease in entropy. Water molecules in the immediate vicinity of a nonpolar solute are constrained in their possible orientations as they form a highly ordered cagelike shell around each solute molecule. These water molecules are not as highly oriented as those in clathrates, crystalline compounds of nonpolar solutes and water, but the effect is the same in both cases: the ordering of water molecules reduces entropy. The number of ordered water molecules, and therefore the magnitude of the entropy decrease, is proportional to the surface area of the hydrophobic solute enclosed within the cage of water molecules. The free-energy change for dissolving a nonpolar solute in water is thus unfavorable: $\Delta G = \Delta H - T \Delta S$, where $\Delta H$ has a positive value, $\Delta S$ has a negative value, and $\Delta G$ is positive.

**Amphipathic compounds** contain regions that are polar (or charged) and regions that are nonpolar (Table 2-2). When an amphipathic compound is mixed with water, the polar, hydrophilic region interacts favorably with the solvent and tends to dissolve, but the nonpolar, hydrophobic region tends to avoid contact with the water (Fig. 2-7a). The nonpolar regions of the molecules cluster together to present the smallest hydrophobic area to the aqueous solvent, and the polar regions are arranged to maximize their interaction with the solvent (Fig. 2-7b). These stable structures of amphipathic compounds in water, called micelles, may contain hundreds or thousands of molecules. The forces

![Amphipathic compounds in aqueous solution](image)

**Figure 2-7** Amphipathic compounds in aqueous solution. (a) Long-chain fatty acids have very hydrophobic alkyl chains, each of which is surrounded by a layer of highly ordered water molecules. (b) By clustering together in micelles, the fatty acid molecules expose the smallest possible hydrophobic surface area to the water, and fewer water molecules are required in the shell of ordered water. The energy gained by freeing immobilized water molecules stabilizes the micelle.
that hold the nonpolar regions of the molecules together are called **hydrophobic interactions**. The strength of hydrophobic interactions is not due to any intrinsic attraction between nonpolar moieties. Rather, it results from the system's achieving greatest thermodynamic stability by minimizing the number of ordered water molecules required to surround hydrophobic portions of the solute molecules.

Many biomolecules are amphipathic; proteins, pigments, certain vitamins, and the sterols and phospholipids of membranes all have both polar and nonpolar surface regions. Structures composed of these molecules are stabilized by hydrophobic interactions among the nonpolar regions. Hydrophobic interactions among lipids, and between lipids and proteins, are the most important determinants of structure in biological membranes. Hydrophobic interactions between nonpolar amino acids also stabilize the three-dimensional structures of proteins.

Hydrogen bonding between water and polar solutes also causes an ordering of water molecules, but the energetic effect is less significant than with nonpolar solutes. Part of the driving force for binding of a polar substrate (reactant) to the complementary polar surface of an enzyme is the entropy increase as the enzyme displaces ordered water from the substrate, and as the substrate displaces ordered water from the enzyme surface (Fig. 2–8).

### van der Waals Interactions Are Weak Interatomic Attractions

When two uncharged atoms are brought very close together, their surrounding electron clouds influence each other. Random variations in the positions of the electrons around one nucleus may create a transient electric dipole, which induces a transient, opposite electric dipole in the nearby atom. The two dipoles weakly attract each other, bringing the two nuclei closer. These weak attractions are called **van der Waals interactions** (also known as London forces). As the two nuclei draw closer together, their electron clouds begin to repel each other. At the point where the net attraction is maximal, the nuclei are said to be in van der Waals contact. Each atom has a characteristic **van der Waals radius**, a measure of how close that atom will allow another to approach (Table 2–4). In the “space-filling” molecular models shown throughout this book, the atoms are depicted in sizes proportional to their van der Waals radii.

**Notes:** van der Waals radii describe the space-filling dimensions of atoms. When two atoms are joined covalently, the atomic radii at the point of bonding are less than the van der Waals radii, because the joined atoms are pulled together by the shared electron pair. The distance between nuclei in a van der Waals interaction or a covalent bond is about equal to the sum of the van der Waals or covalent radii, respectively, for the two atoms. Thus the length of a carbon–carbon single bond is about 0.077 nm + 0.077 nm = 0.154 nm.
Weak Interactions Are Crucial to Macromolecular Structure and Function

The noncovalent interactions we have described—hydrogen bonds and ionic, hydrophobic, and van der Waals interactions (Table 2-5)—are much weaker than covalent bonds. An input of about 350 kJ of energy is required to break a mole (6 x 10^23) of C—C single bonds, and about 410 kJ to break a mole of C—H bonds, but as little as 4 kJ is sufficient to disrupt a mole of typical van der Waals interactions. Hydrophobic interactions are also much weaker than covalent bonds, although they are substantially strengthened by a highly polar solvent (a concentrated salt solution, for example). Ionic interactions and hydrogen bonds are variable in strength, depending on the polarity of the solvent and the alignment of the hydrogen-bonded atoms, but they are always significantly weaker than covalent bonds. In aqueous solvent at 25 °C, the available thermal energy can be of the same order of magnitude as the strength of these weak interactions, and the interaction between solute and solvent (water) molecules is nearly as favorable as solute-solute interactions. Consequently, hydrogen bonds and ionic, hydrophobic, and van der Waals interactions are continually forming and breaking.

Although these four types of interactions are individually weak relative to covalent bonds, the cumulative effect of many such interactions can be very significant. For example, the noncovalent binding of an enzyme to its substrate may involve several hydrogen bonds and one or more ionic interactions, as well as hydrophobic and van der Waals interactions. The formation of each of these weak bonds contributes to a net decrease in the free energy of the system. We can calculate the stability of a noncovalent interaction, such as that of a small molecule hydrogen-bonded to its macromolecular partner, from the binding energy. Stability, as measured by the equilibrium constant (see below) of the binding reaction, varies exponentially with binding energy. The dissociation of two biomolecules (such as an enzyme and its bound substrate) that are associated noncovalently through multiple weak interactions requires all these interactions to be disrupted at the same time. Because the interactions fluctuate randomly, such simultaneous disruptions are very unlikely. The molecular stability bestowed by 5 or 20 weak interactions is therefore much greater than would be expected intuitively from a simple summation of small binding energies.

Macromolecules such as proteins, DNA, and RNA contain so many sites of potential hydrogen bonding or ionic, van der Waals, or hydrophobic interactions that the cumulative effect of the many small binding forces can be enormous. For macromolecules, the most stable (that is, the native) structure is usually that in which weak interactions are maximized. The folding of a single polypeptide or polynucleotide chain into its three-dimensional shape is determined by this principle. The binding of an antigen to a specific antibody depends on the cumulative effects of many weak interactions. As noted earlier, the energy released when an enzyme binds noncovalently to its substrate is the main source of the enzyme’s catalytic power. The binding of a hormone or a neurotransmitter to its cellular receptor protein is the result of multiple weak interactions. One consequence of the large size of enzymes and receptors (relative to their substrates or ligands) is that their extensive surfaces provide many opportunities for weak interactions. At the molecular level, the complementarity between interacting biomolecules reflects the complementarity and weak interactions between polar, charged, and hydrophobic groups on the surfaces of the molecules.

When the structure of a protein such as hemoglobin (Fig. 2-9) is determined by x-ray crystallography (see Box 4-5, p. 132), water molecules are often found to be bound so tightly that they are part of the crystal structure; the same is true for water in crystals of RNA or DNA. These bound water molecules, which can also be detected in aqueous solutions by nuclear magnetic resonance, have distinctly different properties from those of the “bulk” water of the solvent. They are, for example, not osmotically active (see below). For many proteins, tightly bound water molecules are essential to their function. In a reaction central to the process of photosynthesis, for example, light drives protons across a biological membrane as electrons flow through a series of electron-carrying proteins (see Fig. 19–60). One of these proteins, cytochrome f, has a chain of five bound water molecules (Fig. 2-10) that may provide a path for protons to move through the membrane by a process

Solutes Affect the Colligative Properties of Aqueous Solutions

Solutes of all kinds alter certain physical properties of the solvent, water: its vapor pressure, boiling point, melting point (freezing point), and osmotic pressure. These are called **colligative properties** (colligative meaning “tied together”), because the effect of solutes on all four properties has the same basis: the concentration of water is lower in solutions than in pure water. The effect of solute concentration on the colligative properties of water is independent of the chemical properties of the solute; it depends only on the **number** of solute particles (molecules, ions) in a given amount of water. A compound such as NaCl, which dissociates in solution, has an effect on osmotic pressure, for example, that is twice that of an equal number of moles of a nondissociating solute such as glucose.

Water molecules tend to move from a region of higher water concentration to one of lower water concentration, in accordance with the tendency in nature for a system to become disordered. When two different aqueous solutions are separated by a semipermeable membrane (one that allows the passage of water but not solute molecules), water molecules diffusing from the region of higher water concentration to the region of lower water concentration produce osmotic pressure (Fig. 2-11). This pressure, \( \Pi \), measured as the force

---

**FIGURE 2-9** Water binding in hemoglobin. (PDB ID 1A3N) The crystal structure of hemoglobin, shown (a) with bound water molecules (red spheres) and (b) without the water molecules. The water molecules are so firmly bound to the protein that they affect the x-ray diffraction pattern as though they were fixed parts of the crystal. The two \( \alpha \) subunits of hemoglobin are shown in gray, the two \( \beta \) subunits in blue. Each subunit has a bound heme group (red stick structure), visible only in the \( \beta \) subunits in this view. The structure and function of hemoglobin are discussed in detail in Chapter 5.

known as “proton hopping” (described below). Another such light-driven proton pump, bacteriorhodopsin, almost certainly uses a chain of precisely oriented bound water molecules in the transmembrane movement of protons (see Fig. 19-67).

**FIGURE 2-10** Water chain in cytochrome \( f \). Water is bound in a proton channel of the membrane protein cytochrome \( f \), which is part of the energy-trapping machinery of photosynthesis in chloroplasts (see Fig. 19-64). Five water molecules are hydrogen-bonded to each other and to functional groups of the protein: the peptide backbone atoms of valine, proline, arginine, and alanine residues, and the side chains of three asparagine and two glutamine residues. The protein has a bound heme (see Fig. 5-1), its iron ion facilitating electron flow during photosynthesis. Electron flow is coupled to the movement of protons across the membrane, which probably involves “proton hopping” (see Fig. 2-13) through this chain of bound water molecules.
necessary to resist water movement (Fig. 2-11c), is approximated by the van't Hoff equation:

$$\Pi = icRT$$

in which $R$ is the gas constant and $T$ is the absolute temperature. The term $ic$ is the osmolarity of the solution, the product of the van't Hoff factor $i$, which is a measure of the extent to which the solute dissociates into two or more ionic species, and the solute’s molar concentration $c$. In dilute NaCl solutions, the solute completely dissociates into Na$^+$ and Cl$^-$, doubling the number of solute particles, and thus $i = 2$. For all nonionizing solutes, $i = 1$. For solutions of several ($n$) solutes, $\Pi$ is the sum of the contributions of each species:

$$\Pi = RT (i_1c_1 + i_2c_2 + \cdots + i_nc_n)$$

**Osmosis**, water movement across a semipermeable membrane driven by differences in osmotic pressure, is an important factor in the life of most cells. Plasma membranes are more permeable to water than to most other small molecules, ions, and macromolecules. This permeability is due largely to protein channels (aquaporins; see Fig. 11-46) in the membrane that selectively permit the passage of water. Solutions of osmolarity equal to that of a cell's cytosol are said to be isotonic relative to that cell. Surrounded by an isotonic solution, a cell neither gains nor loses water (Fig. 2-12). In a hypertonic solution, one with higher osmolarity than that of the cytosol, the cell shrinks as water moves out. In a hypotonic solution, one with a lower osmolarity than the cytosol, the cell swells as water enters. In their natural environments, cells generally contain higher concentrations of biomolecules and ions than their surroundings, so osmotic pressure tends to drive water into cells. If not somehow counterbalanced, this inward movement of water would distend the plasma membrane and eventually cause bursting of the cell (osmotic lysis).

Several mechanisms have evolved to prevent this catastrophe. In bacteria and plants, the plasma membrane is surrounded by a nonexpandable cell wall of sufficient rigidity and strength to resist osmotic pressure and prevent osmotic lysis. Certain freshwater protists that live in a highly hypotonic medium have an organelle (contractile vacuole) that pumps water out of the cell. In multicellular animals, blood plasma and interstitial fluid (the extracellular fluid of tissues) are maintained at an osmolarity close to that of the cytosol. The high concentration of albumin and other proteins in blood plasma contributes to its osmolarity. Cells also actively pump out Na$^+$ and other ions into the interstitial fluid to stay in osmotic balance with their surroundings.

Because the effect of solutes on osmolarity depends on the *number* of dissolved particles, not their *mass*, macromolecules (proteins, nucleic acids, polysaccharides) have far less effect on the osmolarity of a solution than would an equal mass of their monomeric compo-

---

**FIGURE 2–12 Effect of extracellular osmolarity on water movement across a plasma membrane.** When a cell in osmotic balance with its surrounding medium—that is, a cell in (a) an isotonic medium—is transferred into (b) a hypertonic solution or (c) a hypotonic solution, water moves across the plasma membrane in the direction that tends to equalize osmolarity outside and inside the cell.

---

nents. For example, a *gram* of a polysaccharide composed of 1,000 glucose units has the same effect on osmolarity as a *milligram* of glucose. Storing fuel as polysaccharides (starch or glycogen) rather than as glucose or other simple sugars avoids an enormous increase in osmotic pressure in the storage cell.

Plants use osmotic pressure to achieve mechanical rigidity. The very high solute concentration in the plant cell vacuole draws water into the cell (Fig. 2-12), but the nonexpandable cell wall prevents swelling; instead, the pressure exerted against the cell wall (turgor pressure) increases, stiffening the cell, the tissue, and the plant body. When the lettuce in your salad wilts, it is because loss of water has reduced turgor pressure. Osmosis also has consequences for laboratory protocols. Mitochondria, chloroplasts, and lysosomes, for example, are enclosed by semipermeable membranes. In isolating these organelles from broken cells, biochemists must perform the fractionations in isotonic solutions (see Fig. 1–8) to prevent excessive entry of water into the organelles and the swelling and bursting that would follow. Buffers used in cellular fractionations commonly contain sufficient concentrations of sucrose or some other inert solute to protect the organelles from osmotic lysis.
WORKED EXAMPLE 2-1  Osmotic Strength of an Organelle I

Suppose the major solutes in intact lysosomes are KCl (~0.1 M) and NaCl (~0.03 M). When isolating lysosomes, what concentration of sucrose is required in the extracting solution at room temperature (25 °C) to prevent swelling and lysis?

Solution: We want to find a concentration of sucrose that gives an osmotic strength equal to that produced by the KCl and NaCl in the lysosomes. The equation for calculating osmotic strength (the van’t Hoff equation) is

$$\Pi = RT\left(i_1c_1 + i_2c_2 + i_3c_3 + \cdots + i_nc_n\right)$$

where R is the gas constant 8.315 J/mol · K, T is the absolute temperature (Kelvin), c1, c2, and c3 are the molar concentrations of each solute, and i1, i2, and i3 are the numbers of particles each solute yields in solution (i = 2 for KCl and NaCl).

The osmotic strength of the lysosomal contents is

$$\Pi_{lyosome} = RT\left(i_{KCl}c_{KCl} + i_{NaCl}c_{NaCl}\right)$$

$$= RT[(2)(0.03 \text{ mol/L}) + (2)(0.1 \text{ mol/L})] = RT(0.26 \text{ mol/L})$$

Because the solute concentrations are only accurate to one significant figure, this becomes $$\Pi_{lyosome} = RT(0.3 \text{ mol/L})$$.

The osmotic strength of a sucrose solution is given by

$$\Pi_{sucrose} = RT\left(i_{sucrose}c_{sucrose}\right)$$

In this case, $$i_{sucrose} = 1$$, because sucrose does not ionize. Thus,

$$\Pi_{sucrose} = RT(c_{sucrose})$$

The osmotic strength of the lysosomal contents equals that of the sucrose solution when

$$\Pi_{sucrose} = \Pi_{lyosome}$$

$$RT(c_{sucrose}) = RT(0.3 \text{ mol/L})$$

$$c_{sucrose} = 0.3 \text{ mol/L}$$

So the required concentration of sucrose (FW 342) is (0.3 mol/L)(342 g/mol) = 102.6 g/L. Or, when significant figures are taken into account, $$c_{sucrose} = 0.1 \text{ kg/L}$$.

WORKED EXAMPLE 2-2  Osmotic Strength of an Organelle II

Suppose we decided to use a solution of a polysaccharide, say glycogen (see p. 246), to balance the osmotic strength of the lysosomes (described in Worked Example 2-1). Assuming a linear polymer of 100 glucose units, calculate the amount of this polymer needed to achieve the same osmotic strength as the sucrose solution in Worked Example 2-1. The Mw of the glucose polymer is ~18,000, and, like sucrose, it does not ionize in solution.

Solution: As derived in Worked Example 2-1,

$$\Pi_{sucrose} = RT(0.3 \text{ mol/L})$$

Similarly,

$$\Pi_{glycogen} = RT\left(i_{glycogen}c_{glycogen}\right) = RT(c_{glycogen})$$

For a glycogen solution with the same osmotic strength as the sucrose solution,

$$\Pi_{glycogen} = \Pi_{sucrose}$$

$$RT(c_{glycogen}) = RT(0.3 \text{ mol/L})$$

$$c_{glycogen} = 0.3 \text{ mol/L} = (0.3 \text{ mol/L})(18,000 \text{ g/mol}) = 5.4 \text{ kg/L}$$

Or, when significant figures are taken into account, $$c_{glycogen} = 5 \text{ kg/L}$$, an absurdly high concentration.

As we’ll see later (p. 246), cells of liver and muscle store carbohydrate not as low molecular weight sugars such as glucose or sucrose but as the high molecular weight polymer glycogen. This allows the cell to contain a large mass of glycogen with a minimal effect on the osmolarity of the cytosol.
SUMMARY 2.1 Weak Interactions in Aqueous Systems

- The very different electronegativities of H and O make water a highly polar molecule, capable of forming hydrogen bonds with itself and with solutes. Hydrogen bonds are fleeting, primarily electrostatic, and weaker than covalent bonds. Water is a good solvent for polar (hydrophilic) solutes, with which it forms hydrogen bonds, and for charged solutes, with which it interacts electrostatically.

- Nonpolar (hydrophobic) compounds dissolve poorly in water; they cannot hydrogen-bond with the solvent, and their presence forces an energetically unfavorable ordering of water molecules at their hydrophobic surfaces. To minimize the surface exposed to water, nonpolar compounds such as lipids form aggregates (micelles) in which the hydrophobic moieties are sequestered in the interior, associating through hydrophobic interactions, and only the more polar moieties interact with water.

- Weak, noncovalent interactions, in large numbers, decisively influence the folding of macromolecules such as proteins and nucleic acids. The most stable macromolecular conformations are those in which hydrogen bonding is maximized within the molecule and between the molecule and the solvent, and in which hydrophobic moieties cluster in the interior of the molecule away from the aqueous solvent.

- The physical properties of aqueous solutions are strongly influenced by the concentrations of solutes. When two aqueous compartments are separated by a semipermeable membrane (such as the plasma membrane separating a cell from its surroundings), water moves across that membrane to equalize the osmolarity in the two compartments. This tendency for water to move across a semipermeable membrane is the osmotic pressure.

2.2 Ionization of Water, Weak Acids, and Weak Bases

Although many of the solvent properties of water can be explained in terms of the uncharged H₂O molecule, the small degree of ionization of water to hydrogen ions (H⁺) and hydroxide ions (OH⁻) must also be taken into account. Like all reversible reactions, the ionization of water can be described by an equilibrium constant. When weak acids are dissolved in water, they contribute H⁺ by ionizing; weak bases consume H⁺ by becoming protonated. These processes are also governed by equilibrium constants. The total hydrogen ion concentration from all sources is experimentally measurable and is expressed as the pH of the solution. To predict the state of ionization of solutes in water, we must take into account the relevant equilibrium constants for each ionization reaction. We therefore turn now to a brief discussion of the ionization of water and of weak acids and bases dissolved in water.

**Pure Water Is Slightly Ionized**

Water molecules have a slight tendency to undergo reversible ionization to yield a hydrogen ion (a proton) and a hydroxide ion, giving the equilibrium

$$\text{H}_2\text{O} \rightleftharpoons \text{H}^+ + \text{OH}^- \quad (2-1)$$

Although we commonly show the dissociation product of water as H⁺, free protons do not exist in solution; hydrogen ions formed in water are immediately hydrated to hydronium ions (H₃O⁺). Hydrogen bonding between water molecules makes the hydration of dissociating protons virtually instantaneous:

$$\text{H}_2\text{O} + \text{H}^+ \rightarrow \text{H}_3\text{O}^+$$

The ionization of water can be measured by its electrical conductivity; pure water carries electrical current as H₃O⁺ migrates toward the cathode and OH⁻ toward the anode. The movement of hydronium and hydroxide ions in the electric field is extremely fast compared with that of other ions such as Na⁺, K⁺, and Cl⁻. This high ionic mobility results from the kind of “proton hopping” shown in Figure 2-13. No individual proton moves very far through the bulk solution, but a series of proton hops

**FIGURE 2-13 Proton hopping.** Short “hops” of protons between a series of hydrogen-bonded water molecules result in an extremely rapid net movement of a proton over a long distance. As a hydronium ion (upper left) gives up a proton, a water molecule some distance away (lower right) acquires one, becoming a hydronium ion. Proton hopping is much faster than true diffusion and explains the remarkably high ionic mobility of H⁺ ions compared with other monovalent cations such as Na⁺ and K⁺.
between hydrogen-bonded water molecules causes the net movement of a proton over a long distance in a remarkably short time. As a result of the high ionic mobility of H\(^+\) (and of OH\(^-\), which also moves rapidly by proton hopping, but in the opposite direction), acid-base reactions in aqueous solutions are exceptionally fast. As noted above, proton hopping very likely also plays a role in biological proton-transfer reactions (Fig. 2-10; see also Fig. 19–67).

Because reversible ionization is crucial to the role of water in cellular function, we must have a means of expressing the extent of ionization of water in quantitative terms. A brief review of some properties of reversible chemical reactions shows how this can be done.

The position of equilibrium of any chemical reaction is given by its equilibrium constant, \(K_{eq}\) (sometimes expressed simply as \(K\)). For the generalized reaction
\[
A + B \rightleftharpoons C + D
\]
an equilibrium constant can be defined in terms of the concentrations of reactants (A and B) and products (C and D) at equilibrium:
\[
K_{eq} = \frac{[C][D]}{[A][B]}
\]
Strictly speaking, the concentration terms should be the activities, or effective concentrations in nonideal solutions, of each species. Except in very accurate work, however, the equilibrium constant may be approximated by measuring the concentrations at equilibrium. For reasons beyond the scope of this discussion, equilibrium constants are dimensionless. Nonetheless, we have generally retained the concentration units (\(\text{mol/L}\)) in the equilibrium expressions used in this book to remind you that molarity is the unit of concentration used in calculating \(K_{eq}\).

The equilibrium constant is fixed and characteristic for any given chemical reaction at a specified temperature. It defines the composition of the final equilibrium mixture, regardless of the starting amounts of reactants and products. Conversely, we can calculate the equilibrium constant for a given reaction at a given temperature if the equilibrium concentrations of all its reactants and products are known. As we showed in Chapter 1 (p. 24), the standard free-energy change (\(\Delta G^\circ\)) is directly related to \(\ln K_{eq}\).

The Ionization of Water Is Expressed by an Equilibrium Constant

The degree of ionization of water at equilibrium (Eqn 2–1) is small; at 25 \(\text{°C}\) only about two of every \(10^6\) molecules in pure water are ionized at any instant. The equilibrium constant for the reversible ionization of water is
\[
K_{eq} = \frac{[H^+][OH^-]}{[H_2O]}
\]
In pure water at 25 \(\text{°C}\), the concentration of water is 55.5 \(\text{mol/L}\)—grams of \(\text{H}_2\text{O}\) in 1 L divided by its gram molecular weight: (1,000 \(\text{g/L})/(18.015 \text{g/mol}))—and is essentially constant in relation to the very low concentrations of H\(^+\) and OH\(^-\), namely, 1 \(\times\) \(10^{-7}\) \(\text{mol/L}\). Accordingly, we can substitute 55.5 \(\text{mol/L}\) in the equilibrium constant expression (Eqn 2–3) to yield
\[
K_{eq} = \frac{[H^+][OH^-]}{[H_2O]} = \frac{[H^+][OH^-]}{55.5 \text{mol/L}}
\]
On rearranging, this becomes
\[
K_w = \frac{[H^+][OH^-]}{[H_2O]} = K_{eq} = \frac{(55.5 \text{mol/L})(1.8 \times 10^{-16} \text{mol/L})}{1 \times 10^{-14} \text{mol}^2}
\]
Thus the product \([H^+][OH^-]\) in aqueous solutions at 25 \(\text{°C}\) always equals 1 \(\times\) \(10^{-14}\) \(\text{mol}^2\). When there are exactly equal concentrations of H\(^+\) and OH\(^-\), as in pure water, the solution is said to be at neutral \(\text{pH}\). At this \(\text{pH}\), the concentration of H\(^+\) and OH\(^-\) can be calculated from the ion product of water as follows:
\[
K_w = \frac{[H^+][OH^-]}{[H_2O]} = (55.5 \text{mol/L})(1.8 \times 10^{-16} \text{mol/L}) = 1.0 \times 10^{-14} \text{mol}^2
\]
Solving for \([H^+]\) gives
\[
[H^+] = \sqrt{K_w} = \sqrt{1 \times 10^{-14} \text{mol}^2} = 10^{-7} \text{mol/L}
\]
As the ion product of water is constant, whenever \([H^+]\) is greater than 1 \(\times\) \(10^{-7}\) \(\text{mol/L}\), \([\text{OH}^-]\) must be less than 1 \(\times\) \(10^{-7}\) \(\text{mol/L}\), and vice versa. When \([H^+]\) is very high, as in a solution of hydrochloric acid, \([\text{OH}^-]\) must be very low. From the ion product of water we can calculate \([H^+]\) if we know \([\text{OH}^-]\), and vice versa.

**WORKED EXAMPLE 2–3 Calculation of \([H^+]\)**

What is the concentration of H\(^+\) in a solution of 0.1 \(\text{mol/L}\) NaOH?

**Solution:** We begin with the equation for the ion product of water:
\[
K_w = [H^+][OH^-]
\]
With \([\text{OH}^-] = 0.1 \text{mol/L}\), solving for \([H^+]\) gives
\[
[H^+] = \frac{K_w}{[\text{OH}^-]} = \frac{1 \times 10^{-14} \text{mol}^2}{0.1 \text{mol/L}} = \frac{10^{-14} \text{mol}^2}{10^{-1} \text{mol/L}} = 10^{-13} \text{mol/L}
\]
**WORKED EXAMPLE 2–4 Calculation of \([\text{OH}^-]\)**

What is the concentration of \(\text{OH}^-\) in a solution with an \(\text{H}^+\) concentration of \(1.3 \times 10^{-4}\) M?

**Solution:** We begin with the equation for the ion product of water:

\[
K_w = [\text{H}^+][\text{OH}^-]
\]

With \([\text{H}^+] = 1.3 \times 10^{-4}\) M, solving for \([\text{OH}^-]\) gives

\[
[\text{OH}^-] = \frac{K_w}{[\text{H}^+]} = \frac{1 \times 10^{-14}}{0.0013} = \frac{10^{-14}}{1.3 \times 10^{-4}} M = 7.7 \times 10^{-11} M
\]

In all calculations be sure to round your answer to the correct number of significant figures, as here.

---

**The pH Scale Designates the \(\text{H}^+\) and \(\text{OH}^-\) Concentrations**

The ion product of water, \(K_w\), is the basis for the **pH scale** (Table 2–6). It is a convenient means of designating the concentration of \(\text{H}^+\) (and thus of \(\text{OH}^-\)) in any aqueous solution in the range between 1.0 M \(\text{H}^+\) and 1.0 M \(\text{OH}^-\). The term **pH** is defined by the expression

\[
\text{pH} = \log \frac{1}{[\text{H}^+]} = -\log [\text{H}^+]
\]

The symbol \(p\) denotes “negative logarithm of.” For a precisely neutral solution at 25 °C, in which the concentration of hydrogen ions is \(1.0 \times 10^{-7}\) M, the pH can be calculated as follows:

\[
\text{pH} = \log \frac{1}{1.0 \times 10^{-7}} = 7.0
\]

Note that the concentration of \(\text{H}^+\) must be expressed in molar (M) terms.

The value of 7 for the pH of a precisely neutral solution is not an arbitrarily chosen figure; it is derived from the absolute value of the ion product of water at 25 °C, which by convenient coincidence is a round number. Solutions having a pH greater than 7 are alkaline or basic; the concentration of \(\text{OH}^-\) is greater than that of \(\text{H}^+\). Conversely, solutions having a pH less than 7 are acidic.

Keep in mind that the pH scale is logarithmic, not arithmetic. To say that two solutions differ in pH by 1 pH unit means that one solution has ten times the \(\text{H}^+\) concentration of the other, but it does not tell us the absolute magnitude of the difference. **Figure 2–14** gives the pH values of some common aqueous fluids. A cola drink (pH 3.0) or red wine (pH 3.7) has an \(\text{H}^+\) concentration approximately 10,000 times that of blood (pH 7.4).

The pH of an aqueous solution can be approximately measured with various indicator dyes, including litmus, phenolphthalein, and phenol red, which undergo color changes as a proton dissociates from the dye molecule. Accurate determinations of pH in the chemical or

*The expression pOH is sometimes used to describe the basicity, or \(\text{OH}^-\) concentration, of a solution; pOH is defined by the expression pOH = \(-\log[\text{OH}^-]\), which is analogous to the expression for pH. Note that in all cases, pH + pOH = 14.*
clinical laboratory are made with a glass electrode that is selectively sensitive to H⁺ concentration but insensitive to Na⁺, K⁺, and other cations. In a pH meter, the signal from the glass electrode placed in a test solution is amplified and compared with the signal generated by a solution of accurately known pH.

Measurement of pH is one of the most important and frequently used procedures in biochemistry. The pH affects the structure and activity of biological macromolecules; for example, the catalytic activity of enzymes is strongly dependent on pH (see Fig. 2-21). Measurements of the pH of blood and urine are commonly used in medical diagnoses. The pH of the blood plasma of people with severe, uncontrolled diabetes, for example, is often below the normal value of 7.4; this condition is called acidosis (described in more detail below). In certain other diseases the pH of the blood is higher than normal, a condition known as alkalosis. Extreme acidosis or alkalosis can be life-threatening.

Weak Acids and Bases Have Characteristic Acid Dissociation Constants

Hydrochloric, sulfuric, and nitric acids, commonly called strong acids, are completely ionized in dilute aqueous solutions; the strong bases NaOH and KOH are also completely ionized. Of more interest to biochemists is the behavior of weak acids and bases—those not completely ionized when dissolved in water. These are ubiquitous in biological systems and play important roles in metabolism and its regulation. The behavior of aqueous solutions of weak acids and bases is best understood if we first define some terms.

Acids may be defined as proton donors and bases as proton acceptors. A proton donor and its corresponding proton acceptor make up a conjugate acid-base pair (Fig. 2-15). Acetic acid (CH₃COOH), a proton donor, and the acetate anion (CH₃COO⁻), the corresponding proton acceptor, constitute a conjugate acid-base pair, related by the reversible reaction

\[
\text{CH}_3\text{COOH} \rightleftharpoons \text{CH}_3\text{COO}^- + \text{H}^+
\]

Each acid has a characteristic tendency to lose its proton in an aqueous solution. The stronger the acid, the greater its tendency to lose its proton. The tendency of any acid (HA) to lose a proton and form its conjugate base (A⁻) is defined by the equilibrium constant \(K_{eq}\) for the reversible reaction

\[
\text{HA} \rightleftharpoons \text{H}^+ + \text{A}^-
\]

for which

\[
K_{eq} = \frac{[\text{H}^+][\text{A}^-]}{[\text{HA}]} = K_a
\]

**FIGURE 2–15** Conjugate acid-base pairs consist of a proton donor and a proton acceptor. Some compounds, such as acetic acid and ammonium ion, are monoprotic; they can give up only one proton. Others are diprotic (carbonic acid and glycine) or triprotic (phosphoric acid). The dissociation reactions for each pair are shown where they occur along a pH gradient. The equilibrium or dissociation constant \(K_a\) and its negative logarithm, the pKₐ, are shown for each reaction. *For an explanation of apparent discrepancies in pKₐ values for carbonic acid (H₂CO₃), see p. 63.
Equilibrium constants for ionization reactions are usually called ionization constants or acid dissociation constants, often designated $K_a$. The dissociation constants of some acids are given in Figure 2-15. Stronger acids, such as phosphoric and carbonic acids, have larger ionization constants; weaker acids, such as monohydrogen phosphate ($\text{HPO}_4^{2-}$), have smaller ionization constants.

Also included in Figure 2-15 are values of $pK_a^\prime$, which is analogous to pH and is defined by the equation

$$pK_a^\prime = \log \frac{1}{K_a} = -\log K_a$$

The stronger the tendency to dissociate a proton, the stronger is the acid and the lower its $pK_a$. As we shall now see, the $pK_a^\prime$ of any weak acid can be determined quite easily.

**Titration Curves Reveal the $pK_a^\prime$ of Weak Acids**

Titration is used to determine the amount of an acid in a given solution. A measured volume of the acid is titrated with a solution of a strong base, usually sodium hydroxide (NaOH), of known concentration. The NaOH is added in small increments until the acid is consumed (neutralized), as determined with an indicator dye or a pH meter. The concentration of the acid in the original solution can be calculated from the volume and concentration of NaOH added.

A plot of pH against the amount of NaOH added (a titration curve) reveals the $pK_a^\prime$ of the weak acid. Consider the titration of a 0.1 m solution of acetic acid with 0.1 m NaOH at 25 °C (Fig. 2-16). Two reversible equilibria are involved in the process (here, for simplicity, acetic acid is denoted HAc):

$$\text{H}_2\text{O} \rightleftharpoons \text{H}^+ + \text{OH}^- \quad (2-5)$$
$$\text{HAc} \rightleftharpoons \text{H}^+ + \text{Ac}^- \quad (2-6)$$

The equilibria must simultaneously conform to their characteristic equilibrium constants, which are, respectively,

$$K_w = [\text{H}^+][\text{OH}^-] = 1 \times 10^{-14} \text{ M}^2 \quad (2-7)$$
$$K_a = \frac{[\text{H}^+][\text{Ac}^-]}{[\text{HAc}]} = 1.74 \times 10^5 \text{ M} \quad (2-8)$$

At the beginning of the titration, before any NaOH is added, the acetic acid is already slightly ionized, to an extent that can be calculated from its ionization constant (Eqn 2-8).

As NaOH is gradually introduced, the added OH$^-$ combines with the free H$^+$ in the solution to form H$_2$O, to an extent that satisfies the equilibrium relationship in Equation 2-7. As free H$^+$ is removed, HAc dissociates further to satisfy its own equilibrium constant (Eqn 2-8). The net result as the titration proceeds is that more and more HAc ionizes, forming Ac$^-$, as the NaOH is added. At the midpoint of the titration, at which exactly 0.5 equivalent of NaOH has been added, one-half of the original acetic acid has undergone dissociation, so that the concentration of the proton donor, [HAc], now equals that of the proton acceptor, [Ac$^-$]. At this midpoint a very important relationship holds: the pH of the equimolar solution of acetic acid and acetate is exactly equal to the $pK_a$ of acetic acid ($pK_a = 4.76$; Figs 2-15, 2-16). The basis for this relationship, which holds for all weak acids, will soon become clear.

As the titration is continued by adding further increments of NaOH, the remaining nondissociated acetic acid is gradually converted into acetate. The end point of the titration occurs at about pH 7.0: all the acetic acid has lost its protons to OH$^-$, to form H$_2$O and acetate. Throughout the titration the two equilibria (Eqns 2-5, 2-6) coexist, each always conforming to its equilibrium constant.

Figure 2-17 compares the titration curves of three weak acids with very different ionization constants: acetic acid ($pK_a = 4.76$); dihydrogen phosphate, $\text{H}_2\text{PO}_4^-$ ($pK_a = 6.86$); and ammonium ion, $\text{NH}_4^+$ ($pK_a = 9.25$). Although the titration curves of these acids have the same shape, they are displaced along the pH axis because the three acids have different strengths. Acetic acid, with the highest $K_a$ (lowest $pK_a$) of the three, is the

![Figure 2-16 The titration curve of acetic acid. After addition of each increment of NaOH to the acetic acid solution, the pH of the mixture is measured. This value is plotted against the amount of NaOH added, expressed as a fraction of the total NaOH required to convert all the acetic acid ($\text{CH}_3\text{COOH}$) to its deprotonated form, acetate ($\text{CH}_3\text{COO}^-$). The points so obtained yield the titration curve. Shown in the boxes are the predominant ionic forms at the points designated. At the midpoint of the titration, the concentrations of the proton donor and proton acceptor are equal, and the pH is numerically equal to the $pK_a$. The shaded zone is the useful region of buffering power, generally between 10% and 90% titration of the weak acid.](image-url)
The pH of an aqueous solution reflects, on a logarithmic scale, the concentration of hydrogen ions:

\[ \text{pH} = \log \frac{1}{[H^+]} = -\log [H^+] \]

- The greater the acidity of a solution, the lower its pH. Weak acids partially ionize to release a hydrogen ion, thus lowering the pH of the aqueous solution. Weak bases accept a hydrogen ion, increasing the pH. The extent of these processes is characteristic of each particular weak acid or base and is expressed as an acid dissociation constant:

\[ K_{eq} = \frac{[H^+][A^-]}{[HA]} = K_a \]

- The pK_a expresses, on a logarithmic scale, the relative strength of a weak acid or base:

\[ pK_a = \log \frac{1}{K_a} = -\log K_a \]

- The stronger the acid, the lower its pK_a; the stronger the base, the higher its pK_a. The pK_a can be determined experimentally; it is the pH at the midpoint of the titration curve for the acid or base.

### 2.3 Buffering against pH Changes in Biological Systems

Almost every biological process is pH-dependent; a small change in pH produces a large change in the rate of the process. This is true not only for the many reactions in which the H^+ ion is a direct participant, but also for those in which there is no apparent role for H^+ ions. The enzymes that catalyze cellular reactions, and many of the molecules on which they act, contain ionizable groups with characteristic pK_a values. The protonated amino and carboxyl groups of amino acids and the phosphate groups of nucleotides, for example, function as weak acids; their ionic state is determined by the pH of the surrounding medium. (When an ionizable group is sequestered in the middle of a protein, away from the aqueous solvent, its pK_a, or apparent pK_a, can be significantly different from its pK_a in water.) As we noted above, ionic interactions are among the forces that stabilize a protein molecule and allow an enzyme to recognize and bind its substrate.

Cells and organisms maintain a specific and constant cytosolic pH, usually near pH 7, keeping biomolecules in their optimal ionic state. In multicellular organisms, the pH of extracellular fluids is also tightly regulated. Constancy of pH is achieved primarily by biological buffers: mixtures of weak acids and their conjugate bases.

**Buffers Are Mixtures of Weak Acids and Their Conjugate Bases**

Buffers are aqueous systems that tend to resist changes in pH when small amounts of acid (H^+) or base...
Acetic acid
(CH₃COOH)

Acetate
(CH₃COO⁻)

\[ K_w = \frac{[H^+][OH^-]}{[HA]} \]

**Figure 2-18** The acetic acid—acetate pair as a buffer system. The system is capable of absorbing either H⁺ or OH⁻ through the reversibility of the dissociation of acetic acid. The proton donor, acetic acid (HAc), contains a reserve of bound H⁺, which can be released to neutralize an addition of OH⁻ to the system, forming H₂O. This happens because the product [H⁺][OH⁻] transiently exceeds K_w (1 x 10⁻¹⁴ M²). The equilibrium quickly adjusts to restore the product to 1 x 10⁻¹⁴ M² (at 25 °C), thus transiently reducing the concentration of H⁺. But now the quotient [H⁺][Ac⁻]/[HAc] is less than K_a, so HAc dissociates further to restore equilibrium. Similarly, the conjugate base, AC⁻, reacts with H⁺ ions added to the system: again, the two ionization reactions simultaneously come to equilibrium. Thus a conjugate acid-base pair, such as acetic acid and acetate ion, tends to resist a change in pH when small amounts of acid or base are added. Buffering action is simply the consequence of two reversible reactions taking place simultaneously and reaching their points of equilibrium as governed by their equilibrium constants, K_w and K_a.

(OH⁻) are added. A buffer system consists of a weak acid (the proton donor) and its conjugate base (the proton acceptor). As an example, a mixture of equal concentrations of acetic acid and acetate ion, found at the midpoint of the titration curve in Figure 2-16, is a buffer system. Notice that the titration curve of acetic acid has a relatively flat zone extending about 1 pH unit on either side of its midpoint pH of 4.76. In this zone, a given amount of H⁺ or OH⁻ added to the system has much less effect on pH than the same amount added outside the zone. This relatively flat zone is the **buffering region** of the acetic acid–acetate buffer pair. At the midpoint of the buffering region, where the concentration of the proton donor (acetic acid) exactly equals that of the proton acceptor (acetate), the buffering power of the system is maximal; that is, its pH changes least on addition of H⁺ or OH⁻. The pH at this point in the titration curve of acetic acid is equal to its pK_a. The pH of the acetate buffer system does change slightly when a small amount of H⁺ or OH⁻ is added, but this change is very small compared with the pH change that would result if the same amount of H⁺ or OH⁻ were added to pure water or to a solution of the salt of a strong acid and strong base, such as NaCl, which has no buffering power.

Buffering results from two reversible reaction equilibria occurring in a solution of nearly equal concentrations of a proton donor and its conjugate proton acceptor. **Figure 2-18** explains how a buffer system works. Whenever H⁺ or OH⁻ is added to a buffer, the result is a small change in the ratio of the relative concentrations of the weak acid and its anion and thus a small change in pH. The decrease in concentration of one component of the system is balanced exactly by an increase in the other. The sum of the buffer components does not change, only their ratio.

Each conjugate acid-base pair has a characteristic pH zone in which it is an effective buffer (Fig. 2-17). The H₂PO₄⁻/HPO₄²⁻ pair has a pK_a of 6.86 and thus can serve as an effective buffer system between approximately pH 5.9 and pH 7.9; the NH₃⁻/NH₄⁺ pair, with a pK_a of 9.25, can act as a buffer between approximately pH 8.3 and pH 10.3.

**The Henderson-Hasselbalch Equation Relates pH, pK_a, and Buffer Concentration**

The titration curves of acetic acid, H₂PO₄⁻, and NH₄⁺ (Fig. 2-17) have nearly identical shapes, suggesting that these curves reflect a fundamental law or relationship. This is indeed the case. The shape of the titration curve of any weak acid is described by the Henderson-Hasselbalch equation, which is important for understanding buffer action and acid-base balance in the blood and tissues of vertebrates. This equation is simply a useful way of restating the expression for the ionization constant of an acid. For the ionization of a weak acid HA, the Henderson-Hasselbalch equation can be derived as follows:

\[ pH = pK_a + \log \left( \frac{[A^-]}{[HA]} \right) \]

First solve for [H⁺]:

\[ [H^+] = K_a \left( \frac{[HA]}{[A^-]} \right) \]

Then take the negative logarithm of both sides:

\[ -\log [H^+] = -\log K_a - \log \left( \frac{[HA]}{[A^-]} \right) \]

Substitute pH for -log [H⁺] and pK_a for -log K_a:

\[ pH = pK_a - \log \left( \frac{[HA]}{[A^-]} \right) \]

Now invert -log [HA]/[A⁻], which involves changing its sign, to obtain the **Henderson-Hasselbalch equation**:

\[ pH = pK_a + \log \left( \frac{[A^-]}{[HA]} \right) \] (2-9)

This equation fits the titration curve of all weak acids and enables us to deduce some important quantitative relationships. For example, it shows that the pK_a of a weak acid is equal to the pH of the solution at the midpoint of its titration. At that point, [HA] = [A⁻], and

\[ pH = pK_a + \log 1 = pK_a + 0 = pK_a \]
The Henderson-Hasselbalch equation also allows us to (1) calculate $pK_a$, given pH and the molar ratio of proton donor and acceptor; (2) calculate pH, given $pK_a$ and the molar ratio of proton donor and acceptor; and (3) calculate the molar ratio of proton donor and acceptor, given pH and $pK_a$.

### Weak Acids or Bases Buffer Cells and Tissues against pH Changes

The intracellular and extracellular fluids of multicellular organisms have a characteristic and nearly constant pH. The organism's first line of defense against changes in internal pH is provided by buffer systems. The cytoplasm of most cells contains high concentrations of proteins, which contain many amino acids with functional groups that are weak acids or weak bases. For example, the side chain of histidine (Fig. 2-19) has a $pK_a$ of 6.0; proteins containing histidine residues therefore buffer effectively near neutral pH, and histidine side chains exist in either the protonated or unprotonated form near neutral pH.

#### WORKED EXAMPLE 2-5 Ionization of Histidine

Calculate the fraction of histidine that has its imidazole side chain protonated at pH 7.3. The $pK_a$ values for histidine are $pK_1 = 1.82$, $pK_2$ (imidazole) = 6.00, and $pK_3 = 9.17$ (see Fig. 3-12b).

**Solution:** The three ionizable groups in histidine have sufficiently different $pK_a$ values that the first acid (—COOH) is completely ionized before the second (protonated imidazole) begins to dissociate a proton, and the second ionizes completely before the third (—NH$_3^+$) begins to dissociate its proton. (With the Henderson-Hasselbalch equation, we can easily show that a weak acid goes from 1% ionized at 2 pH units below its $pK_a$, to 99% ionized at 2 pH units above its $pK_a$; see also Fig. 3-12b.) At pH 7.3, the carboxyl group of histidine is entirely deprotonated (—COO$^-$) and the α-amino group is fully protonated (—NH$_3^+$). We can therefore assume that at pH 7.3, the only group that is partially dissociated is the imidazole group, which can be protonated (we'll abbreviate as HisH$^+$) or not (His).

We use the Henderson-Hasselbalch equation:

$$\text{pH} = pK_a + \log \frac{[\text{A}^-]}{[\text{HA}]}$$

Substituting $pK_2 = 6.0$ and pH = 7.3:

$$7.3 = 6.0 + \log \frac{[\text{His}]}{[\text{HisH}^+]}$$

$$1.3 = \log \frac{[\text{His}]}{[\text{HisH}^+]}$$

antilog 1.3 = \frac{[\text{His}]}{[\text{HisH}^+]} = 2.0 \times 10^1$$

So the fraction of total histidine that is in the protonated form HisH$^+$ at pH 7.3 is 1/21 (1 part HisH$^+$ in a total of 21 parts histidine in either form), or about 4.8%.

Nucleotides such as ATP, as well as many low molecular weight metabolites, contain ionizable groups that can contribute buffering power to the cytoplasm. Some highly specialized organelles and extracellular compartments have high concentrations of compounds that contribute buffering capacity: organic acids buffer the vacuoles of plant cells; ammonia buffers urine.

Two especially important biological buffers are the phosphate and bicarbonate systems. The phosphate buffer system, which acts in the cytoplasm of all cells, consists of H$_2$PO$_4^-$ as proton donor and HPO$_4^{2-}$ as proton acceptor:

$$H_2PO_4^- \rightleftharpoons H^+ + HPO_4^{2-}$$

The phosphate buffer system is maximally effective at a pH close to its $pK_a$ of 6.86 (Figs 2-15, 2-17) and thus tends to resist pH changes in the range between about 5.9 and 7.9. It is therefore an effective buffer in biological fluids; in mammals, for example, extracellular fluids and most cytoplasmic compartments have a pH in the range of 6.9 to 7.4 (see Worked Example 2-6).

Blood plasma is buffered in part by the bicarbonate system, consisting of carbonic acid (H$_2$CO$_3$) as proton donor and bicarbonate (HCO$_3^-$) as proton acceptor ($K_1$ is the first of several equilibrium constants in the bicarbonate buffering system):

$$H_2CO_3 \rightleftharpoons H^+ + HCO_3^-$$

$$K_1 = \frac{[H^+][HCO_3^-]}{[H_2CO_3]}$$

This buffer system is more complex than other conjugate acid-base pairs because one of its components, carbonic acid (H$_2$CO$_3$), is formed from dissolved (d) carbon dioxide and water, in a reversible reaction:

$$CO_2(d) + H_2O \rightleftharpoons H_2CO_3$$

$$K_2 = \frac{[H_2CO_3]}{[CO_2(d)][H_2O]}$$

![FIGURE 2-19 Ionization of histidine. The amino acid histidine, a component of proteins, is a weak acid. The $pK_a$ of the protonated nitrogen of the side chain is 6.0.](image-url)
WORKED EXAMPLE 2-6 Phosphate Buffers

(a) What is the pH of a mixture of 0.042 M NaH$_2$PO$_4$ and 0.058 M Na$_2$HPO$_4$?

Solution: We use the Henderson-Hasselbalch equation, which we’ll express here as

$$\text{pH} = \text{pK}_a + \log \frac{[\text{conjugate base}]}{[\text{acid}]}$$

In this case, the acid (the species that gives up a proton) is H$_2$PO$_4^-$, and the conjugate base (the species that loses a proton) is HPO$_4^{2-}$. Substituting the given concentrations of acid and conjugate base and the pK$_a$ (6.86),

$$\text{pH} = 6.86 + \log \left( \frac{0.058}{0.042} \right) = 6.86 + 1.38 = 7.0$$

We can roughly check this answer. When more conjugate base than acid is present, the acid is more than 50% titrated and thus the pH is above the pK$_a$ (6.86), where the acid is exactly 50% titrated.

(b) If 1.0 mL of 10.0 N NaOH is added to a liter of the buffer prepared in (a), how much will the pH change?

Solution: A liter of the buffer contains 0.042 mol of NaH$_2$PO$_4$. Adding 1.0 mL of 10.0 N NaOH (0.010 mol) would titrate an equivalent amount (0.010 mol) of NaH$_2$PO$_4$ to Na$_2$HPO$_4$, resulting in 0.032 mol of NaH$_2$PO$_4$ and 0.068 mol of Na$_2$HPO$_4$. The new pH is

$$\text{pH} = \text{pK}_a + \log \frac{[\text{HPO}_4^{2-}]}{[\text{H}_2\text{PO}_4^-]}$$

$$= 6.86 + \log \left( \frac{0.068}{0.032} \right) = 6.86 + 0.33 = 7.2$$

(c) If 1.0 mL of 10.0 N NaOH is added to a liter of pure water at pH 7.0, what is the final pH? Compare this with the answer in (b).

Solution: The NaOH dissociates completely into Na$^+$ and OH$^-$, giving [OH$^-$] = 0.010 mol/L = 1.0 x 10$^{-2}$ M. The pOH is the negative logarithm of [OH$^-$], so pOH = 2.0. Given that in all solutions, pH + pOH = 14, the pH of the solution is 12.

So, an amount of NaOH that increases the pH of water from 7 to 12 increases the pH of a buffered solution, as in (b), from 7.0 to just 7.2. Such is the power of buffering!

Carbon dioxide is a gas under normal conditions, and the concentration of dissolved CO$_2$ is the result of equilibration with CO$_2$ of the gas (g) phase:

$$\text{CO}_2(\text{g}) \rightleftharpoons \text{CO}_2(\text{d})$$

$$K_3 = \frac{[\text{CO}_2(\text{d})]}{[\text{CO}_2(\text{g})]}$$

The pH of a bicarbonate buffer system depends on the concentration of H$_2$CO$_3$ and HCO$_3^-$, the proton donor and acceptor components. The concentration of H$_2$CO$_3$ in turn depends on the concentration of dissolved CO$_2$, which in turn depends on the concentration of CO$_2$ in the gas phase, or the partial pressure of CO$_2$, denoted pCO$_2$. Thus the pH of a bicarbonate buffer exposed to a gas phase is ultimately determined by the concentration of HCO$_3^-$ in the aqueous phase and by pCO$_2$ in the gas phase.

The bicarbonate buffer system is an effective physiological buffer near pH 7.4, because the H$_2$CO$_3$ of blood plasma is in equilibrium with a large reserve capacity of CO$_2(g)$ in the air space of the lungs. As noted above, this buffer system involves three reversible equilibria, in this case between gaseous CO$_2$ in the lungs and bicarbonate (HCO$_3^-$) in the blood plasma (Fig. 2-20).

![FIGURE 2-20 The bicarbonate buffer system. CO$_2$ in the air space of the lungs is in equilibrium with the bicarbonate buffer in the blood plasma passing through the lung capillaries. Because the concentration of dissolved CO$_2$ can be adjusted rapidly through changes in the rate of breathing, the bicarbonate buffer system of the blood is in near-equilibrium with a large potential reservoir of CO$_2$.](image-url)
When $H^+$ (from the lactic acid produced in muscle tissue during vigorous exercise, for example) is added to blood as it passes through the tissues, reaction 1 in Figure 2–20 proceeds toward a new equilibrium, in which $[H_2CO_3]$ is increased. This in turn increases $[CO_2(d)]$ in the blood (reaction 2) and thus increases the partial pressure of $CO_2(g)$ in the air space of the lungs (reaction 3); the extra $CO_2$ is exhaled. Conversely, when the pH of blood is raised (by the $NH_3$ produced during protein catabolism, for example), the opposite events occur: $[H^+]$ of blood plasma is lowered, causing more $H_2CO_3$ to dissociate into $H^+$ and $HCO_3^-$ and thus more $CO_2(g)$ from the lungs to dissolve in blood plasma. The rate of respiration, or breathing—that is, the rate of inhaling and exhaling—can quickly adjust these equilibria to keep the blood pH nearly constant. The rate of respiration is controlled by the brain stem, where detection of an increased blood $pCO_2$ or decreased blood pH triggers deeper and more frequent breathing.

At the pH of blood plasma (7.4) very little $H_2CO_3$ is present in comparison with $HCO_3^-$, and the addition of a small amount of base ($NH_3$ or $OH^-$) would titrate this $H_2CO_3$, exhausting the buffering capacity. The important role for carbonic acid ($pK_a = 3.57$ at 37 °C) in buffering blood plasma (−pH 7.4) seems inconsistent with our earlier statement that a buffer is most effective in the range of 1 pH unit above and below its $pK_a$. The explanation for this paradox is the large reservoir of $CO_2(d)$ in blood and its rapid equilibration with $H_2CO_3$: $CO_2(d) + H_2O \rightleftharpoons H_2CO_3$.

We can define a constant, $K_h$, which is the equilibrium constant for the hydration of $CO_2$:

$$K_h = \frac{[H_2CO_3]}{[CO_2(d)]}$$

Then, to take the $CO_2(d)$ reservoir into account, we can express $[H_2CO_3]$ as $K_h[CO_2(d)]$, and substitute this expression for $[H_2CO_3]$ in the equation for the acid dissociation of $H_2CO_3$:

$$K_a = \frac{[H^+][HCO_3^-]}{[H_2CO_3]} = \frac{[H^+][HCO_3^-]}{K_h[CO_2(d)]}$$

Now, the overall equilibrium for dissociation of $H_2CO_3$ can be expressed in these terms:

$$K_hK_a = K_{combined} = \frac{[H^+][HCO_3^-]}{[CO_2(d)]}$$

We can calculate the value of the new constant, $K_{combined}$, and the corresponding apparent $pK_a$ or $pK_{combined}$ from the experimentally determined values of $K_h$ (3.0 × 10⁻³ M) and $K_a$ (2.7 × 10⁻⁴ M) at 37 °C:

$$K_{combined} = (3.0 \times 10^{-3} \text{ M})(2.7 \times 10^{-4} \text{ M})$$

$$= 8.1 \times 10^{-7} \text{ M}$$

$$pK_{combined} = 6.1$$

In clinical medicine, it is common to refer to $CO_2(d)$ as the conjugate acid and to use the apparent, or combined, $pK_a$ of 6.1 to simplify calculation of pH from $[CO_2(d)]$. In this convention,

$$\text{pH} = 6.1 + \log \frac{[HCO_3^-]}{(0.23 \times pCO_2)}$$

where $pCO_2$ is expressed in kilopascals (kPa; typically, $pCO_2$ is 4.6 to 6.7 kPa) and 0.23 is the corresponding solubility coefficient for $CO_2$ in water; thus the term $0.23 \times pCO_2 \approx 1.2 \text{ kPa}$. Plasma $[HCO_3^-]$ is normally about 24 mM.

### Untreated Diabetes Produces Life-Threatening Acidosis

Human blood plasma normally has a pH between 7.35 and 7.45, and many of the enzymes that function in the blood have evolved to have maximal activity in that pH range. Although many aspects of cell structure and function are influenced by pH, the catalytic activity of enzymes is especially sensitive. Enzymes typically show maximal catalytic activity at a characteristic pH, called the pH optimum (Fig. 2–21). On either side of this optimum pH, catalytic activity often declines sharply. Thus, a small change in pH can make a large difference in the rate of some crucial enzyme-catalyzed reactions. Biological control of the pH of cells and body fluids is therefore of central importance in all aspects of metabolism and cellular activities, and changes in blood pH have marked physiological consequences (described with gusto in Box 2–1).

In individuals with untreated diabetes, the lack of insulin, or insensitivity to insulin (depending on the type...
This is an account by J.B.S. Haldane of physiological experiments on controlling blood pH, from his book Possible Worlds (Harper and Brothers, 1928).

"I wanted to find out what happened to a man when one made him more acid or more alkaline . . . One might, of course, have tried experiments on a rabbit first, and some work had been done along these lines; but it is difficult to be sure how a rabbit feels at any time. Indeed, some rabbits make no serious attempt to cooperate with one.

". . . A human colleague and I therefore began experiments on one another . . . My colleague Dr. H.W. Davies and I made ourselves alkaline by over-breathing and by eating anything up to three ounces of bicarbonate of soda. We made ourselves acid by sitting in an air-tight room with between six and seven per cent of carbon dioxide in the air. This makes one breathe as if one had just completed a boat-race, and also gives one a rather violent headache . . . Two hours was as long as any one wanted to stay in the carbon dioxide, even if the gas chamber at our disposal had not retained an ineradicable odour of 'yellow cross gas' from some wartime experiments, which made one weep gently every time one entered it. The most obvious thing to try was drinking hydrochloric acid. If one takes it strong it dissolves one's teeth and burns one's throat, whereas I wanted to let it diffuse gently all through my body. The strongest I ever cared to drink was about one part of the commercial strong acid in a hundred of water, but a pint of that was enough for me, as it irritated my throat and stomach, while my calculations showed that I needed a gallon and a half to get the effect I wanted . . . I argued that if one ate ammonium chloride, it would partly break up in the body, liberating hydrochloric acid. This proved to be correct . . . the liver turns ammonia into a harmless substance called urea before it reaches the heart and brain on absorption from the gut. The hydrochloric acid is left behind and combines with sodium bicarbonate, which exists in all the tissues, producing sodium chloride and carbon dioxide. I have had this gas produced in me in this way at the rate of six quarts an hour (though not for an hour on end at that rate) . . .

"I was quite satisfied to have reproduced in myself the type of shortness of breath which occurs in the terminal stages of kidney disease and diabetes. This had long been known to be due to acid poisoning, but in each case the acid poisoning is complicated by other chemical abnormalities, and it had been rather uncertain which of the symptoms were due to the acid as such.

"The scene now shifts to Heidelberg, where Freudenberg and György were studying tetany in babies . . . it occurred to them that it would be well worth trying the effect of making the body unusually acid. For tetany had occasionally been observed in patients who had been treated for other complaints by very large doses of sodium bicarbonate, or had lost large amounts of hydrochloric acid by constant vomiting, and if alkalinity of the tissues will produce tetany, acidity may be expected to cure it. Unfortunately, one could hardly try to cure a dying baby by shutting it up in a room full of carbonic acid, and still less would one give it hydrochloric acid to drink; so nothing had come of their idea, and they were using lime salts, which are not very easily absorbed, and which upset the digestion, but certainly benefit many cases of tetany.

"However, the moment they read my paper on the effects of ammonium chloride, they began giving it to babies, and were delighted to find that the tetany cleared up in a few hours. Since then it has been used with effect both in England and America, both on children and adults. It does not remove the cause, but it brings the patient into a condition from which he has a very fair chance of recovering."
WORKED EXAMPLE 2–7 Treatment of Acidosis with Bicarbonate

Why does intravenous administration of a bicarbonate solution raise the plasma pH?

Solution: The ratio of $[\text{HCO}_3^-]$ to $[\text{CO}_2(d)]$ determines the pH of the bicarbonate buffer, according to the equation

$$\text{pH} = 6.1 + \log \left( \frac{[\text{HCO}_3^-]}{0.23 \times [\text{CO}_2]} \right)$$

If $[\text{HCO}_3^-]$ is increased with no change in $\text{pCO}_2$, the pH will rise.

SUMMARY 2.3 Buffering against pH Changes in Biological Systems

- A mixture of a weak acid (or base) and its salt resists changes in pH caused by the addition of $\text{H}^+$ or $\text{OH}^-$, The mixture thus functions as a buffer.
- The pH of a solution of a weak acid (or base) and its salt is given by the Henderson-Hasselbalch equation: $\text{pH} = \text{pK}_a + \log \left( \frac{[\text{A}^-]}{[\text{HA}]} \right)$.
- In cells and tissues, phosphate and bicarbonate buffer systems maintain intracellular and extracellular fluids at their optimum (physiological) pH, which is usually close to pH 7. Enzymes generally work optimally at this pH.
- Medical conditions that lower the pH of blood, causing acidosis, or raise it, causing alkalosis, can be life threatening.

2.4 Water as a Reactant

Water is not just the solvent in which the chemical reactions of living cells occur; it is very often a direct participant in those reactions. The formation of ATP from ADP and inorganic phosphate is an example of a condensation reaction in which the elements of water are eliminated (Fig. 2–22). The reverse of this reaction—cleavage accompanied by the addition of the elements of water—is a hydrolysis reaction. Hydrolysis reactions are also responsible for the enzymatic depolymerization of proteins, carbohydrates, and nucleic acids. Hydrolysis reactions, catalyzed by enzymes called hydrolases, are almost invariably exergonic; by producing two molecules from one, they lead to an increase in the randomness of the system. The formation of cellular polymers from their subunits by simple reversal of hydrolysis (that is, by condensation reactions) would be endergonic and therefore does not occur. As we shall see, cells circumvent this thermodynamic obstacle by coupling endergonic condensation reactions to exergonic processes, such as breakage of the anhydride bond in ATP.

You are (we hope!) consuming oxygen as you read. Water and carbon dioxide are the end products of the oxidation of fuels such as glucose. The overall reaction can be summarized as

$$\text{C}_6\text{H}_{12}\text{O}_6 + 6\text{O}_2 \rightarrow 6\text{CO}_2 + 6\text{H}_2\text{O}$$

Glucose

The “metabolic water” formed by oxidation of foods and stored fats is actually enough to allow some animals in very dry habitats (gerbils, kangaroo rats, camels) to survive for extended periods without drinking water.

The CO$_2$ produced by glucose oxidation is converted in erythrocytes to the more soluble HCO$_3^-$, in a reaction catalyzed by the enzyme carbonic anhydrase:

$$\text{CO}_2 + \text{H}_2\text{O} \rightarrow \text{HCO}_3^- + \text{H}^+$$

In this reaction, water not only is a substrate but also functions in proton transfer by forming a network of hydrogen-bonded water molecules through which proton hopping occurs (Fig. 2–13).

Green plants and algae use the energy of sunlight to split water in the process of photosynthesis:

$$2\text{H}_2\text{O} + 2\text{A} \rightarrow 2\text{O}_2 + 2\text{AH}_2$$

In this reaction, A is an electron-accepting species, which varies with the type of photosynthetic organism, and water serves as the electron donor in an oxidation-reduction sequence (see Fig. 19–57) that is fundamental to all life.

SUMMARY 2.4 Water as a Reactant

- Water is both the solvent in which metabolic reactions occur and a reactant in many biochemical processes, including hydrolysis, condensation, and oxidation-reduction reactions.

2.5 The Fitness of the Aqueous Environment for Living Organisms

Organisms have effectively adapted to their aqueous environment and have evolved means of exploiting the unusual properties of water. The high specific heat of water (the heat energy required to raise the temperature
of 1 g of water by 1 °C) is useful to cells and organisms because it allows water to act as a “heat buffer,” keeping the temperature of an organism relatively constant as the temperature of the surroundings fluctuates and as heat is generated as a byproduct of metabolism. Furthermore, some vertebrates exploit the high heat of vaporization of water (Table 2–1) by using (thus losing) excess body heat to evaporate sweat. The high degree of internal cohesion of liquid water, due to hydrogen bonding, is exploited by plants as a means of transporting dissolved nutrients from the roots to the leaves during the process of transpiration. Even the density of ice, lower than that of liquid water, has important biological consequences in the life cycles of aquatic organisms. Ponds freeze from the top down, and the layer of ice at the top insulates the water below from frigid air, preventing the pond (and the organisms in it) from freezing solid. Most fundamental to all living organisms is the fact that many physical and biological properties of cell macromolecules, particularly the proteins and nucleic acids, derive from their interactions with water molecules of the surrounding medium. The influence of water on the course of biological evolution has been profound and determinative. If life forms have evolved elsewhere in the universe, they are unlikely to resemble those of Earth unless their extraterrestrial origin is also a place in which plentiful liquid water is available.

Aqueous environments support countless species. Soft corals, sponges, bryozoans, and algae compete for space on this reef off the Philippine Islands.

Key Terms

Terms in bold are defined in the glossary.

- hydrogen bond 44
- bond energy 44
- hydrophilic 46
- hydrophobic 46
- amphipathic 48
- micelle 48
- hydrophobic interactions 49
- London forces 49
- van der Waals interactions 49
- osmolarity 52
- osmosis 52
- isotonic 52
- hypertonic 52
- hypotonic 52
- equilibrium constant \((K_{eq})\) 55
- ion product of water \((K_w)\) 55
- pH 56
- acidosis 57
- alkalosis 57
- conjugate acid-base pair 57
- acid dissociation constant \((K_a)\) 58
- \(pK_a\) 58
- titration curve 58
- buffer 59
- buffering region 60
- Henderson-Hasselbalch equation 60
- condensation 65
- hydrolysis 65

Further Reading

General

A wonderful investigation of the biological relevance of the properties of water.

An advanced, classic treatment of the physical chemistry of water and hydrophobic interactions.

A large collection of papers on the structure of pure water and of the cytoplasm.

A well-illustrated description of the use of computer simulation to study the biologically important association of water with proteins and nucleic acids.

Intermediate-level review of the role of an internal chain of water molecules in proton movement through this protein.

A short, useful summary of the ways in which bound water influences the structure and activity of proteins.

A brief review of the physical state of cytosolic water and its interactions with dissolved biomolecules.

Advanced review of a proton pump that employs an internal chain of water molecules.

A short review of the properties of water, introducing several excellent advanced reviews published in the same issue (see especially Pocker, 2000, and Rand et al., 2000, below).

Fourteen chapters, each by a different author, cover (at an advanced level) the structure of water and its interactions with proteins, nucleic acids, polysaccharides, and lipids.

A review of water in biology, including discussion of the physical structure of liquid water, its interaction with biomolecules, and the state of water in living cells.

Osmosis

An advanced physical investigation of the cytoplasmic water fraction of the bacterium Escherichia coli grown in media of different osmolarities. (See also Record et al., 1998, below.)

Review of the roles of water in enzyme catalysis as revealed by studies in water-poor solutes.

Intermediate-level review of the ways in which a bacterial cell changes in the osmolarity of its surroundings. (See also Cayley et al., 2000, above.)

Weak Interactions in Aqueous Systems

A clear, brief, quantitative discussion of the contribution of hydrogen bonding to molecular recognition and enzyme catalysis.

Review of the four kinds of weak interactions that stabilize macromolecules and confer biological specificity, with clear examples.

A detailed, advanced discussion of the structure and properties of hydrogen bonds, including those in water and biomolecules.

An advanced discussion of the role of water in protein structure.

Brief review of the evidence that hydrogen bonds have some covalent character.

Review of the role of water in enzyme catalysis, with carbonic anhydrase as the featured example.

An example of the important role of water in both the specificity and the affinity of protein-DNA interactions.

A short review of the physical structure of water, including the importance of hydrogen bonding and the nature of hydrophobic interactions.

A classic review of the chemical and energetic bases for hydrophobic interactions between biomolecules in aqueous solutions.

Weak Acids, Weak Bases, and Buffers: Problems for Practice

Problems

1. Solubility of Ethanol in Water Explain why ethanol (CH₃CH₂OH) is more soluble in water than is methane (CH₄).

2. Calculation of pH from Hydrogen Ion Concentration

   What is the pH of a solution that has an H⁺ concentration of (a) 1.75 x 10⁻⁵ mol/L; (b) 6.50 x 10⁻¹⁰ mol/L; (c) 1.0 x 10⁻⁴ mol/L; (d) 1.50 x 10⁻⁸ mol/L?

3. Calculation of Hydrogen Ion Concentration from pH

   What is the H⁺ concentration of a solution with pH of (a) 3.82; (b) 6.52; (c) 11.11?

4. Acidity of Gastric HCl In a hospital laboratory, a 10.0 mL sample of gastric juice, obtained several hours after a meal, was titrated with 0.1 M NaOH to neutrality; 7.2 mL of NaOH was required. The patient’s stomach contained no ingested food or drink, thus assume that no buffers were present. What was the pH of the gastric juice?

5. Calculation of the pH of a Strong Acid or Base

   (a) Write out the acid dissociation reaction for hydrochloric acid.

   (b) Calculate the pH of a solution of 5.0 x 10⁻⁴ M HCl.

   (c) Write out the acid dissociation reaction for sodium hydroxide.

   (d) Calculate the pH of a solution of 7.0 x 10⁻⁵ M NaOH.

6. Calculation of pH from Concentration of Strong Acid

   Calculate the pH of a solution prepared by diluting 3.0 mL of 2.5 M HCl to a final volume of 100 mL with H₂O.

7. Measurement of Acetylcholine Levels by pH Changes

   The concentration of acetylcholine (a neurotransmitter) in a sample can be determined from the pH changes that accompany its hydrolysis. When the sample is incubated with the enzyme acetylcholinesterase, acetylcholine is quantitatively
converted to choline and acetic acid, which dissociates to yield acetate and a hydrogen ion:

\[
\text{Acetylcholine} \rightarrow \text{Choline} + \text{Acetate} + \text{H}^+
\]

In a typical analysis, 15 mL of an aqueous solution containing an unknown amount of acetylcholine had a pH of 7.65. When incubated with acetylcholinesterase, the pH of the solution decreased to 6.87. Assuming there was no buffer in the assay mixture, determine the number of moles of acetylcholine in the 15 mL sample.

8. Physical Meaning of pKₐ Which of the following aqueous solutions has the lowest pH: 0.1 M HCl; 0.1 M acetic acid (pKₐ = 4.86); 0.1 M formic acid (pKₐ = 3.75)?

9. Simulated Vinegar One way to make vinegar (not the preferred way) is to prepare a solution of acetic acid, the sole acid component of vinegar, at the proper pH (see Fig. 2-14) and add appropriate flavoring agents. Acetic acid (Mₘ 60) is a liquid at 25 °C, with a density of 1.049 g/mL. Calculate the volume that must be added to distilled water to make 1 L of simulated vinegar (see Fig. 2-15).

10. Identifying the Conjugate Base Which is the conjugate base in each of the pairs below?
   (a) RCOOH, RCOO⁻
   (b) RNH₂, RNH₃⁺
   (c) H₂PO₃⁻, H₃PO₄
   (d) H₂CO₃, HCO₃⁻

11. Calculation of the pH of a Mixture of a Weak Acid and Its Conjugate Base Calculate the pH of a dilute solution that contains a molar ratio of potassium acetate to acetic acid (pKₐ = 4.76) of (a) 2:1; (b) 1:3; (c) 5:1; (d) 1:1; (e) 1:10.

12. Effect of pH on Solubility The strongly polar, hydrogen-bonding properties of water make it an excellent solvent for ionic (charged) species. By contrast, nonionized, nonpolar organic molecules, such as benzene, are relatively insoluble in water. In principle, the aqueous solubility of any organic acid or base can be increased by converting the molecules to charged species. For example, the solubility of benzoic acid in water is low. The addition of sodium bicarbonate to a mixture of water and benzoic acid raises the pH and deprotonates the benzoic acid to form benzoate ion, which is quite soluble in water.

Are the following compounds more soluble in an aqueous solution of 0.1 M NaOH or 0.1 M HCl? (The dissociable protons are shown in red.)

13. Treatment of Poison Ivy Rash The components of poison ivy and poison oak that produce the characteristic itchy rash are catechols substituted with long-chain alkyl groups.

If you were exposed to poison ivy, which of the treatments below would you apply to the affected area? Justify your choice.
   (a) Wash the area with cold water.
   (b) Wash the area with dilute vinegar or lemon juice.
   (c) Wash the area with soap and water.
   (d) Wash the area with soap, water, and baking soda (sodium bicarbonate).

14. pH and Drug Absorption Aspirin is a weak acid with a pKₐ of 3.5:

It is absorbed into the blood through the cells lining the stomach and the small intestine. Absorption requires passage through the plasma membrane, the rate of which is determined by the polarity of the molecule: charged and highly polar molecules pass slowly, whereas neutral hydrophobic ones pass rapidly. The pH of the stomach contents is about 1.5, and the pH of the contents of the small intestine is about 6. Is more aspirin absorbed into the bloodstream from the stomach or from the small intestine? Clearly justify your choice.
15. Calculation of pH from Molar Concentrations What is the pH of a solution containing 0.12 mol/L of NH₄Cl and 0.03 mol/L of NaOH (pKₐ of NH₄⁺/NH₃ is 9.25)?

16. Calculation of pH after Titration of Weak Acid A compound has a pKₐ of 7.4. To 100 mL of a 1.0 M solution of this compound at pH 8.0 is added 30 mL of 1.0 M hydrochloric acid. What is the pH of the resulting solution?

17. Properties of a Buffer The amino acid glycine is often used as the main ingredient of a buffer in biochemical experiments. The amino group of glycine, which has a pKₐ of 9.6, can exist either in the protonated form (—NH₃⁺) or as the free base (—NH₂), because of the reversible equilibrium

\[ R—NH_{3} \rightleftharpoons R—NH_{2} + H^{+} \]

(a) In what pH range can glycine be used as an effective buffer due to its amino group?
(b) In a 0.1 M solution of glycine at pH 9.0, what fraction of glycine has its amino group in the —NH₃⁺ form?
(c) How much 5 M KOH must be added to 1.0 L of 0.1 M glycine at pH 9.0 to bring its pH to exactly 10.0?
(d) When 99% of the glycine is in its —NH₃⁺ form, what is the numerical relation between the pH of the solution and the pKₐ of the amino group?

18. Preparation of a Phosphate Buffer What molar ratio of HPO₄²⁻ to H₂PO₄⁻ in solution would produce a pH of 7.0? Phosphoric acid (H₃PO₄), a triprotic acid, has 3 pKₐ values: 2.14, 6.86, and 12.4. Hint: Only one of the pKₐ values is relevant here.

19. Preparation of Standard Buffer for Calibration of a pH Meter The glass electrode used in commercial pH meters gives an electrical response proportional to the concentration of hydrogen ion. To convert these responses to a pH reading, the electrode must be calibrated against standard solutions of known H⁺ concentration. Determine the weight in grams of sodium dihydrogen phosphate (Na₂HPO₄, FW 142) and disodium hydrogen phosphate (Na₂H₂PO₄, FW 138) needed to prepare 1 L of a standard buffer at pH 7.00 with a total phosphate concentration of 0.10 M (see Fig. 2-15). See problem 18 for the pKₐ values of phosphoric acid.

20. Calculation of Molar Ratios of Conjugate Base to Weak Acid from pH For a weak acid with a pKₐ of 6.0, calculate the ratio of conjugate base to acid at a pH of 5.0.

21. Preparation of Buffer of Known pH and Strength Given 0.10 M solutions of acetic acid (pKₐ = 4.76) and sodium acetate, describe how you would go about preparing 1.0 L of 0.10 M acetate buffer of pH 4.00.

22. Choice of Weak Acid for a Buffer Which of these compounds would be the best buffer at pH 5.0: formic acid (pKₐ = 3.8), acetic acid (pKₐ = 4.76), or ethylamine (pKₐ = 9.0)? Briefly justify your answer.

23. Working with Buffers A buffer contains 0.010 mol of lactic acid (pKₐ = 3.86) and 0.050 mol of sodium lactate per liter. (a) Calculate the pH of the buffer. (b) Calculate the change in pH when 5 mL of 0.5 M HCl is added to 1 L of the buffer. (c) What pH change would you expect if you added the same quantity of HCl to 1 L of pure water?

24. Use of Molar Concentrations to Calculate pH What is the pH of a solution that contains 0.20 M sodium acetate and 0.60 M acetic acid (pKₐ = 4.76)?

25. Preparation of an Acetate Buffer Calculate the concentrations of acetic acid (pKₐ = 4.76) and sodium acetate necessary to prepare a 0.2 M buffer solution at pH 5.0.

26. pH of Insect Defensive Secretion You have been observing an insect that defends itself from enemies by secreting a caustic liquid. Analysis of the liquid shows it to have a total concentration of formate plus formic acid (Kₐ = 1.8 x 10⁻⁴) of 1.45 M; the concentration of formate ion is 0.015 M. What is the pH of the secretion?

27. Calculation of pKₐ An unknown compound, X, is thought to have a carboxyl group with a pKₐ of 2.0 and another ionizable group with a pKₐ between 5 and 8. When 75 mL of 0.1 M NaOH is added to 100 mL of a 0.1 M solution of X at pH 2.0, the pH increases to 6.72. Calculate the pKₐ of the second ionizable group of X.

28. Ionic Forms of Alanine Alanine is a diprotic acid that can undergo two dissociation reactions (see Table 3-1 for pKₐ values). (a) Given the structure of the partially protonated form (or zwitterion; see Fig. 3-9) below, draw the chemical structures of the other two forms of alanine that predominate in aqueous solution: the fully protonated form and the fully deprotonated form.

Of the three possible forms of alanine, which would be present at the highest concentration in solutions of the following pH: (b) 1.0; (c) 6.2; (d) 8.02; (e) 11.9. Explain your answers in terms of pH relative to the two pKₐ values.

29. Control of Blood pH by Respiratory Rate

(a) The partial pressure of CO₂ in the lungs can be varied rapidly by the rate and depth of breathing. For example, a common remedy to alleviate hiccups is to increase the concentration of CO₂ in the lungs. This can be achieved by holding one’s breath, by very slow and shallow breathing (hypoventilation), or by breathing in and out of a paper bag. Under such conditions, pCO₂ in the air space of the lungs rises above normal. Qualitatively explain the effect of these procedures on the blood pH.

(b) A common practice of competitive short-distance runners is to breathe rapidly and deeply (hyperventilate) for about half a minute to remove CO₂ from their lungs just before the race begins. Blood pH may rise to 7.60. Explain why the blood pH increases.

(c) During a short-distance run, the muscles produce a large amount of lactic acid (CH₃CH(OH)COOH; Kₐ =
1.38 \times 10^{-4} \text{mol} from their glucose stores. In view of this fact, why might hyperventilation before a dash be useful?

30. Calculation of Blood pH from CO$_2$ and Bicarbonate Levels Calculate the pH of a blood plasma sample with a total CO$_2$ concentration of 26.9 mm and bicarbonate concentration of 25.6 mm. Recall from page 63 that the relevant pK$_a$ of carbonic acid is 6.1.

31. Effect of Holding One’s Breath on Blood pH The pH of the extracellular fluid is buffered by the bicarbonate/carbonic acid system. Holding your breath can increase the concentration of CO$_2$(g) in the blood. What effect might this have on the pH of the extracellular fluid? Explain by showing the relevant equilibrium equation(s) for this buffer system.

Data Analysis Problem

32. “Switchable” Surfactants Hydrophobic molecules do not dissolve well in water. Given that water is a very commonly used solvent, this makes certain processes very difficult: washing oily food residue off dishes, cleaning up spilled oil, keeping the oil and water phases of salad dressings well mixed, and carrying out chemical reactions that involve both hydrophobic and hydrophilic components.

Surfactants are a class of amphipathic compounds that includes soaps, detergents, and emulsifiers. With the use of surfactants, hydrophobic compounds can be suspended in aqueous solution by forming micelles (see Fig. 2–7). A micelle has a hydrophobic core consisting of the hydrophobic compound and the hydrophobic “tails” of the surfactant; the hydrophilic “heads” of the surfactant cover the surface of the micelle. A suspension of micelles is called an emulsion. The more hydrophilic the head group of the surfactant, the more powerful it is—that is, the greater its capacity to emulsify hydrophobic material.

When you use soap to remove grease from dirty dishes, the soap forms an emulsion with the grease that is easily removed by water through interaction with the hydrophilic head of the soap molecules. Likewise, a detergent can be used to emulsify spilled oil for removal by water. And emulsifiers in commercial salad dressings keep the oil suspended evenly throughout the water-based mixture.

There are some situations in which it would be very useful to have a “switchable” surfactant: a molecule that could be reversibly converted between a surfactant and a nonsurfactant.

(a) Imagine such a “switchable” surfactant existed. How would you use it to clean up and then recover the oil from an oil spill?

(b) Given that the pK$_a$ of a typical amidinium ion is 12.4, in which direction (left or right) would you expect the equilibrium of the above reaction to lie? (See Fig. 2–16 for relevant pK$_a$ values.) Justify your answer. Hint: Remember the reaction H$_2$O + CO$_2$ $\rightleftharpoons$ H$_2$CO$_3$.

Liu and colleagues produced a switchable surfactant for which R = C$_{18}$H$_{37}$. They do not name the molecule in their article; for brevity, we’ll call it s-surf.

(c) The amidinium form of s-surf is a powerful surfactant; the amidine form is not. Explain this observation.

Liu and colleagues found that they could switch between the two forms of s-surf by changing the gas that they bubbled through a solution of the surfactant. They demonstrated this switch by measuring the electrical conductivity of the s-surf solution; aqueous solutions of ionic compounds have higher conductivity than solutions of nonionic compounds. They started with a solution of the amidine form of s-surf in water. Their results are shown below; dotted lines indicate the switch from one gas to another.

(d) In which form is the majority of s-surf at point A? At point B?

(e) Why does the electrical conductivity rise from time 0 to point A?

(f) Why does the electrical conductivity fall from point A to point B?

(g) Explain how you would use s-surf to clean up and recover the oil from an oil spill.

Reference

The word protein that I propose to you . . . I would wish to derive from proteios, because it appears to be the primitive or principal substance of animal nutrition that plants prepare for the herbivores, and which the latter then furnish to the carnivores.

—J. J. Berzelius, letter to G. J. Mulder, 1838

# Amino Acids, Peptides, and Proteins

3.1 Amino Acids 72
3.2 Peptides and Proteins 82
3.3 Working with Proteins 85
3.4 The Structure of Proteins: Primary Structure 92

Proteins mediate virtually every process that takes place in a cell, exhibiting an almost endless diversity of functions. To explore the molecular mechanism of a biological process, a biochemist almost inevitably studies one or more proteins. Proteins are the most abundant biological macromolecules, occurring in all cells and all parts of cells. Proteins also occur in great variety; thousands of different kinds may be found in a single cell. As the arbiters of molecular function, proteins are the most important final products of the information pathways discussed in Part III of this book. Proteins are the molecular instruments through which genetic information is expressed.

Relatively simple monomeric subunits provide the key to the structure of the thousands of different proteins. All proteins, whether from the most ancient lines of bacteria or from the most complex forms of life, are constructed from the same ubiquitous set of 20 amino acids, covalently linked in characteristic linear sequences. Because each of these amino acids has a side chain with distinctive chemical properties, this group of 20 precursor molecules may be regarded as the alphabet in which the language of protein structure is written. Proteins are found in a wide range of sizes, from relatively small peptides with just a few amino acid residues to huge polymers with molecular weights in the millions.

What is most remarkable is that cells can produce proteins with strikingly different properties and activities by joining the same 20 amino acids in many different combinations and sequences. From these building blocks different organisms can make such widely diverse products as enzymes, hormones, antibodies, transporters, muscle fibers, the lens protein of the eye, feathers, spider webs, rhinoceros horn, milk proteins, antibiotics, mushroom poisons, and myriad other substances having distinct biological activities (Fig. 3–1). Among these protein products, the enzymes are the most varied and specialized. Virtually all cellular reactions are catalyzed by enzymes.

Protein structure and function are the topics of this and the next three chapters. Here, we begin with a description of the fundamental chemical properties of amino acids, peptides, and proteins. We also consider how a biochemist works with proteins.

![Some functions of proteins](image-url)

(a) The light produced by fireflies is the result of a reaction involving the protein luciferin and ATP, catalyzed by the enzyme luciferase (see Box 13–1). (b) Erythrocytes contain large amounts of the oxygen-transporting protein hemoglobin. (c) The protein keratin, formed by all vertebrates, is the chief structural component of hair, scales, horn, wool, nails, and feathers. The black rhinoceros is nearing extinction in the wild because of the belief prevalent in some parts of the world that a powder derived from its horn has aphrodisiac properties. In reality, the chemical properties of powdered rhinoceros horn are no different from those of powdered bovine hooves or human fingernails.
3.1 Amino Acids

Protein Architecture—Amino Acids. Proteins are polymers of amino acids, with each amino acid residue joined to its neighbor by a specific type of covalent bond. (The term “residue” reflects the loss of the elements of water when one amino acid is joined to another.) Proteins can be broken down (hydrolyzed) to their constituent amino acids by a variety of methods, and the earliest studies of proteins naturally focused on the free amino acids derived from them. Twenty different amino acids are commonly found in proteins. The first to be discovered was asparagine, in 1806. The last of the 20 to be found, threonine, was not identified until 1938. All the amino acids have trivial or common names, in some cases derived from the source from which they were first isolated. Asparagine was first found in asparagus, and glutamate in wheat gluten; tyrosine was first isolated from cheese (its name is derived from the Greek tyros, “cheese”); and glycine (Greek glykos, “sweet”) was so named because of its sweet taste.

Amino Acids Share Common Structural Features

All 20 of the common amino acids are α-amino acids. They have a carboxyl group and an amino group bonded to the same carbon atom (the α carbon) (Fig. 3-2). They differ from each other in their side chains, or R groups, which vary in structure, size, and electric charge, and which influence the solubility of the amino acids in water. In addition to these 20 amino acids there are many less common ones. Some are residues modified after a protein has been synthesized; others are amino acids present in living organisms but not as constituents of proteins. The common amino acids of proteins have been assigned three-letter abbreviations and one-letter symbols (Table 3-1), which are used as shorthand to indicate the composition and sequence of amino acids polymerized in proteins.

KEY CONVENTION: The three-letter code is transparent, the abbreviations generally consisting of the first three letters of the amino acid name. The one-letter code was devised by Margaret Oakley Dayhoff (1925–1983), considered by many to be the founder of the field of bioinformatics. The one-letter code reflects an attempt to reduce the size of the data files (in an era of punch-card computing) used to describe amino acid sequences. It was designed to be easily memorized, and understanding its origin can help students do just that. For six amino acids (CHIMSV), the first letter of the amino acid name is unique and thus is assigned as the symbol. For five others (AGLPT), the first letter is not unique but is assigned to the amino acid that is most common in proteins (for example, leucine is more common than lysine). For another four, the letter used is phonetically suggestive (RFYW: arginine, Phe-nylalanine, Tyr-rosine, Trp-tophan). The rest were harder to assign. Four (DNEQ) were assigned letters found within or suggested by their names (aspar-Dic, asparagine, glutamEke, Q-tamine). That left lysine. Only a few letters were left in the alphabet, and K was chosen because it was the closest to L.

For all the common amino acids except glycine, the α carbon is bonded to four different groups: a carboxyl group, an amino group, an R group, and a hydrogen atom (Fig. 3-2; in glycine, the R group is another hydrogen atom). The α-carbon atom is thus a chiral center (p. 16). Because of the tetrahedral arrangement of the bonding orbitals around the α-carbon atom, the four different groups can occupy two unique spatial arrangements, and thus amino acids have two possible stereoisomers. Since they are nonsuperposable mirror images of each other (Fig. 3-3), the two forms represent a class of stereoisomers called enantiomers.

![FIGURE 3-2 General structure of an amino acid. This structure is common to all but one of the α-amino acids. (Proline, a cyclic amino acid, is the exception.) The R group, or side chain (red), attached to the α carbon (blue) is different in each amino acid.](image)

![FIGURE 3-3 Stereoisomerism in α-amino acids. (a) The two stereoisomers of alanine, L- and D-alanine, are nonsuperposable mirror images of each other (enantiomers). (b, c) Two different conventions for showing the configurations in space of stereoisomers. In perspective formulas (b) the solid wedge-shaped bonds project out of the plane of the paper, the dashed bonds behind it. In projection formulas (c) the horizontal bonds are assumed to project out of the plane of the paper, the vertical bonds behind. However, projection formulas are often used casually and are not always intended to portray a specific stereochemical configuration.](image)

* $M_r$ values reflect the structures as shown in Figure 3-5. The elements of water ($M$, 18) are deleted when the amino acid is incorporated into a polypeptide.

+A scale combining hydrophobicity and hydrophilicity of R groups. The values reflect the free energy ($\Delta G$) of transfer of the amino acid side chain from a hydrophobic solvent to water. This transfer is favorable ($\Delta G < 0$; negative value in the index) for charged or polar amino acid side chains, and unfavorable ($\Delta G > 0$; positive value in the index) for amino acids with nonpolar or more hydrophobic side chains. See Chapter 11. From Kyte, J. & Doolittle, R.F. (1982) A simple method for displaying the hydropathic character of a protein. J. Mol. Biol. 157, 105-132.

$^5$ Cysteine is generally classified as polar despite having a positive hydropathy index. This reflects the ability of the sulfhydryl group to act as a weak acid and to form a weak hydrogen bond with oxygen or nitrogen.

(see Fig. 1–19). All molecules with a chiral center are also optically active—that is, they rotate plane-polarized light (see Box 1–2).

**KEY CONVENTION:** Two conventions are used to identify the carbons in an amino acid—a practice that can be confusing. The additional carbons in an R group are commonly designated $\beta, \gamma, \delta, \epsilon$, and so forth, proceeding out from the $\alpha$ carbon. For most other organic molecules, carbon atoms are simply numbered from one end, giving highest priority (C-1) to the carbon with the substituent containing the atom of highest atomic number.
Within this latter convention, the carboxyl carbon of an amino acid would be C-1 and the \( \alpha \) carbon would be C-2.

\[
\begin{align*}
\text{Lysine} & : & \text{CH}_2 \text{CH} - \text{CH}_2 \text{CH}_2 \text{CH} - \text{CH} - \text{COO}^- & +\text{NH}_3 \\
\text{o-Alanine} & : & \text{CH}_2 \text{CH} - \text{CH}_2 \text{CH}_2 \text{CH} - \text{CH} - \text{COO}^- & +\text{NH}_3
\end{align*}
\]

In some cases, such as amino acids with heterocyclic R groups (such as histidine), the Greek lettering system is ambiguous and the numbering convention is therefore used. For branched amino acid side chains, equivalent carbons are given numbers after the Greek letters. Leucine thus has 61 and 62 carbons (see the structure in Fig. 3–5).

Special nomenclature has been developed to specify the absolute configuration of the four substituents of asymmetric carbon atoms. The absolute configurations of simple sugars and amino acids are specified by the D, L system (Fig. 3–4), based on the absolute configuration of the three-carbon sugar glyceraldehyde, a convention proposed by Emil Fischer in 1891. (Fischer knew what groups surrounded the asymmetric carbon of glyceraldehyde but had to guess at their absolute configuration; his guess was later confirmed by x-ray diffraction analysis.) For all chiral compounds, stereoisomers having a configuration related to that of L-glyceraldehyde are designated L, and stereoisomers related to D-glyceraldehyde are designated D. The functional groups of L-alanine are matched with those of L-glyceraldehyde by aligning those that can be interconverted by simple, one-step chemical reactions. Thus the carboxyl group of L-alanine occupies the same position about the chiral carbon as does the aldehyde group of L-glyceraldehyde, because an aldehyde is readily converted to a carboxyl group via a one-step oxidation. Historically, the similar L and D designations were used for levorotatory (rotating plane-polarized light to the left) and dextrorotatory (rotating light to the right). However, not all L-amino acids are levorotatory, and the convention shown in Figure 3–4 was needed to avoid potential ambiguities about absolute configuration. By Fischer’s convention, L and D refer only to the absolute configuration of the four substituents around the chiral carbon, not to optical properties of the molecule.

Another system of specifying configuration around a chiral center is the RS system, which is used in the systematic nomenclature of organic chemistry and describes more precisely the configuration of molecules with more than one chiral center (see p. 17).

The Amino Acid Residues in Proteins Are L Stereoisomers

Nearly all biological compounds with a chiral center occur naturally in only one stereoisomeric form, either D or L. The amino acid residues in protein molecules are exclusively L stereoisomers. D-Amino acid residues have been found in only a few, generally small peptides, including some peptides of bacterial cell walls and certain peptide antibiotics.

It is remarkable that virtually all amino acid residues in proteins are L stereoisomers. When chiral compounds are formed by ordinary chemical reactions, the result is a racemic mixture of D and L isomers, which are difficult for a chemist to distinguish and separate. But to a living system, D and L isomers are as different as the right hand and the left. The formation of stable, repeating substructures in proteins (Chapter 4) generally requires that their constituent amino acids be of one stereochiral series. Cells are able to specifically synthesize the L isomers of amino acids because the active sites of enzymes are asymmetric, causing the reactions they catalyze to be stereospecific.

### Amino Acids Can Be Classified by R Group

Knowledge of the chemical properties of the common amino acids is central to an understanding of biochemistry. The topic can be simplified by grouping the amino acids into five main classes based on the properties of their R groups (Table 3–1), in particular, their polarity, or tendency to interact with water at biological pH (near pH 7.0). The polarity of the R groups varies widely, from nonpolar and hydrophobic (water-insoluble) to highly polar and hydrophilic (water-soluble).

The structures of the 20 common amino acids are shown in Figure 3–5, and some of their properties are listed in Table 3–1. Within each class there are gradations of polarity, size, and shape of the R groups.

#### Nonpolar, Aliphatic R Groups

The R groups in this class of amino acids are nonpolar and hydrophobic.
The side chains of **alanine**, **valine**, **leucine**, and **isoleucine** tend to cluster together within proteins, stabilizing protein structure by means of hydrophobic interactions. **Glycine** has the simplest structure. Although it is most easily grouped with the nonpolar amino acids, its very small side chain makes no real contribution to hydrophobic interactions. **Methionine**, one of the two sulfur-containing amino acids, has a nonpolar thioether group in its side chain. **Proline** has an aliphatic side chain with a distinctive cyclic structure. The secondary amino (imino) group of **proline residues** is held in a rigid conformation that reduces the structural flexibility of polypeptide regions containing proline.

**Aromatic R Groups** **Phenylalanine**, **tyrosine**, and **tryptophan**, with their aromatic side chains, are relatively nonpolar (hydrophobic). All can participate in hydrophobic interactions. The hydroxyl group of tyrosine can form hydrogen bonds, and it is an important functional group in some enzymes. Tyrosine and tryptophan are significantly more polar than phenylalanine, because
of the tyrosine hydroxyl group and the nitrogen of the tryptophan indole ring.

Tryptophan and tyrosine, and to a much lesser extent phenylalanine, absorb ultraviolet light (Fig. 3-6; see also Box 3-1). This accounts for the characteristic strong absorbance of light by most proteins at a wavelength of 280 nm, a property exploited by researchers in the characterization of proteins.

### BOX 3-1 METHODS Absorption of Light by Molecules: The Lambert-Beer Law

A wide range of biomolecules absorb light at characteristic wavelengths, just as tryptophan absorbs light at 280 nm (see Fig. 3-6). Measurement of light absorption by a spectrophotometer is used to detect and identify molecules and to measure their concentration in solution. The fraction of the incident light absorbed by a solution at a given wavelength is related to the thickness of the absorbing layer (path length) and the concentration of the absorbing species (Fig. 1). These two relationships are combined into the Lambert-Beer law,

$$\log \frac{I_0}{I} = -\varepsilon cl$$

where $I_0$ is the intensity of the incident light, $I$ is the intensity of the transmitted light, the ratio $I/I_0$ (the inverse of the ratio in the equation) is the transmittance, $\varepsilon$ is the molar extinction coefficient (in units of liters per mole-centimeter), $c$ is the concentration of the absorbing species (in moles per liter), and $l$ is the path length of the light-absorbing sample (in centimeters). The Lambert-Beer law assumes that the incident light is parallel and monochromatic (of a single wavelength) and that the solvent and solute molecules are randomly oriented. The expression $\log (I_0/I)$ is called the absorbance, designated $A$.

It is important to note that each successive millimeter of path length of absorbing solution in a 1.0 cm cell absorbs not a constant amount but a constant fraction of the light that is incident upon it. However, with an absorbing layer of fixed path length, the absorbance, $A$, is directly proportional to the concentration of the absorbing solute.

The molar extinction coefficient varies with the nature of the absorbing compound, the solvent, and the wavelength, and also with pH if the light-absorbing species is in equilibrium with an ionization state that has different absorbance properties.

---

**FIGURE 3-6** Absorption of ultraviolet light by aromatic amino acids. Comparison of the light absorption spectra of the aromatic amino acids tryptophan and tyrosine at pH 6.0. The amino acids are present in equimolar amounts ($10^{-3} \text{M}$) under identical conditions. The measured absorbance of tryptophan is as much as four times that of tyrosine. Note that the maximum light absorption for both tryptophan and tyrosine occurs near a wavelength of 280 nm. Light absorption by the third aromatic amino acid, phenylalanine (not shown), generally contributes little to the spectroscopic properties of proteins.

**FIGURE 1** The principal components of a spectrophotometer. A light source emits light along a broad spectrum, then the monochromator selects and transmits light of a particular wavelength. The monochromatic light passes through the sample in a cuvette of path length $l$ and is absorbed by the sample in proportion to the concentration of the absorbing species. The transmitted light is measured by a detector.
FIGURE 3-7 Reversible formation of a disulfide bond by oxidation of two molecules of cysteine. Disulfide bonds between Cys residues stabilize the structures of many proteins.

**Polar, Uncharged R Groups** The R groups of these amino acids are more soluble in water or more hydrophilic, than those of the nonpolar amino acids, because they contain functional groups that form hydrogen bonds with water. This class of amino acids includes **serine**, **threonine**, **cysteine**, **asparagine**, and **glutamine**. The polarity of serine and threonine is contributed by their hydroxyl groups; that of cysteine by its sulfhydryl group, which is a weak acid and can make weak hydrogen bonds with oxygen or nitrogen; and that of asparagine and glutamine by their amide groups.

Asparagine and glutamine are the amides of two other amino acids also found in proteins, aspartate and glutamate, respectively, to which asparagine and glutamine are easily hydrolyzed by acid or base. Cysteine is readily oxidized to form a covalently linked dimeric amino acid called **cystine**, in which two cysteine molecules or residues are joined by a disulfide bond (Fig. 3-7). The disulfide-linked residues are strongly hydrophobic (nonpolar). Disulfide bonds play a special role in the structures of many proteins by forming covalent links between parts of a polypeptide molecule or between two different polypeptide chains.

**Positively Charged (Basic) R Groups** The most hydrophilic R groups are those that are either positively or negatively charged. The amino acids in which the R groups have significant positive charge at pH 7.0 are **lysine**, which has a secondary amino group at the α position on its aliphatic chain; **arginine**, which has a positively charged guanidinium group; and **histidine**, which has an aromatic imidazole group. As the only common amino acid having an ionizable side chain with pKₐ near neutrality, histidine may be positively charged (protonated form) or uncharged at pH 7.0. His residues facilitate many enzyme-catalyzed reactions by serving as proton donors/acceptors.

**Negatively Charged (Acidic) R Groups** The two amino acids having R groups with a net negative charge at pH 7.0 are **aspartate** and **glutamate**, each of which has a second carboxyl group.

**Uncommon Amino Acids Also Have Important Functions**

In addition to the 20 common amino acids, proteins may contain residues created by modification of common residues already incorporated into a polypeptide (Fig. 3-8a). Among these uncommon amino acids are **4-hydroxyproline**, a derivative of proline, and **5-hydroxylysine**, derived from lysine. The former is found in plant cell wall proteins, and both are found in collagen, a fibrous protein of connective tissues. **6-N-Methyllysine** is a constituent of myosin, a contractile protein of muscle. Another important uncommon amino acid is **γ-carboxyglutamate**, found in the blood-clotting protein prothrombin and in certain other proteins that bind Ca²⁺ as part of their biological function. More complex is **desmosine**, a derivative of four Lys residues, which is found in the fibrous protein elastin.

**Selenocysteine** is a special case. This rare amino acid residue is introduced during protein synthesis rather than created through a postsynthetic modification. It contains selenium rather than the sulfur of cysteine. Actually derived from serine, selenocysteine is a constituent of just a few known proteins.

Some amino acid residues in a protein may be modified transiently to alter the protein's function. The addition of phosphoryl, methyl, acetyl, adenyl, ADP-ribosyl, or other groups to particular amino acid residues can increase or decrease a protein's activity (Fig. 3-8b). Phosphorylation is a particularly common regulatory modification. Covalent modification as a protein regulatory strategy is discussed in more detail in Chapter 6.

Some 300 additional amino acids have been found in cells. They have a variety of functions but are not all constituents of proteins. **Ornithine** and **citrulline** (Fig. 3-8c) deserve special note because they are key intermediates (metabolites) in the biosynthesis of arginine (Chapter 22) and in the urea cycle (Chapter 18).
Amino Acids Can Act as Acids and Bases

The amino and carboxyl groups of amino acids, along with the ionizable R groups of some amino acids, function as weak acids and bases. When an amino acid lacking an ionizable R group is dissolved in water at neutral pH, it exists in solution as the dipolar ion, or zwitterion (German for “hybrid ion”), which can act as either an acid or a base (Fig. 3-9). Substances having this dual (acid-base) nature are amphoteric and are often called...
ampholytes (from “amphoteric electrolytes”). A simple monoamino monocarboxylic α-amino acid, such as alanine, is a diprotic acid when fully protonated; it has two groups, the —COOH group and the —NH₃⁺ group, that can yield protons:

\[
\begin{align*}
\text{Nonionic form} & : \quad \text{R}-\text{C}-\text{C}^- \quad \text{as acid} \\
\text{Zwitterion} & : \quad \text{R}-\text{C}^-\text{C}-\text{O}^- \\
\text{Base} & : \quad \text{R}-\text{C}-\text{C}^- \quad \text{as base}
\end{align*}
\]

Aminoo Acids Have Characteristic Titration Curves

Acid-base titration involves the gradual addition or removal of protons (Chapter 2). Figure 3-10 shows the titration curve of the diprotic form of glycine. The two ionizable groups of glycine, the carboxyl group and the amino group, are titrated with a strong base such as NaOH. The plot has two distinct stages, corresponding to deprotonation of two different groups on glycine. Each of the two stages resembles in shape the titration curve of a monoprotic acid, such as acetic acid (see Fig. 2-16), and can be analyzed in the same way. At very low pH, the predominant ionic species of glycine is the fully protonated form, \( ^+\text{H}_3\text{N}^-\text{CH}_2\text{COO}^- \). At the midpoint of the first stage of the titration, in which the —COOH group of glycine loses its proton, equimolar concentrations of the proton-donor \( ^+\text{H}_3\text{N}^-\text{CH}_2\text{COO}^- \) and proton-acceptor \( ^+\text{H}_3\text{N}^-\text{CH}_2\text{COO}^- \) species are present. At the midpoint of any titration, a point of inflection is reached where the pH is equal to the pKₐ of the protonated group being titrated (see Fig. 2-17). For glycine, the pH at the midpoint is 2.34, thus its —COOH group has a pKₐ (labeled pK₁ in Fig. 3-10) of 2.34. (Recall from Chapter 2 that pH and pKₐ are simply convenient notations for proton concentration and the equilibrium constant for ionization, respectively. The pKₐ is a measure of the tendency of a group to give up a proton, with that tendency decreasing tenfold as the pKₐ increases by one unit.) As the titration proceeds, another important point is reached at pH 5.97. Here there is another point of inflection, at which removal of the first proton is essentially complete and removal of the second has just begun. At this pH glycine is present largely as the dipolar ion (zwitterion) \( ^+\text{H}_3\text{N}^-\text{CH}_2\text{COO}^- \). We shall return to the significance of this inflection point in the titration curve (labeled pI in Fig. 3-10) shortly.

The second stage of the titration corresponds to the removal of a proton from the —NH₃⁺ group of glycine. The pH at the midpoint of this stage is 9.60, equal to the pKₐ (labeled pK₂ in Fig. 3-10) for the —NH₃⁺ group. The titration is essentially complete at a pH of about 12, at which point the predominant form of glycine is \( ^+\text{H}_2\text{N}^-\text{CH}_2\text{COO}^- \).

From the titration curve of glycine we can derive several important pieces of information. First, it gives a quantitative measure of the pKₐ of each of the two ionizing groups: 2.34 for the —COOH group and 9.60 for the —NH₃⁺ group. Note that the carboxyl group of glycine is over 100 times more acidic (more easily ionized) than...
PKt
Methyl-substituted carboxyl and amino groups

FIGURE 3-11 Effect of the chemical environment on pKₐ. The pKₐ values for the ionizable groups in glycine are lower than those for simple, methyl-substituted amino and carboxyl groups. These downward perturbations of pKₐ are due to intramolecular interactions. Similar effects can be caused by chemical groups that happen to be positioned nearby—for example, in the active site of an enzyme.

glycine, the Henderson-Hasselbalch equation (p. 60) can be used to calculate the proportions of proton-donor and proton-acceptor species of glycine required to make a buffer at a given pH.

Titration Curves Predict the Electric Charge of Amino Acids

Another important piece of information derived from the titration curve of an amino acid is the relationship between its net charge and the pH of the solution. At pH 5.97, the point of inflection between the two stages in its titration curve, glycine is present predominantly as its dipolar form, fully ionized but with no net electric charge (Fig. 3-10). The characteristic pH at which the net electric charge is zero is called the isoelectric point or isoelectric pH, designated pI. For glycine, which has no ionizable group in its side chain, the isoelectric point is simply the arithmetic mean of the two pKₐ values:

\[
pI = \frac{1}{2} (pK_1 + pK_2) = \frac{1}{2} (2.34 + 9.60) = 5.97
\]

As is evident in Figure 3-10, glycine has a net negative charge at any pH above its pI and will thus move toward the positive electrode (the anode) when placed in an electric field. At any pH below its pI, glycine has a net positive charge and will move toward the negative electrode (the cathode). The farther the pH of a glycine solution is from its isoelectric point, the greater the net electric charge of the population of glycine molecules. At pH 1.0, for example, glycine exists almost entirely as the form \(+H_2N\text{-CH}_2\text{COOH}\) with a net positive charge.
of 1.0. At pH 2.34, where there is an equal mixture of $^1\text{H}_3\text{N}—\text{CH}_2—\text{COOH}$ and $^1\text{H}_3\text{N}—\text{CH}_2—\text{CO}^-\text{O}^-$, the average or net positive charge is 0.5. The sign and the magnitude of the net charge of any amino acid at any pH can be predicted in the same way.

**Amino Acids Differ in Their Acid-Base Properties**

The shared properties of many amino acids permit some simplifying generalizations about their acid-base behaviors. First, all amino acids with a single $a$-amino group, a single $a$-carboxyl group, and an R group that does not ionize have titration curves resembling that of glycine (Fig. 3-10). These amino acids have very similar, although not identical, $pK_a$ values: $pK_a$ of the $-\text{COOH}$ group in the range of 1.8 to 2.4, and $pK_a$ of the $-\text{NH}_3^+$ group in the range of 8.8 to 11.0 (Table 3-1). The differences in these $pK_a$ values reflect the effects of the R groups. Second, amino acids with an ionizable R group have more complex titration curves, with three stages corresponding to the three possible ionization steps; thus they have three $pK_a$ values. The additional stage for the titration of the ionizable R group merges to some extent with the other two. The titration curves for two amino acids of this type, glutamate and histidine, are shown in Figure 3-12. The isoelectric points reflect the nature of the ionizing R groups present. For example, glutamate has a pI of 3.22, considerably lower than that of glycine. This is due to the presence of two carboxyl groups, which, at the average of their $pK_a$ values (3.22), contribute a net charge of $-1$ that balances the $+1$ contributed by the amino group. Similarly, the pI of histidine, with two groups that are positively charged when protonated, is 7.59 (the average of the $pK_a$ values of the amino and imidazole groups), much higher than that of glycine.

Finally, as pointed out earlier, under the general condition of free and open exposure to the aqueous environment, only histidine has an R group ($pK_a = 6.0$) providing significant buffering power near the neutral pH usually found in the intracellular and extracellular fluids of most animals and bacteria (Table 3-1).

**SUMMARY 3.1 Amino Acids**

- The 20 amino acids commonly found as residues in proteins contain an $a$-carboxyl group, an $a$-amino group, and a distinctive R group substituted on the $a$-carbon atom. The $a$-carbon atom of all amino acids except glycine is asymmetric, and thus amino acids can exist in at least two stereoisomeric forms. Only the $l$ stereoisomers, with a configuration related to the absolute configuration of the reference molecule $l$-glyceraldehyde, are found in proteins.

- Other, less common amino acids also occur, either as constituents of proteins (through modification of common amino acid residues after protein synthesis) or as free metabolites.

- Amino acids are classified into five types on the basis of the polarity and charge (at pH 7) of their R groups.

- Amino acids vary in their acid-base properties and have characteristic titration curves. Monoamino monocarboxylic amino acids (with nonionizable R groups) are diprotic acids ($^1\text{H}_3\text{NCH(R)COOH}$) at low pH and exist in several different ionic forms as the pH is increased. Amino acids with ionizable R groups have additional ionic species, depending on the pH of the medium and the $pK_a$ of the R group.
3.2 Peptides and Proteins

We now turn to polymers of amino acids, the peptides and proteins. Biologically occurring polypeptides range in size from small to very large, consisting of two or three to thousands of linked amino acid residues. Our focus is on the fundamental chemical properties of these polymers.

Peptides Are Chains of Amino Acids

Two amino acid molecules can be covalently joined through a substituted amide linkage, termed a peptide bond, to yield a dipeptide. Such a linkage is formed by removal of the elements of water (dehydration) from the α-carboxyl group of one amino acid and the α-amino group of another (Fig. 3-13). Peptide bond formation is an example of a condensation reaction, a common class of reactions in living cells. Under standard biochemical conditions, the equilibrium for the reaction shown in Figure 3-13 favors the amino acids over the dipeptide. To make the reaction thermodynamically more favorable, the carboxyl group must be chemically modified or activated so that the hydroxyl group can be more readily eliminated. A chemical approach to this problem is outlined later in this chapter. The biological approach to peptide bond formation is a major topic of Chapter 27.

Three amino acids can be joined by two peptide bonds to form a tripeptide; similarly, four amino acids can be linked to form tetrapeptides, and so forth. When a few amino acids are joined in this fashion, the structure is called an oligopeptide. When many amino acids are joined, the product is called a polypeptide. Proteins may have thousands of amino acid residues. Although the terms “protein” and “polypeptide” are sometimes used interchangeably, molecules referred to as polypeptides generally have molecular weights below 10,000, and those called proteins have higher molecular weights.

Peptide Can Be Distinguished by Their Ionization Behavior

Peptides contain only one free α-amino group and one free α-carboxyl group, at opposite ends of the chain (Fig. 3-15). These groups ionize as they do in free amino acids, although the ionization constants are different because an oppositely charged group is no longer linked to the α carbon. The α-amino and α-carboxyl groups of all nonterminal amino acids are covalently joined in the peptide bonds, which do not ionize and thus do not contribute to the total acid-base behavior of peptides. However, the R groups of some amino acids can ionize (Table 3-1), and in a peptide these contribute to the overall acid-base properties of the molecule (Fig. 3-15). Thus the acid-base behavior of a peptide can be predicted from its free α-amino and α-carboxyl groups as well as the nature and number of its ionizable R groups.

Like free amino acids, peptides have characteristic titration curves and a characteristic isoelectric pH (pI) at which they do not move in an electric field. These properties are exploited in some of the techniques used...
to separate peptides and proteins, as we shall see later in the chapter. It should be emphasized that the $pK_a$ value for an ionizable $R$ group can change somewhat when an amino acid becomes a residue in a peptide. The loss of charge in the $\alpha$-carboxyl and $\alpha$-amino groups, the interactions with other peptide $R$ groups, and other environmental factors can affect the $pK_a$. The $pK_a$ values for $R$ groups listed in Table 3–1 can be a useful guide to the pH range in which a given group will ionize, but they cannot be strictly applied to peptides.

**Biologically Active Peptides and Polypeptides Occur in a Vast Range of Sizes and Compositions**

No generalizations can be made about the molecular weights of biologically active peptides and proteins in relation to their functions. Naturally occurring peptides range in length from two to many thousands of amino acid residues. Even the smallest peptides can have biologically important effects. Consider the commercially synthesized dipeptide L-aspartyl-L-phenylalanine methyl ester, the artificial sweetener better known as aspartame or NutraSweet.

Many small peptides exert their effects at very low concentrations. For example, a number of vertebrate hormones (Chapter 23) are small peptides. These include oxytocin (nine amino acid residues), which is secreted by the posterior pituitary and stimulates uterine contractions, and thyrotropin-releasing factor (three residues), which is formed in the hypothalamus and stimulates the release of another hormone, thyrotropin, from the anterior pituitary gland. Some extremely toxic mushroom poisons, such as amanitin, are also small peptides, as are many antibiotics.

How long are the polypeptide chains in proteins? As Table 3–2 shows, lengths vary considerably. Human cytochrome $c$ has 104 amino acid residues linked in a single chain; bovine chymotrypsinogen has 245 residues. At the extreme is titin, a constituent of vertebrate muscle, which has nearly 27,000 amino acid residues and a molecular weight of about 3,000,000. The vast majority of naturally occurring proteins are much smaller than this, containing fewer than 2,000 amino acid residues.
Amino Acids, Peptides, and Proteins

In some common analyses, such as acid hydrolysis, Asp and Asn are not readily distinguished from each other and are together designated Asx (or B). Similarly, when Glu and Gln cannot be distinguished, they are together designated Glx (or Z). In addition, Trp is destroyed by acid hydrolysis. Additional procedures must be employed to obtain an accurate assessment of complete amino acid content.

Some proteins consist of a single polypeptide chain, but others, called multisubunit proteins, have two or more polypeptides associated noncovalently (Table 3-2). The individual polypeptide chains in a multisubunit protein may be identical or different. If at least two are identical the protein is said to be oligomeric, and the identical units (consisting of one or more polypeptide chains) are referred to as protomers. Hemoglobin, for example, has four polypeptide subunits: two identical α chains and two identical β chains, all four held together by noncovalent interactions. Each α subunit is paired in an identical way with a β subunit within the structure of this multisubunit protein, so that hemoglobin can be considered either a tetramer of four polypeptide subunits or a dimer of αβ protomers.

A few proteins contain two or more polypeptide chains linked covalently. For example, the two polypeptide chains of insulin are linked by disulfide bonds. In such cases, the individual polypeptides are not considered subunits but are commonly referred to simply as chains.

The amino acid composition of proteins is also highly variable. The 20 common amino acids almost never occur in equal amounts in a protein. Some amino acids may occur only once or not at all in a given type of protein; others may occur in large numbers. Table 3–3 shows the amino acid composition of bovine cytochrome c and chymotrypsinogen, the inactive precursor of the digestive enzyme chymotrypsin. These two proteins, with very different functions, also differ significantly in the relative numbers of each kind of amino acid residue.

We can calculate the approximate number of amino acid residues in a simple protein containing no other chemical constituents by dividing its molecular weight by 110. Although the average molecular weight of the 20 common amino acids is about 138, the smaller amino acids predominate in most proteins. If we take into account the proportions in which the various amino acids occur in an average protein (Table 3–1; the averages are determined by surveying the amino acid compositions of thousands of different proteins), the average molecular weight of protein amino acids is nearer to 128. Because a molecule of water (M, 18) is removed to create each peptide bond, the average molecular weight of an amino acid residue in a protein is about 128 - 18 = 110.

Some proteins contain chemical groups other than amino acids

Many proteins, for example the enzymes ribonuclease A and chymotrypsin, contain only amino acid residues and no other chemical constituents; these are considered simple proteins. However, some proteins contain permanently associated chemical components in addition to amino acids; these are called conjugated proteins. The non-amino acid part of a conjugated protein is usually called its prosthetic group. Conjugated proteins are classified on the basis of the chemical nature of their prosthetic groups (Table 3–4); for example, lipoproteins contain lipids, glycoproteins contain sugar groups, and metalloproteins contain a specific metal. Some proteins contain more than one prosthetic group. Usually the prosthetic group plays an important role in the protein’s biological function.

Additional procedures must be employed to obtain an accurate assessment of complete amino acid content.

SUMMARY 3.2 Peptides and Proteins

- Amino acids can be joined covalently through peptide bonds to form peptides and proteins. Cells generally contain thousands of different proteins, each with a different biological activity.
- Proteins can be very long polypeptide chains of 100 to several thousand amino acid residues. However,
some naturally occurring peptides have only a few amino acid residues. Some proteins are composed of several noncovalently associated polypeptide chains, called subunits.

- Simple proteins yield only amino acids on hydrolysis; conjugated proteins contain in addition some other component, such as a metal or organic prosthetic group.

### 3.3 Working with Proteins

Biochemists' understanding of protein structure and function has been derived from the study of many individual proteins. To study a protein in detail, the researcher must be able to separate it from other proteins in pure form and must have the techniques to determine its properties. The necessary methods come from protein chemistry, a discipline as old as biochemistry itself and one that retains a central position in biochemical research.

#### Proteins Can Be Separated and Purified

A pure preparation is essential before a protein's properties and activities can be determined. Given that cells contain thousands of different kinds of proteins, how can one protein be purified? Classical methods for separating proteins take advantage of properties that vary from one protein to the next, including size, charge, and binding properties. Some additional modern methods, involving DNA cloning and genome sequencing, can simplify the process of protein purification and are presented in Chapter 9.

The source of a protein is generally tissue or microbial cells. The first step in any protein purification procedure is to break open these cells, releasing their proteins into a solution called a **crude extract**. If necessary, differential centrifugation can be used to prepare subcellular fractions or to isolate specific organelles (see Fig. 1–8).

Once the extract or organelle preparation is ready, various methods are available for purifying one or more of the proteins it contains. Commonly, the extract is subjected to treatments that separate the proteins into different **fractions** based on a property such as size or charge, a process referred to as **fractionation**. Early fractionation steps in a purification utilize differences in protein solubility, which is a complex function of pH, temperature, salt concentration, and other factors. The solubility of proteins is generally lowered at high salt concentrations, an effect called "salting out." The addition of certain salts in the right amount can selectively precipitate some proteins, while others remain in solution. Ammonium sulfate \((\text{NH}_4)_2\text{SO}_4\) is particularly effective and is often used to salt out proteins. The proteins thus precipitated are removed from those remaining in solution by low-speed centrifugation.

A solution containing the protein of interest usually must be further altered before subsequent purification steps are possible. For example, **dialysis** is a procedure that separates proteins from small solutes by taking advantage of the proteins' larger size. The partially purified extract is placed in a bag or tube made of a semipermeable membrane. When this is suspended in a much larger volume of buffered solution of appropriate ionic strength, the membrane allows the exchange of salt and buffer but not proteins. Thus dialysis retains large proteins within the membranous bag or tube while allowing the concentration of other solutes in the protein preparation to change until they come into equilibrium with the solution outside the membrane. Dialysis might be used, for example, to remove ammonium sulfate from the protein preparation.

The most powerful methods for fractionating proteins make use of **column chromatography**, which

Column chromatography.

The standard elements of a chromatographic column include a solid, porous material (matrix) supported inside a column, generally made of plastic or glass. A solution, the mobile phase, flows through the matrix, the stationary phase. The solution that passes out of the column at the bottom (the effluent) is constantly replaced by solution supplied from a reservoir at the top. The protein solution to be separated is layered on top of the column and allowed to percolate into the solid matrix. Additional solution is added on top. The protein solution forms a band within the mobile phase that is initially the depth of the protein solution applied to the column. As proteins migrate through the column, they are retarded to different degrees by their different interactions with the matrix material. The overall protein band thus widens as it moves through the column. Individual types of proteins (such as A, B, and C, shown in blue, red, and green) gradually separate from each other, forming bands within the broader protein band. Separation improves (i.e., resolution increases) as the length of the column increases. However, each individual protein band also broadens with time due to diffusional spreading, a process that decreases resolution. As the protein-containing solution exits a column, successive portions (fractions) of this effluent are collected in test tubes. Each fraction can be tested for the presence of the protein of interest as well as other properties, such as ionic strength or total protein concentration. All fractions positive for the protein of interest can be combined as the product of this chromatographic step of the protein purification.

WORKED EXAMPLE 3–1 Ion Exchange of Peptides

A biochemist wants to separate two peptides by ion-exchange chromatography. At the pH of the mobile phase to be used on the column, one peptide (A) has a net charge of -3, due to the presence of more Glu and Asp residues than Arg, Lys, and His residues. Peptide B has a net charge of +1. Which peptide would elute first from a cation-exchange resin? Which would elute first from an anion-exchange resin?
3.3 Working with Proteins

O Large net positive charge
O Net positive charge
O Net negative charge
O Large net negative charge

Polymer beads with negatively charged functional groups

Protein mixture is added to column containing cation exchangers.

Proteins move through the column at rates determined by their net charge at the pH being used. With cation exchangers, proteins with a more negative net charge move faster and elute earlier.

(a) Ion-exchange chromatography

Polymer beads

Porous polymer beads

Protein mixture is added to column containing cross-linked polymer.

Protein molecules separate by size; larger molecules pass more freely, appearing in the earlier fractions.

(b) Size-exclusion chromatography

Solution: A cation-exchange resin has negative charges and binds positively charged molecules, retarding their progress through the column. Peptide B, with its net positive charge, will interact more strongly with the cation-exchange resin than peptide A, and thus peptide A will elute first. On the anion-exchange resin, peptide B will elute first. Peptide A, being negatively charged, will be retarded by its interaction with the positively charged resin.

Figure 3-17 shows two other variations of column chromatography in addition to ion exchange. **Size-exclusion chromatography**, also called gel filtration (Fig. 3-17b), separates proteins according to size. In this method, large proteins emerge from the column sooner than small ones—a somewhat counterintuitive result. The solid phase consists of cross-linked polymer beads with engineered pores or cavities of a particular size. Large proteins cannot enter the cavities and so take a

(c) Affinity chromatography
short (and rapid) path through the column, around the beads. Small proteins enter the cavities and are slowed by their more labyrinthine path through the column.

**Affinity chromatography** is based on binding affinity (Fig. 3-17c). The beads in the column have a covalently attached chemical group called a ligand—a group or molecule that binds to a macromolecule such as a protein. When a protein mixture is added to the column, any protein with affinity for this ligand binds to the beads, and its migration through the matrix is retarded. For example, if the biological function of a protein involves binding to ATP, then attaching ATP to the beads in the column creates an affinity matrix that can help purify the protein. As the protein solution moves through the column, ATP-binding proteins (including the protein of interest) bind to the ligand used in the column. After proteins that do not bind are washed through the column, the bound protein is eluted by a solution containing either a high concentration of salt or free ligand—in this case, ATP. Salt weakens the binding of the protein to the immobilized ligand, interfering with ionic interactions. Free ligand competes with the ligand attached to the beads, releasing the protein from the matrix; the protein product that elutes from the column is often bound to the ligand used to elute it.

A modern refinement in chromatographic methods is HPLC, or high-performance liquid chromatography. HPLC makes use of high-pressure pumps that speed the movement of the protein molecules down the column, as well as higher-quality chromatographic materials that can withstand the crushing force of the pressurized flow. By reducing the transit time on the column, HPLC can limit diffusional spreading of protein bands and thus greatly improve resolution.

The approach to purification of a protein that has not previously been isolated is guided both by established precedents and by common sense. In most cases, several different methods must be used sequentially to purify a protein completely, each method separating proteins on the basis of different properties. For example, if one step separates ATP-binding proteins from those that do not bind ATP, then the next step must separate the various ATP-binding proteins on the basis of size or charge to isolate the particular protein that is wanted. The choice of methods is somewhat empirical, and many strategies may be tried before the most effective one is found. Trial and error can often be minimized by basing the procedure on purification techniques developed for similar proteins. Published purification protocols are available for many thousands of proteins. Common sense dictates that inexpensive procedures such as salting out be used first, when the total volume and the number of contaminants are greatest. Chromatographic methods are often impractical at early stages, because the amount of chromatographic medium needed increases with sample size. As each purification step is completed, the sample size generally becomes smaller. Table 3–5, making it feasible to use more sophisticated (and expensive) chromatographic procedures at later stages.

**Proteins Can Be Separated and Characterized by Electrophoresis**

Another important technique for the separation of proteins is based on the migration of charged proteins in an electric field, a process called electrophoresis. These procedures are not generally used to purify proteins in large amounts, because simpler alternatives are usually available and electrophoretic methods often adversely affect the structure and thus the function of proteins. Electrophoresis is, however, especially useful as an analytical method. Its advantage is that proteins can be visualized as well as separated, permitting a researcher to estimate quickly the number of different proteins in a mixture or the degree of purity of a particular protein preparation. Also, electrophoresis allows determination of crucial properties of a protein such as its isoelectric point and approximate molecular weight.

FIGURE 3-18 Electrophoresis. (a) Different samples are loaded in wells or depressions at the top of the polyacrylamide gel. The proteins move into the gel when an electric field is applied. The gel minimizes convection currents caused by small temperature gradients, as well as protein movements other than those induced by the electric field. (b) Proteins can be visualized after electrophoresis by treating the gel with a stain such as Coomassie blue, which binds to the proteins but not to the gel itself. Each band on the gel represents a different protein (or protein subunit); smaller proteins move through the gel more rapidly than larger proteins and therefore are found nearer the bottom of the gel. This gel illustrates purification of the RecA protein of Escherichia coli (described in Chapter 25). The gene for the RecA protein was cloned (Chapter 9) so that its expression (synthesis of the protein) could be controlled. The first lane shows a set of standard proteins (of known \( M_r \), serving as molecular weight markers. The next two lanes show proteins from E. coli cells before and after synthesis of RecA protein was induced. The fourth lane shows the proteins in a crude cellular extract. Subsequent lanes (left to right) show the proteins present after successive purification steps. The purified protein is a single polypeptide chain (\( M_r \approx 38,000 \)), as seen in the rightmost lane.

electrophoresis, the force moving the macromolecule is the electrical potential, \( E \). The electrophoretic mobility, \( \mu \), of a molecule is the ratio of its velocity, \( V \), to the electrical potential. Electrophoretic mobility is also equal to the net charge, \( Z \), of the molecule divided by the frictional coefficient, \( f \), which reflects in part a protein’s shape. Thus:

\[
\mu = \frac{V}{E} = \frac{Z}{f}
\]

The migration of a protein in a gel during electrophoresis is therefore a function of its size and its shape.

An electrophoretic method commonly employed for estimation of purity and molecular weight makes use of the detergent sodium dodecyl sulfate (SDS) (“dodecyl” denoting a 12-carbon chain).

\[
\text{SDS} = \text{Na}^+ - \overset{-}{\text{O}} - \overset{\text{S}}{\overset{-}{\text{O}} - \overset{\text{CH}_2}{\text{CH}_3}} - \overset{\text{O}}{\overset{-}{\text{O}}}
\]

Sodium dodecyl sulfate (SDS)

SDS binds to most proteins in amounts roughly proportional to the molecular weight of the protein, about one molecule of SDS for every two amino acid residues. The bound SDS contributes a large net negative charge, rendering the intrinsic charge of the protein insignificant and conferring on each protein a similar charge-to-mass ratio. In addition, SDS binding partially unfolds proteins, such that most SDS-bound proteins assume a similar shape. Electrophoresis in the presence of SDS therefore separates proteins almost exclusively on the basis of mass (molecular weight), with smaller polypeptides migrating more rapidly. After electrophoresis, the proteins are visualized by adding a dye such as Coomassie blue, which binds to proteins but not to the gel itself (Fig. 3–18b). Thus, a researcher can monitor the progress of a protein purification procedure as the number of protein bands visible on the gel decreases after each new fractionation step. When compared with the positions to which proteins of known molecular weight migrate in the gel, the position of an unidentified protein can provide a good approximation of its molecular weight (Fig. 3–19). If the protein has two or more different subunits, the subunits are generally separated by the SDS treatment, and a separate band appears for each.
Isoelectric focusing is a procedure used to determine the isoelectric point (pI) of a protein (Fig. 3-20). A pH gradient is established by allowing a mixture of low molecular weight organic acids and bases (ampholytes; p. 79) to distribute themselves in an electric field generated across the gel. When a protein mixture is applied, each protein migrates until it reaches the pH that matches its pI (Table 3-6). Proteins with different isoelectric points are thus distributed differently throughout the gel.

Combining isoelectric focusing and SDS electrophoresis sequentially in a process called two-dimensional electrophoresis permits the resolution of complex mixtures of proteins (Fig. 3-21). This is a more sensitive analytical method than either electrophoretic method alone. Two-dimensional electrophoresis separates proteins of identical molecular weight that differ in pI, or proteins with similar pI values but different molecular weights.

**FIGURE 3-19** Estimating the molecular weight of a protein. The electrophoretic mobility of a protein on an SDS polyacrylamide gel is related to its molecular weight, M, (a) Standard proteins of known molecular weight are subjected to electrophoresis (lane 1). These marker proteins can be used to estimate the molecular weight of an unknown protein (lane 2). (b) A plot of log M, of the marker proteins versus relative migration during electrophoresis is linear, which allows the molecular weight of the unknown protein to be read from the graph.

**FIGURE 3-20** Isoelectric focusing. This technique separates proteins according to their isoelectric points. A stable pH gradient is established in the gel by the addition of appropriate ampholytes. A protein mixture is placed in a well on the gel. With an applied electric field, proteins enter the gel and migrate until each reaches a pH equivalent to its pI. Remember that when pH = pI, the net charge of a protein is zero.
Unseparated Proteins Can Be Quantified

To purify a protein, it is essential to have a way of detecting and quantifying that protein in the presence of many other proteins at each stage of the procedure. Often, purification must proceed in the absence of any information about the size and physical properties of the protein or about the fraction of the total protein mass it represents in the extract. For proteins that are enzymes, the amount in a given solution or tissue extract can be measured, or assayed, in terms of the catalytic effect the enzyme produces—that is, the increase in the rate at which its substrate is converted to reaction products when the enzyme is present. For this purpose one must know (1) the overall equation of the reaction catalyzed, (2) an analytical procedure for determining the disappearance of the substrate or the appearance of a reaction product, (3) whether the enzyme requires cofactors such as metal ions or coenzymes, (4) the dependence of the enzyme activity on substrate concentration, (5) the optimum pH, and (6) a temperature zone in which the enzyme is stable and has high activity. Enzymes are usually assayed at their optimum pH and at some convenient temperature within the range 25 to 38°C. Also, very high substrate concentrations are generally used so that the initial reaction rate, measured experimentally, is proportional to enzyme concentration (Chapter 6).

By international agreement, 1.0 unit of enzyme activity for most enzymes is defined as the amount of enzyme causing transformation of 1.0 μmol of substrate per minute at 25°C under optimal conditions of measurement (for some enzymes, this definition is inconvenient, and a unit may be defined differently). The term activity refers to the total units of enzyme in a solution. The specific activity is the number of enzyme units per milligram of total protein (Fig. 3–22). The specific activity is a measure of enzyme purity: it increases during purification of an enzyme and becomes maximal and constant when the enzyme is pure (Table 3–5, p. 88).

**FIGURE 3–21** Two-dimensional electrophoresis. (a) Proteins are first separated by isoelectric focusing in a cylindrical gel. The gel is then laid horizontally on a second, slab-shaped gel, and the proteins are separated by SDS polyacrylamide gel electrophoresis. Horizontal separation reflects differences in pI; vertical separation reflects differences in molecular weight. (b) More than 1,000 different proteins from E. coli can be resolved using this technique.

**FIGURE 3–22** Activity versus specific activity. The difference between these terms can be illustrated by considering two beakers of marbles. The beakers contain the same number of red marbles, but different numbers of marbles of other colors. If the marbles represent proteins, both beakers contain the same activity of the protein represented by the red marbles. The second beaker, however, has the higher specific activity because red marbles represent a higher fraction of the total.
After each purification step, the activity of the preparation (in units of enzyme activity) is assayed, the total amount of protein is determined independently, and the ratio of the two gives the specific activity. Activity and total protein generally decrease with each step. Activity decreases because there is always some loss due to inactivation or nonideal interactions with chromatographic materials or other molecules in the solution. Total protein decreases because the objective is to remove as much unwanted or nonspecific protein as possible. In a successful step, the loss of nonspecific protein is much greater than the loss of activity; therefore, specific activity increases even as total activity falls. The data are assembled in a purification table similar to Table 3-5. A protein is generally considered pure when further purification steps fail to increase specific activity and when only a single protein species can be detected (for example, by electrophoresis).

For proteins that are not enzymes, other quantification methods are required. Transport proteins can be assayed by their binding to the molecule they transport, and hormones and toxins by the biological effect they produce; for example, growth hormones will stimulate the growth of certain cultured cells. Some structural proteins represent such a large fraction of a tissue mass that they can be readily extracted and purified without a functional assay. The approaches are as varied as the proteins themselves.

**SUMMARY 3.3 Working with Proteins**

- Proteins are separated and purified on the basis of differences in their properties. Proteins can be selectively precipitated by the addition of certain salts. A wide range of chromatographic procedures makes use of differences in size, binding affinities, charge, and other properties. These include ion-exchange, size-exclusion, affinity, and high-performance liquid chromatography.

- Electrophoresis separates proteins on the basis of mass or charge. SDS gel electrophoresis and isoelectric focusing can be used separately or in combination for higher resolution.

- All purification procedures require a method for quantifying or assaying the protein of interest in the presence of other proteins. Purification can be monitored by assaying specific activity.

### 3.4 The Structure of Proteins: Primary Structure

Purification of a protein is usually only a prelude to a detailed biochemical dissection of its structure and function. What is it that makes one protein an enzyme, another a hormone, another a structural protein, and still another an antibody? How do they differ chemically? The most obvious distinctions are structural, and to protein structure we now turn.

For large macromolecules such as proteins, the tasks of describing and understanding structure are approached at several levels of complexity, arranged in a kind of conceptual hierarchy. Four levels of protein structure are commonly defined (Fig. 3-23). A description of all covalent bonds (mainly peptide bonds and disulfide bonds) linking amino acid residues in a polypeptide chain is its primary structure. The most important element of primary structure is the sequence of amino acid residues. Secondary structure refers to particularly stable arrangements of amino acid residues giving rise to recurring structural patterns. Tertiary structure describes all aspects of the three-dimensional folding of a polypeptide. When a protein has two or more polypeptide subunits, their arrangement in space is referred to as quaternary structure. Our exploration of proteins will eventually include complex protein machines consisting of dozens to thousands of subunits. Primary structure is the focus of the remainder of this chapter; the higher levels of structure are discussed in Chapter 4.

The differences in primary structure can be especially informative. Each protein has a distinctive number and sequence of amino acid residues. As we shall see in Chapter 4, the primary structure of a protein determines how it folds up into its unique three-dimensional structure, and this in turn determines the function of the protein. We first consider empirical clues that amino acid sequence and protein function are closely linked, then describe how...
The Function of a Protein Depends on Its Amino Acid Sequence

The bacterium *Escherichia coli* produces more than 3,000 different proteins; a human has ~25,000 genes encoding a much larger number of proteins (through genetic processes discussed in Part III of this text). In both cases, each type of protein has a unique three-dimensional structure and this structure confers a unique function. Each type of protein also has a unique amino acid sequence. Intuition suggests that the amino acid sequence must play a fundamental role in determining the three-dimensional structure of the protein, and ultimately its function, but is this supposition correct? A quick survey of proteins and how they vary in amino acid sequence provides some empirical clues that help substantiate the important relationship between amino acid sequence and biological function.

First, as we have already noted, proteins with different functions always have different amino acid sequences. Second, thousands of human genetic diseases have been traced to the production of defective proteins. The defect can range from a single change in the amino acid sequence (as in sickle cell anemia, described in Chapter 5) to deletion of a larger portion of the polypeptide chain (as in most cases of Duchenne muscular dystrophy: a large deletion in the gene encoding the protein dystrophin leads to production of a shortened, inactive protein). Thus we know that if the primary structure is altered, the function of the protein may also be changed. Finally, on comparing functionally similar proteins from different species, we find that these proteins often have similar amino acid sequences. An extreme case is ubiquitin, a 76-residue protein involved in regulating the degradation of other proteins. The amino acid sequence of ubiquitin is identical in species as disparate as fruit flies and humans.

Is the amino acid sequence absolutely fixed, or invariant, for a particular protein? No; some flexibility is possible. An estimated 20% to 30% of the proteins in humans are polymorphic, having amino acid sequence variants in the human population. Many of these variations in sequence have little or no effect on the function of the protein. Furthermore, proteins that carry out a broadly similar function in distantly related species can differ greatly in overall size and amino acid sequence.

Although the amino acid sequence in some regions of the primary structure might vary considerably without affecting biological function, most proteins contain crucial regions that are essential to their function and whose sequence is therefore conserved. The fraction of the overall sequence that is critical varies from protein to protein, complicating the task of relating sequence to three-dimensional structure, and structure to function. Before we can consider this problem further, however, we must examine how sequence information is obtained.

The Amino Acid Sequences of Millions of Proteins Have Been Determined

Two major discoveries in 1953 were of crucial importance in the history of biochemistry. In that year, James D. Watson and Francis Crick deduced the double-helical structure of DNA and proposed a structural basis for its precise replication (Chapter 8). Their proposal illuminated the molecular reality behind the idea of a gene. In the same year, Frederick Sanger worked out the sequence of amino acid residues in the polypeptide chains of the hormone insulin (Fig. 3–24), surprising...
many researchers who had long thought that determining the amino acid sequence of a polypeptide would be a hopelessly difficult task. It quickly became evident that the nucleotide sequence in DNA and the amino acid sequence in proteins were somehow related. Barely a decade after these discoveries, the genetic code relating the nucleotide sequence of DNA to the amino acid sequence of protein molecules was elucidated (Chapter 27). An enormous number of protein sequences can now be derived indirectly from the DNA sequences in the rapidly growing genome databases. However, modern protein chemistry still makes frequent use of traditional methods of polypeptide sequencing, which can reveal details not evident in the gene sequence, such as modifications that occur after proteins are synthesized. Chemical protein sequencing now complements the newer methods, providing multiple avenues to obtain amino acid sequence data. Such data are now critical to every area of biochemical investigation.

Short Polypeptides Are Sequenced with Automated Procedures

Various procedures are used to analyze protein primary structure. To start, biochemists have several strategies for labeling and identifying the amino-terminal amino acid residue (Fig. 3–25a). Sanger developed the reagent 1-fluoro-2,4-dinitrobenzene (FDNB) for this purpose; other available reagents are dansyl chloride and dabsyl chloride, which yield derivatives that are more easily detectable than the dinitrophenyl derivatives. After the amino-terminal residue is labeled with one of these reagents, the polypeptide is hydrolyzed (in

**Figure 3–25** Steps in sequencing a polypeptide. (a) Identification of the amino-terminal residue can be the first step in sequencing a polypeptide. Sanger’s method for identifying the amino-terminal residue is shown here. (b) The Edman degradation procedure reveals the entire sequence of a peptide. For shorter peptides, this method alone readily yields the entire sequence, and step (a) is often omitted. Step (a) is useful in the case of larger polypeptides, which are often fragmented into smaller peptides for sequencing (see Fig. 3–27).
6 M HCl) to its constituent amino acids and the labeled amino acid is identified. Because the hydrolysis stage destroys the polypeptide, this procedure cannot be used to sequence a polypeptide beyond its amino-terminal residue. However, it can help determine the number of chemically distinct polypeptides in a protein, provided each has a different amino-terminal residue. For example, two residues—Phe and Gly—would be labeled if insulin (Fig. 3–24) were subjected to this procedure.

Then cleaved in a step carried out in anhydrous trifluoroacetic acid sequence can be determined starting with only a few micrograms of protein.

Enzymes called proteases catalyze the hydrolytic cleavage of peptide bonds. Some proteases cleave only the peptide bond adjacent to particular amino acid residues (Table 3–7) and thus fragment a polypeptide chain in a predictable and reproducible way. A number of chemical reagents also cleave the peptide bond adjacent to specific residues.
Disulfide bond (cystine)

\[
\begin{align*}
\text{NH} & \quad \text{O} : \quad \text{C} \\
\text{HC} - \text{CH}_2 & \quad \text{S} - \text{S} - \text{CH}_2 & \quad \text{CH} \\
\text{rl} & \quad \text{rl} & \quad \text{rl} & \quad \text{rl}
\end{align*}
\]

Reduction by dithiothreitol or \( \beta \)-mercaptoethanol to form Cys residues must be followed by further modification of the reactive \(-\text{SH}\) groups to prevent re-formation of the disulfide bond. Acetylation by iodoacetate serves this purpose.

**FIGURE 3-26** Breaking disulfide bonds in proteins. Two common methods are illustrated. Oxidation of a cystine residue with performic acid produces two cysteic acid residues. Reduction by dithiothreitol or \( \beta \)-mercaptoethanol to form Cys residues must be followed by further modification of the reactive \(-\text{SH}\) groups to prevent re-formation of the disulfide bond. Acetylation by iodoacetate serves this purpose.

†Residues furnishing the primary recognition point for the protease or reagent; peptide bond cleavage occurs on either the carbonyl (C) or the amino (N) side of the indicated amino acid residues.

Among proteases, the digestive enzyme trypsin catalyzes the hydrolysis of only those peptide bonds in which the carbonyl group is contributed by either a Lys or an Arg residue, regardless of the length or amino acid sequence of the chain. The number of smaller peptides produced by trypsin cleavage can thus be predicted from the total number of Lys or Arg residues in the original polypeptide, as determined by hydrolysis of an intact sample (Fig. 3-27). A polypeptide with three Lys and/or Arg residues (as in Fig. 3-27) will usually yield four smaller peptides on cleavage with trypsin. Moreover, all except one of these will have a carboxyl-terminal Lys or Arg. The fragments produced by trypsin (or other enzyme or chemical) action are then separated by chromatographic or electrophoretic methods.

**Sequencing the Peptides** Each peptide fragment resulting from the action of trypsin is sequenced separately by the Edman procedure.

**Ordering the Peptide Fragments** The order of the "trypsin fragments" in the original polypeptide chain must now be determined. Another sample of the intact polypeptide is cleaved into fragments using a different...
enzyme or reagent, one that cleaves peptide bonds at points other than those cleaved by trypsin. For example, cyanogen bromide cleaves only those peptide bonds in which the carbonyl group is contributed by Met. The fragments resulting from this second procedure are then separated and sequenced as before.

The amino acid sequences of each fragment obtained by the two cleavage procedures are examined, with the objective of finding peptides from the second procedure whose sequences establish continuity, because of overlaps, between the fragments obtained by the first cleavage procedure (Fig. 3-27). Overlapping peptides obtained from the second fragmentation yield the correct order of the peptide fragments produced in the first. If the amino-terminal amino acid has been identified before the original cleavage of the protein, this information can be used to establish which fragment is derived from the amino terminus. The two sets of fragments can be compared for possible errors in determining the amino acid sequence of each fragment. If the second cleavage procedure fails to establish continuity between all peptides from the first cleavage, a third or even a fourth cleavage method must be used to obtain a set of peptides that can provide the necessary overlap(s).

**Locating Disulfide Bonds** If the primary structure includes disulfide bonds, their locations are determined in an additional step after sequencing is completed. A sample of the protein is again cleaved with a reagent

![Diagram showing the process of cleaving proteins, sequencing, and ordering peptide fragments.](image)

**Figure 3-27** Cleaving proteins and sequencing and ordering the peptide fragments. First, the amino acid composition and amino-terminal residue of an intact sample are determined. Then any disulfide bonds are broken before fragmenting so that sequencing can proceed efficiently. In this example, there are only two Cys (C) residues and thus only one possibility for location of the disulfide bond. In polypeptides with three or more Cys residues, the position of disulfide bonds can be determined as described in the text. (The one-letter symbols for amino acids are given in Table 3-1.)
such as trypsin, this time without first breaking the
disulfide bond. The resulting peptides are separated by
electrophoresis and compared with the original set of
peptides generated by trypsin. For each disulfide bond,
two of the original peptides will be missing and a new,
larger peptide will appear. The two missing peptides
represent the regions of the intact polypeptide that are
linked by the disulfide bond.

**Amino Acid Sequences Can Also Be Deduced by
Other Methods**

The approach outlined above is not the only way to
determine amino acid sequences. New methods based on
mass spectrometry permit the sequencing of short
polypeptides (20 to 30 amino acid residues) in just a few
minutes (Box 3–2). In addition, with the development of
rapid DNA sequencing methods (Chapter 8), the elucidation
of the genetic code (Chapter 27), and the develop-
ment of techniques for isolating genes (Chapter 9),
researchers can deduce the sequence of a polypeptide by
determining the sequence of nucleotides in the gene that
codes for it (Fig. 3–28). The techniques used to deter-
mine protein and DNA sequences are complementary.

---

**BOX 3–2 METHODS Investigating Proteins with Mass Spectrometry**

The mass spectrometer has long been an indispensable
tool in chemistry. Molecules to be analyzed, referred to as
**analytes**, are first ionized in a vacuum. When the newly
charged molecules are introduced into an electric and/or
magnetic field, their paths through the field are a function
of their mass-to-charge ratio, $m/z$. This measured prop-
erty of the ionized species can be used to deduce the
mass ($M$) of the analyte with very high precision.

Although mass spectrometry has been in use for
many years, it could not be applied to macromolecules
such as proteins and nucleic acids. The $m/z$ measure-
ments are made on molecules in the gas phase, and the
heating or other treatment needed to transfer a macro-
molecule to the gas phase usually caused its rapid de-
composition. In 1988, two different techniques were
developed to overcome this problem. In one, proteins
are placed in a light-absorbing matrix. With a short pulse
of laser light, the proteins are ionized and then desorbed
from the matrix into the vacuum system. This process,
known as **matrix-assisted laser desorption/ioniza-
tion mass spectrometry**, or MALDI MS. Protons added during pas-
 sage through the needle give additional charge to the
macromolecule. The $m/z$ of the molecule can be ana-
lyzed in the vacuum chamber.

Mass spectrometry provides a wealth of information
for proteomics research, enzymology, and protein chem-
istry in general. The techniques require only miniscule
amounts of sample, so they can be readily applied to the
small amounts of protein that can be extracted from a
two-dimensional electrophoretic gel. The accurately
measured molecular mass of a protein is one of the crit-
ical parameters in its identification. Once the mass of a
protein is accurately known, mass spectrometry is a
convenient and accurate method for detecting changes
in mass due to the presence of bound cofactors, bound
metal ions, covalent modifications, and so on.

The process for determining the molecular mass of
a protein with ESI MS is illustrated in Figure 1. As it is
injected into the gas phase, a protein acquires a variable
number of protons, and thus positive charges, from the
solvent. This creates a spectrum of species with differ-
ent mass-to-charge ratios. Each successive peak corre-
sponds to a species that differs from that of its
neighboring peak by a charge difference of 1 and a mass
difference of 1 (1 proton). The mass of the protein can be
determined from any two neighboring peaks.
The measured $m/z$ of one peak is

$$(m/z)_2 = \frac{M + n_2X}{n_2}$$

where $M$ is the mass of the protein, $n_2$ is the number of charges, and $X$ is the mass of the added groups (protons in this case). Similarly for the neighboring peak,

$$(m/z)_1 = \frac{M + (n_2 + 1)X}{n_2 + 1}$$

We now have two unknowns ($M$ and $n_2$) and two equations. We can solve first for $n_2$ and then for $M$:

$$n_2 = \frac{(m/z)_2 - X}{(m/z)_2 - (m/z)_1}$$

$$M = n_2[(m/z)_2 - X]$$

This calculation using the $m/z$ values for any two peaks in a spectrum such as that shown in Figure 1b usually provides the mass of the protein (in this case, aerolysin k; 47,342 Da) with an error of only ±0.01%. Generating several sets of peaks, repeating the calculation, and averaging the results generally provides an even more accurate value for $M$. Computer algorithms can transform the $m/z$ spectrum into a single peak that also provides a very accurate mass measurement (Fig. 1b, inset).

Mass spectrometry can also be used to sequence short stretches of polypeptide, an application that has emerged as an invaluable tool for quickly identifying unknown proteins. Sequence information is extracted using a technique called tandem MS, or MS/MS. A solution containing the protein under investigation is first treated with a protease or chemical reagent to hydrolyze it to a mixture of shorter peptides. The mixture is then injected into a device that is essentially two mass spectrometers in tandem (Fig. 2a, top). In the first, the peptide mixture is sorted and the ionized fragments are manipulated so that only one of the several types of peptides produced by cleavage emerges at the other end. The sample of the selected peptide, each molecule of which has a charge somewhere along its length, then travels through a vacuum chamber between the two mass spectrometers. In this collision cell, the peptide is further fragmented by high-energy impact with a "collision gas," a small amount of a noble gas such as helium or argon that is bled into the vacuum chamber. This procedure is designed to fragment many of the peptide molecules in the sample, with each individual peptide broken in only one place, on average. Most breaks occur at peptide bonds. This fragmentation does not involve the addition of water (it is done in a near-vacuum), so the products may include molecular ion radicals such as carbonyl radicals (Fig. 2a, bottom). The charge on the original peptide is retained on one of the fragments generated from it.

The second mass spectrometer then measures the $m/z$ ratios of all the charged fragments (uncharged fragments are not detected). This generates one or more sets of peaks. A given set of peaks (Fig. 2b) consists of all the charged fragments that were generated by breaking the same type of bond (but at different points in the peptide) and are derived from the same side of the bond breakage, either the carboxyl- or amino-terminal side. Each successive peak in a given set has one less amino acid than the peak before. The difference in mass from peak to peak identifies the amino acid that was lost in each case, thus revealing the sequence of the peptide. The only ambiguities involve leucine and isoleucine, which have the same mass.

(continued on next page)
The charge on the peptide can be retained on either the carboxyl- or amino-terminal fragment, and bonds other than the peptide bond can be broken in the fragmentation process, with the result that multiple sets of peaks are usually generated. The two most prominent sets generally consist of charged fragments derived from breakage of the peptide bonds. The set consisting of the carboxyl-terminal fragments can be unambiguously distinguished from that consisting of the amino-terminal fragments. Because the bond breaks generated between the spectrometers (in the collision cell) do not yield full carboxyl and amino groups at the sites of the breaks, the only intact α-amino and α-carboxyl groups on the peptide fragments are those at the very ends (Fig. 2a). The two sets of fragments can thereby be identified by the resulting slight differences in mass. The amino acid sequence derived from one set can be confirmed by the other, improving the confidence in the sequence information obtained.

Even a short sequence is often enough to permit unambiguous association of a protein with its gene, if the gene sequence is known. Sequencing by mass spectrometry cannot replace the Edman degradation procedure for the sequencing of long polypeptides, but it is ideal for proteomics research aimed at cataloging the hundreds of cellular proteins that might be separated on a two-dimensional gel.

Small Peptides and Proteins Can Be Chemically Synthesized

Many peptides are potentially useful as pharmacologic agents, and their production is of considerable commercial importance. There are three ways to obtain a peptide: (1) purification from tissue, a task often made difficult by the vanishingly low concentrations of some peptides; (2) genetic engineering (Chapter 9); or (3) direct chemical synthesis. Powerful techniques now make direct chemical synthesis an attractive option in many cases. In addition to commercial applications, the synthesis of specific peptide portions of larger proteins is an increasingly important tool for the study of protein structure and function.

The complexity of proteins makes the traditional synthetic approaches of organic chemistry impractical for peptides with more than four or five amino acid...
residues. One problem is the difficulty of purifying the product after each step. 

The major breakthrough in this technology was provided by R. Bruce Merrifield in 1962. His innovation involved synthesizing a peptide while keeping it attached at one end to a solid support. The support is an insoluble polymer (resin) contained within a column, similar to that used for chromatographic procedures. The peptide is built up on this support one amino acid at a time, through a standard set of reactions in a repeating cycle (Fig. 3-29). At each successive step in the cycle, protective chemical groups block unwanted reactions.

The technology for chemical peptide synthesis is now automated. As in the sequencing reactions considered

**FIGURE 3-29 Chemical synthesis of a peptide on an insoluble polymer support.** Reactions \( \text{1 through 4} \) are necessary for the formation of each peptide bond. The 9-fluorenylmethoxycarbonyl (Fmoc) group (shaded blue) prevents unwanted reactions at the \( \alpha \)-amino group of the residue (shaded red). Chemical synthesis proceeds from the carboxyl terminus to the amino terminus, the reverse of the direction of protein synthesis in vivo (Chapter 27).

Amino Acid Sequences Provide Important Biochemical Information

Knowledge of the sequence of amino acids in a protein can offer insights into its three-dimensional structure and its function, cellular location, and evolution. Most of these insights are derived by searching for similarities between a protein of interest and previously studied proteins. Thousands of sequences are known and available in databases accessible through the Internet. A comparison of a newly obtained sequence with this large bank of stored sequences often reveals relationships both surprising and enlightening.

Key Convention: Much of the functional information encapsulated in protein sequences comes in the form of consensus sequences. This term is applied to such sequences in DNA, RNA, or protein. When a series of related nucleic acid or protein sequences are compared, a consensus sequence is the one that reflects the most common base or amino acid at each position. Parts of the sequence that have particularly good agreement often represent evolutionarily conserved functional domains. A range of mathematical tools available on the Internet can be used to generate consensus sequences, or identify them in sequence databases. Box 3-3 illustrates common conventions for displaying consensus sequences.

Protein Sequences Can Elucidate the History of Life on Earth

The simple string of letters denoting the amino acid sequence of a protein belies the wealth of information this sequence holds. As more protein sequences become available, the development of more powerful methods for extracting information from them has become a major biochemical enterprise. Analysis of the information available in the many, ever-expanding biological databases, including gene and protein sequences.
Consensus sequences can be represented in several ways. To illustrate two types of conventions, we use two examples of consensus sequences, shown in Figure 1: (a) an ATP-binding structure called a P loop (see Box 12-2) and (b) a Ca$_{2+}$-binding structure called an EF hand (see Fig. 12-11). The rules described here are adapted from those used by the sequence comparison website PROSITE (expasy.org/prosite); they use the standard one-letter codes for the amino acids.

![Sequence logos](image)

**FIGURE 1** Representations of two consensus sequences. (a) P loop, an ATP-binding structure; (b) EF hand, a Ca$_{2+}$-binding structure.

In one type of consensus sequence designation (shown at the top of (a) and (b)), each position is separated from its neighbor by a hyphen. A position where any amino acid is allowed is designated x. Ambiguities are indicated by listing the acceptable amino acids for a given position between square brackets. For example, in (a) [AG] means Ala or Gly. If all but a few amino acids are allowed at one position, the amino acids that are not allowed are listed between curly brackets. For example, in (b) [W] means any amino acid except Trp. Repetition of an element of the pattern is indicated by following that element with a number or range of numbers between parentheses. In (a), for example, x(4) means x-x-x-x, and x(2,4) means x-x, or x-x-x, or x-x-x-x. When a pattern is restricted to either the amino or carboxyl terminus of a sequence, that pattern starts with < or ends with >, respectively (not so for either example here). A period ends the pattern. Applying these rules to the consensus sequence in (a), either A or G can be found at the first position. Any amino acid can occupy the next four positions, followed by an invariant G and an invariant K. The last position is either S or T.

Sequence logos provide a more informative and graphic representation of an amino acid (or nucleic acid) multiple sequence alignment. Each logo consists of a stack of symbols for each position in the sequence. The overall height of the stack (in bits) indicates the degree of sequence conservation at that position, while the height of each symbol in the stack indicates the relative frequency of that amino acid (or nucleotide). For amino acid sequences, the colors denote the characteristics of the amino acid: polar (G, S, T, Y, C, Q, N) green; basic (K, R, H) blue; acidic (D, E) red; and hydrophobic (A, V, L, I, P, W, F, M) black. The classification of amino acids in this scheme is somewhat different from that in Table 3-1 and Figure 3-5. The amino acids with aromatic side chains are subsumed into the nonpolar (F, W) and polar (Y) classifications. Glycine, always hard to group, is assigned to the polar group. Note that when multiple amino acids are acceptable at a particular position, they rarely occur with equal probability. One or a few usually predominate. The logo representation makes the predominance clear, and a conserved sequence in a protein is made obvious. However, the logo obscures some amino acid residues that may be allowed at a position, such as the Cys that occasionally occurs at position 8 of the EF hand in (b).

The field of molecular evolution is often traced to Emile Zuckerkandl and Linus Pauling, whose work in the mid-1960s advanced the use of nucleotide and protein sequences to explore evolution. The premise is deceptively straightforward. If two organisms are closely related, the sequences of their genes and proteins should be similar. The sequences increasingly diverge as the evolutionary distance between two organisms increases. The promise of this approach began to be realized in the 1970s, when Carl Woese used ribosomal RNA sequences to define the Archaea as a group of living organisms distinct from the Bacteria and Eukarya (see Fig. 1-4). Protein sequences offer an opportunity to greatly refine the available information. With the advent of genome projects investigating organisms from bacteria to humans, the number of available sequences is growing at an enormous rate. This information can be
Evolution has not taken a simple linear path. Complexities abound in any attempt to mine the evolutionary information stored in protein sequences. For a given protein, the amino acid residues essential for the activity of the protein are conserved over evolutionary time. The residues that are less important to function may vary over time—that is, one amino acid may substitute for another—and these variable residues can provide the information to trace evolution. Amino acid substitutions are not always random, however. At some positions in the primary structure, the need to maintain protein function may mean that only particular amino acid substitutions can be tolerated. Some proteins have more variable amino acid residues than others. For these and other reasons, different proteins can evolve at different rates.

Another complicating factor in tracing evolutionary history is the rare transfer of a gene or group of genes from one organism to another, a process called lateral gene transfer. The transferred genes may be quite similar to the genes they were derived from in the original organism, whereas most other genes in the same two organisms may be quite distantly related. An example of lateral gene transfer is the recent rapid spread of antibiotic-resistance genes in bacterial populations. The proteins derived from these transferred genes would not be good candidates for the study of bacterial evolution, because they share only a very limited evolutionary history with their "host" organisms.

The study of molecular evolution generally focuses on families of closely related proteins. In most cases, the families chosen for analysis have essential functions in cellular metabolism that must have been present in the earliest viable cells, thus greatly reducing the chance that they were introduced relatively recently by lateral gene transfer. For example, a protein called EF-1α (elongation factor 1α) is involved in the synthesis of proteins in all eukaryotes. A similar protein, EF-Tu, with the same function, is found in bacteria. Similarities in sequence and function indicate that EF-1α and EF-Tu are members of a family of proteins that share a common ancestor. The members of protein families are called homologous proteins, or homologs. The concept of a homolog can be further refined. If two proteins in a family (that is, two homologs) are present in the same species, they are referred to as paralogs. Homologs from different species are called orthologs. The process of tracing evolution involves first identifying suitable families of homologous proteins and then using them to reconstruct evolutionary paths.

Homologs are identified through the use of increasingly powerful computer programs that can directly compare two or more chosen protein sequences, or can search vast databases to find the evolutionary relatives of one selected protein sequence. The electronic search process can be thought of as sliding one sequence past the other until a section with a good match is found. Within this sequence alignment, a positive score is assigned for each position where the amino acid residues in the two sequences are identical—the value of the score varying from one program to the next—to provide a measure of the quality of the alignment. The process has some complications. Sometimes the proteins being compared match well at, say, two sequence segments, and these segments are connected by less related sequences of different lengths. Thus the two matching segments cannot be aligned at the same time. To handle this, the computer program introduces "gaps" in one of the sequences to bring the matching segments into register (Fig. 3-30). Of course, if a sufficient number of gaps are introduced, almost any two sequences could be brought into some sort of alignment. To avoid uninformative alignments, the programs include penalties for each gap introduced, thus lowering the overall alignment score. With electronic trial and error, the program selects the alignment with the optimal score that maximizes identical amino acid residues while minimizing the introduction of gaps.

Identical amino acids are often inadequate to identify related proteins or, more importantly, to determine how closely related the proteins are on an evolutionary time scale. A more useful analysis includes a consideration of the chemical properties of substituted amino acids. When amino acid substitutions are found within a protein family, many of the differences may be conservative—that is, an amino acid residue is replaced by a residue having similar chemical properties. For example, a Glu residue may substitute in one family member for the Asp residue found in another; both amino acids are negatively charged. Such a conservative substitution should logically garner a higher score in a sequence alignment than does a nonconservative substitution, such as the replacement of the Asp residue with a hydrophobic Phe residue.

For most efforts to find homologies and explore evolutionary relationships, protein sequences (derived either

---

**FIGURE 3–30** Aligning protein sequences with the use of gaps. Shown here is the sequence alignment of a short section of the Hsp70 proteins (a widespread class of protein-folding chaperones) from two well-studied bacterial species, *E. coli* and *Bacillus subtilis*. Introduction of a gap in the *B. subtilis* sequence allows a better alignment of amino acid residues on either side of the gap. Identical amino acid residues are shaded.
more, and the probability of chance alignment of unre-

directly from protein sequencing or from the sequencing of the DNA encoding the protein) are superior to nongenic nucleic acid sequences (those that do not encode a protein or functional RNA). For a nucleic acid, with its four different types of residues, random alignment of nonhomologous sequences will generally yield matches for at least 25% of the positions. Introduction of a few gaps can often increase the fraction of matched residues to 40% or more, and the probability of chance alignment of unrelated sequences becomes quite high. The 20 different amino acid residues in proteins greatly lower the probability of uninformative chance alignments of this type.

The programs used to generate a sequence alignment are complemented by methods that test the reliability of the alignments. A common computerized test is to shuffle the amino acid sequence of one of the proteins being compared to produce a random sequence, then to instruct the program to align the shuffled sequence with the other, unshuffled one. Scores are assigned to the new alignment, and the shuffling and alignment process is repeated many times. The original alignment, before shuffling, should have a score significantly higher than any of those within the distribution of scores generated by the random alignments; this increases the confidence that the sequence alignment has identified a pair of homologs. Note that the absence of a significant alignment score does not necessarily mean that no evolutionary relationship exists between two proteins. As we shall see in Chapter 4, three-dimensional structural similarities sometimes reveal evolutionary relationships where sequence homology has been wiped away by time.

Use of a protein family to explore evolution requires the identification of family members with similar molecular functions in the widest possible range of organisms. Information from the family can then be used to trace the evolution of those organisms. By analyzing the sequence divergence in selected protein families, investigators can segregate organisms into classes based on their evolutionary relationships. This information must be reconciled with more classical examinations of the physiology and biochemistry of the organisms.

Certain segments of a protein sequence may be found in the organisms of one taxonomic group but not in other groups; these segments can be used as signature sequences for the group in which they are found. An example of a signature sequence is an insertion of 12 amino acids near the amino terminus of the EF-1α/EF-Tu proteins in all archaea and eukaryotes but not in bacteria (Fig. 3–31). This particular signature is one of many biochemical clues that can help establish the evolutionary relatedness of eukaryotes and archaea. Other signature sequences allow the establishment of evolutionary relationships among groups of organisms at many different taxonomic levels.

By considering the entire sequence of a protein, researchers can now construct more elaborate evolutionary trees with many species in each taxonomic group. Figure 3–32 presents one such tree for bacteria, based on sequence divergence in the protein GroEL (a protein present in all bacteria that assists in the proper folding of proteins). The tree can be refined by basing it on the sequences of multiple proteins and by supplementing the sequence information with data on the unique biochemical and physiological properties of each species. There are many methods for generating trees, each method with its own advantages and shortcomings, and many ways to represent the resulting evolutionary relationships. In Figure 3–32, the free end points of lines are called “external nodes”; each represents an extant species, and each is so labeled. The points where two lines come together, the “internal nodes,” represent extinct ancestor species. In most representations (including Fig. 3–32), the lengths of the lines connecting the nodes are proportional to the number of amino acid substitutions separating one species from another. If we trace two extant species to a common internal node (representing the common ancestor of the two species), the length of the branch connecting each external node to the internal node represents the number of amino acid substitutions separating one extant species from this ancestor. The sum of the lengths of all the line segments that connect an extant species to another extant species through a common ancestor reflects the number of substitutions separating the two extant species. To determine how much time was needed for the various species to diverge, the tree must be calibrated by comparing it with information from the fossil record and other sources.
FIGURE 3-32 Evolutionary tree derived from amino acid sequence comparisons. A bacterial evolutionary tree, based on the sequence di-

As more sequence information is made available in databases, we can generate evolutionary trees based on multiple proteins. And we can refine these trees as additional genomic information emerges from increasingly sophisticated methods of analysis. All of this work moves us toward the goal of creating a detailed tree of life that describes the evolution and relationship of every organism on Earth. The story is a work in progress, of course (Fig. 3-33). The questions being asked and answered are fundamental to how humans view themselves and the world around them. The field of molecular evolution promises to be among the most vibrant of the scientific frontiers in the twenty-first century.

FIGURE 3-33 A consensus tree of life. The tree shown here is based on analyses of many different protein sequences and additional genomic features. Branches shown as dashed lines remain under investigation. The tree presents only a fraction of the available information, as well as only a fraction of the issues remaining to be resolved. Each extant group shown is a complex evolutionary story unto itself.
SUMMARY 3.4  The Structure of Proteins: Primary Structure

- Differences in protein function result from differences in amino acid composition and sequence. Some variations in sequence are possible for a particular protein, with little or no effect on function.

- Amino acid sequences are deduced by fragmenting polypeptides into smaller peptides with reagents known to cleave specific peptide bonds; determining the amino acid sequence of each fragment by the automated Edman degradation procedure; then ordering the peptide fragments by finding sequence overlaps between fragments generated by different reagents. A protein sequence can also be deduced from the nucleotide sequence of its corresponding gene in DNA.

- Short proteins and peptides (up to about 100 residues) can be chemically synthesized. The peptide is built up, one amino acid residue at a time, while tethered to a solid support.

- Protein sequences are a rich source of information about protein structure and function, as well as the evolution of life on Earth. Sophisticated methods are being developed to trace evolution by analyzing the resultant slow changes in amino acid sequences of homologous proteins.

Problems

1. Absolute Configuration of Citrulline The citrulline isolated from watermelons has the structure shown below. Is it a D- or L-amino acid? Explain.

   \[
   \begin{align*}
   &\text{CH}_2(\text{CH}_2)_2\text{NH}^+ \quad \text{NH}_2^-
   &\text{H}^+ \quad \text{C}^+ \quad \text{NH}_2^-
   &\text{COO}^-
   \end{align*}
   \]

2. Relationship between the Titration Curve and the Acid-Base Properties of Glycine. A 100 mL solution of 0.1 M glycine at pH 1.72 was titrated with 2 M NaOH solution. The pH was monitored and the results were plotted as shown in the following graph. The key points in the titration are designated I to V. For each of the statements (a) to (o), identify the appropriate key point in the titration and justify your choice.

   (a) Glycine is present predominantly as the species \( \text{H}_2\text{N}^-\text{CH}_2\text{CH}_2\text{COO}^- \).
   (b) The average net charge of glycine is \( +\frac{1}{2} \).
   (c) Half of the amino groups are ionized.
   (d) The pH is equal to the pK_a of the carboxyl group.
   (e) The pH is equal to the pK_a of the protonated amino group.
   (f) Glycine has its maximum buffering capacity.
   (g) The average net charge of glycine is zero.
   (h) The carboxyl group has been completely titrated (first equivalence point).
   (i) Glycine is completely titrated (second equivalence point).
   (j) The predominant species is \( \text{H}_2\text{N}^-\text{CH}_2\text{CH}_2\text{COOH}^- \).
   (k) The average net charge of glycine is \( -1 \).
   (l) Glycine is present predominantly as a 50:50 mixture of \( \text{H}_2\text{N}^-\text{CH}_2\text{CH}_2\text{COOH}^- \) and \( \text{H}_2\text{N}^-\text{CH}_2\text{CH}_2\text{COO}^- \).
   (m) This is the isoelectric point.
   (n) This is the end of the titration.
   (o) These are the worst pH regions for buffering power.

3. How Much Alanine Is Present as the Completely Uncharged Species? At a pH equal to the isoelectric point of alanine, the net charge on alanine is zero. Two structures can be drawn that have a net charge of zero, but the predominant form of alanine at its pI is zwitterionic.

   \[
   \begin{align*}
   &\text{H}_2\text{N}^-\text{C}^+\text{H}_2\text{C}^-\text{O}^-
   &\text{H}_2\text{N}^-\text{C}^+\text{H}_2\text{C}^-\text{OH}^-
   \end{align*}
   \]

   (a) Why is alanine predominantly zwitterionic rather than completely uncharged at its pI?
   (b) What fraction of alanine is in the completely uncharged form at its pI? Justify your assumptions.

4. Ionization State of Histidine Each ionizable group of an amino acid can exist in one of two states, charged or neutral. The electric charge on the functional group is determined by the relationship between its pK_a and the pH of the solution. This relationship is described by the Henderson-Hasselbalch equation.

   (a) Histidine has three ionizable functional groups. Write the equilibrium equations for its three ionizations and assign the proper pK_a for each ionization. Draw the structure of histidine in each ionization state. What is the net charge on the histidine molecule in each ionization state?
   (b) Draw the structures of the predominant ionization state of histidine at pH 1, 4, 8, and 12. Note that the ionization state can be approximated by treating each ionizable group independently.
(c) What is the net charge of histidine at pH 1, 4, 8, and 12? For each pH, will histidine migrate toward the anode (+) or cathode (−) when placed in an electric field?

5. Separation of Amino Acids by Ion-Exchange Chromatography Mixtures of amino acids can be analyzed by first separating the mixture into its components through ion-exchange chromatography. Amino acids placed on a cation-exchange resin (see Fig. 3-17a) containing sulfonate (−SO₄²⁻) groups flow down the column at different rates because of two factors that influence their movement: (1) ionic attraction between the sulfonate residues on the column and positively charged functional groups on the amino acids, and (2) hydrophobic interactions between amino acid side chains and the strongly hydrophobic backbone of the polystyrene resin. For each pair of amino acids listed, determine which will be eluted first from the cation-exchange column by a pH 7.0 buffer.

(a) Asp and Lys
(b) Arg and Met
(c) Glu and Val
(d) Gly and Leu
(e) Ser and Ala

6. Naming the Stereoisomers of Isoleucine The structure of the amino acid isoleucine is

![Isoleucine Structure](image)

(a) How many chiral centers does it have?
(b) How many optical isomers?
(c) Draw perspective formulas for all the optical isomers of isoleucine.

7. Comparing the pKᵣ Values of Alanine and Polyalanine The titration curve of alanine shows the ionization of two functional groups with pKᵣ values of 2.34 and 9.69, corresponding to the ionization of the carboxyl and the protonated amino groups, respectively. The titration of di-, tri-, and larger oligopeptides of alanine also shows the ionization of only two functional groups, although the experimental pKᵣ values are different. The trend in pKᵣ values is summarized in the table.

<table>
<thead>
<tr>
<th>Amino acid or peptide</th>

<td>3.42</td>
<td>7.94</td>
</tr>
</tbody>
</table>

(a) Draw the structure of Ala–Ala–Ala. Identify the functional groups associated with pKᵣ₁ and pKᵣ₂.
(b) Why does the value of pKᵣ₁ increase with each additional Ala residue in the oligopeptide?
(c) Why does the value of pKᵣ₂ decrease with each additional Ala residue in the oligopeptide?

8. The Size of Proteins What is the approximate molecular weight of a protein with 682 amino acid residues in a single polypeptide chain?

9. The Number of Tryptophan Residues in Bovine Serum Albumin A quantitative amino acid analysis reveals that bovine serum albumin (BSA) contains 0.58% tryptophan (M, 204) by weight.

(a) Calculate the minimum molecular weight of BSA (i.e., assume there is only one Trp residue per protein molecule).
(b) Gel filtration of BSA gives a molecular weight estimate of 70,000. How many Trp residues are present in a molecule of serum albumin?

10. Subunit Composition of a Protein A protein has a molecular mass of 400 kDa when measured by gel filtration. When subjected to gel electrophoresis in the presence of sodium dodecyl sulfate (SDS), the protein gives three bands with molecular masses of 180, 160, and 60 kDa. When electrophoresis is carried out in the presence of SDS and dithiothreitol, three bands are again formed, this time with molecular masses of 160, 90, and 60 kDa. Determine the subunit composition of the protein.

11. Net Electric Charge of Peptides A peptide has the sequence

(a) What is the net charge of the molecule at pH 3, 8, and 11? (Use pKᵣ values for side chains and terminal amino and carboxyl groups as given in Table 3–1.)
(b) Estimate the pI for this peptide.

12. Isoelectric Point of Pepsin Pepsin is the name given to a mix of several digestive enzymes secreted (as larger precursor proteins) by glands that line the stomach. These glands also secrete hydrochloric acid, which dissolves the particulate matter in food, allowing pepsin to enzymatically cleave individual protein molecules. The resulting mixture of food, HCl, and digestive enzymes is known as chyme and has a pH near 1.5. What pI would you predict for the pepsin proteins? What functional groups must be present to confer this pI on pepsin? Which amino acids in the proteins would contribute such groups?

13. The Isoelectric Point of Histones Histones are proteins found in eukaryotic cell nuclei, tightly bound to DNA, which has many phosphate groups. The pI of histones is very high, about 10.8. What amino acid residues must be present in relatively large numbers in histones? In what way do these residues contribute to the strong binding of histones to DNA?

14. Solubility of Polypeptides One method for separating polypeptides makes use of their different solubilities. The solubility of large polypeptides in water depends on the relative polarity of their R groups, particularly on the number of ionized groups: the more ionized groups there are, the more soluble the polypeptide. Which of each pair of the polypeptides that follow is more soluble at the indicated pH?

(a) (Gly)₂₀ or (Glu)₂₀ at pH 7.0
(b) (Lys–Ala)₃ or (Phe–Met)₃ at pH 7.0
(c) (Ala–Ser–Gly)₅ or (Asn–Ser–His)₅ at pH 6.0
(d) (Ala–Asp–Gly)₅ or (Asn–Ser–His)₅ at pH 3.0
15. Purification of an Enzyme  A biochemist discovers and purifies a new enzyme, generating the purification table below.

(a) From the information given in the table, calculate the specific activity of the enzyme after each purification procedure.
(b) Which of the purification procedures used for this enzyme is most effective (i.e., gives the greatest relative increase in purity)?
(c) Which of the purification procedures is least effective?
(d) Is there any indication based on the results shown in the table that the enzyme after step 6 is now pure? What else could be done to estimate the purity of the enzyme preparation?

16. Dialysis. A purified protein is in a Hepes (N-(2-hydroxyethyl)piperazine-N'-(2-ethanesulfonic acid)) buffer at pH 7 with 500 mM NaCl. A sample (1 mL) of the protein solution is placed in a tube made of dialysis membrane and dialyzed against 1 L of the same Hepes buffer with 0 mM NaCl. Small molecules and ions (such as Na⁺, Cl⁻, and Hepes) can diffuse across the dialysis membrane, but the protein cannot.

(a) Once the dialysis has come to equilibrium, what is the concentration of NaCl in the protein sample? Assume no volume changes occur in the sample during the dialysis.
(b) If the original 1 mL sample were dialyzed twice, successively, against 100 mL of the same Hepes buffer with 0 mM NaCl, what would be the final NaCl concentration in the sample?

17. Peptide Purification  At pH 7.0, in what order would the following three peptides be eluted from a column filled with a cation-exchange polymer? Their amino acid compositions are:

- **Protein A**: Ala 10%, Glu 5%, Ser 5%, Leu 10%, Arg 10%, His 5%, Ile 10%, Phe 5%, Tyr 5%, Lys 10%, Gly 10%, Pro 5%, and Trp 10%.
- **Protein B**: Ala 5%, Val 5%, Gly 10%, Asp 5%, Leu 5%, Arg 5%, Ile 5%, Phe 5%, Tyr 5%, Lys 5%, Trp 5%, Ser 5%, Thr 5%, Glu 5%, Asn 5%, Pro 10%, Met 5%, and Cys 5%.
- **Protein C**: Ala 10%, Glu 10%, Gly 5%, Leu 5%, Asp 10%, Arg 5%, Met 5%, Cys 5%, Tyr 5%, Phe 5%, His 5%, Val 5%, Pro 5%, Thr 5%, Ser 5%, Asn 5%, and Gln 5%.

18. Sequence Determination of the Brain Peptide Leucine Enkephalin  A group of peptides that influence nerve transmission in certain parts of the brain has been isolated from normal brain tissue. These peptides are known as opioids, because they bind to specific receptors that also bind opiate drugs, such as morphine and naloxone. Opioids thus mimic some of the properties of opiates. Some researchers consider these peptides to be the brain's own painkillers. Using the information below, determine the amino acid sequence of the opioid leucine enkephalin. Explain how your structure is consistent with each piece of information.

(a) Complete hydrolysis by 6 N HCl at 110 °C followed by amino acid analysis indicated the presence of Gly, Leu, Phe, and Tyr, in a 2:1:1:1 molar ratio.
(b) Treatment of the peptide with 1-fluoro-2,4-dinitrobenzene followed by complete hydrolysis and chromatography indicated the presence of the 2,4-dinitrophenyl derivative of tyrosine. No free tyrosine could be found.
(c) Complete digestion of the peptide with chymotrypsin followed by chromatography yielded free tyrosine and leucine, plus a tripeptide containing Phe and Gly in a 1:2 ratio.

19. Structure of a Peptide Antibiotic from Bacillus brevis  Extracts from the bacterium *Bacillus brevis* contain a peptide with antibiotic properties. This peptide forms complexes with metal ions and seems to disrupt ion transport across the cell membranes of other bacterial species, killing them. The structure of the peptide has been determined from the following observations.

(a) Complete acid hydrolysis of the peptide followed by amino acid analysis yielded equimolar amounts of Leu, Orn, Phe, Pro, and Val. Orn is ornithine, an amino acid not present in proteins but present in some peptides. It has the structure

$$\text{H}_3\text{N}-\text{CH}_2-\text{CH}_2-\text{CH}_2-\text{C}-\text{COO}^- $$

(b) The molecular weight of the peptide was estimated as about 1,200.
(c) The peptide failed to undergo hydrolysis when treated with the enzyme carboxypeptidase. This enzyme catalyzes the hydrolysis of the carboxyl-terminal residue of a polypeptide unless the residue is Pro or, for some reason, does not contain a free carboxyl group.
(d) Treatment of the intact peptide with 1-fluoro-2,4-dinitrobenzeno, followed by complete hydrolysis and chromatography, yielded only free amino acids and the following derivative:

$$\text{O}_2\text{N}-\text{NH}-\text{CH}_2-\text{CH}_2-\text{CH}_2-\text{C}-\text{COO}^- $$

(Hint: The 2,4-dinitrophenyl derivative involves the amino group of a side chain rather than the α-amino group.)
(e) Partial hydrolysis of the peptide followed by chromatographic separation and sequence analysis yielded the following di- and tripeptides (the amino-terminal amino acid is always at the left):

- Leu–Phe Phe–Pro Orn–Leu Val–Orn
Given the above information, deduce the amino acid sequence of the peptide antibiotic. Show your reasoning. When you have arrived at a structure, demonstrate that it is consistent with each experimental observation.

20. Efficiency in Peptide Sequencing A peptide with the primary structure Lys–Arg–Pro–Leu–Ille–Asp–Gly–Ala is sequenced by the Edman procedure. If each Edman cycle is 96% efficient, what percentage of the amino acids liberated in the fourth cycle will be leucine? Do the calculation a second time, but assume a 99% efficiency for each cycle.

21. Sequence Comparisons Proteins called molecular chaperones (described in Chapter 4) assist in the process of protein folding. One class of chaperone found in organisms from bacteria to mammals is heat shock protein 90 (Hsp90). All Hsp90 chaperones contain a 10 amino acid “signature sequence,” which allows for ready identification of these proteins in sequence databases. Two representations of this signature sequence are shown below:

<table>
<thead>
<tr>
<th>Bits</th>
<th>YSNKEFLRE</th>
</tr>
</thead>
</table>

(a) In this sequence, which amino acid residues are invariant (conserved across all species)?
(b) At which position(s) are amino acids limited to those with positively charged side chains? For each position, which amino acid is more commonly found?
(c) At which positions are substitutions restricted to amino acids with negatively charged side chains? For each position, which amino acid predominates?
(d) There is one position that can be any amino acid, although one amino acid appears much more often than any other. What position is this, and which amino acid appears most often?

22. Biochemistry Protocols: Your First Protein Purification As the newest and least experienced student in a biochemistry research lab, your first few weeks are spent washing glassware and labeling test tubes. You then graduate to making buffers and stock solutions for use in various laboratory procedures. Finally, you are given responsibility for purifying a protein. It is citrate synthase (an enzyme of the citric acid cycle, to be discussed in Chapter 16), which is located in the mitochondrial matrix. Following a protocol for the purification, you proceed through the steps below. As you work, a more experienced student questions you about the rationale for each procedure. Supply the answers. (Hint: See Chapter 2 for information on osmolarity; see p. 7 for information on separation of organelles from cells.)

(a) You pick up 20 kg of beef hearts from a nearby slaughterhouse (muscle cells are rich in mitochondria, which supply energy for muscle contraction). You transport the hearts on ice, and perform each step of the purification on ice or in a walk-in cold room. You homogenize the beef heart tissue in a high-speed blender in a medium containing 0.2 M sucrose, buffered to a pH of 7.2. Why do you use beef heart tissue, and in such large quantity? What is the purpose of keeping the tissue cold and suspending it in 0.2 M sucrose, at pH 7.2? What happens to the tissue when it is homogenized?
(b) You subject the resulting heart homogenate, which is dense and opaque, to a series of differential centrifugation steps. What does this accomplish?
(c) You proceed with the purification using the supernatant fraction that contains mostly intact mitochondria. Next you osmotically lyse the mitochondria. The lysate, which is less dense than the homogenate, but still opaque, consists primarily of mitochondrial membranes and internal mitochondrial contents. To this lysate you add ammonium sulfate, a highly soluble salt, to a specific concentration. You centrifuge the solution, decant the supernatant, and discard the pellet. To the supernatant, which is clearer than the lysate, you add more ammonium sulfate. Once again, you centrifuge the sample, but this time you save the pellet because it contains the citrate synthase. What is the rationale for the two-step addition of the salt?
(d) You solubilize the ammonium sulfate pellet containing the mitochondrial proteins and dialyze it overnight against large volumes of buffered (pH 7.2) solution. Why isn’t ammonium sulfate included in the dialysis buffer? Why do you use the buffer solution instead of water?
(e) You run the dialyzed solution over a size-exclusion chromatographic column. Following the protocol, you collect the first protein fraction that exits the column and discard the fractions that elute from the column later. You detect the protein by measuring UV absorbance (at 280 nm) by the fractions. What does the instruction to collect the first fraction tell you about the protein? Why is UV absorbance at 280 nm a good way to monitor for the presence of protein in the eluted fractions?
(f) You place the fraction collected in (e) on a cation-exchange chromatographic column. After discarding the initial solution that exits the column (the flowthrough), you add a washing solution of higher pH to the column and collect the protein fraction that immediately elutes. Explain what you are doing.
(g) You run a small sample of your fraction, now very reduced in volume and quite clear (though tinged pink), on an isoelectric focusing gel. When stained, the gel shows three sharp bands. According to the protocol, the citrate synthase is the protein with a pI of 5.6, but you decide to do one more assay of the protein’s purity. You cut out the pI 5.6 band and subject it to SDS polyacrylamide gel electrophoresis. The protein resolves as a single band. Why were you unconvinced of the purity of the “single” protein band on your isoelectric focusing gel? What did the results of the SDS gel tell you? Why is it important to do the SDS gel electrophoresis after the isoelectric focusing?

Data Analysis Problem

23. Determining the Amino Acid Sequence of Insulin Figure 3–24 shows the amino acid sequence of the hormone insulin. This structure was determined by Frederick Sanger and
his coworkers. Most of this work is described in a series of articles published in the *Biochemical Journal* from 1945 to 1955.

When Sanger and colleagues began their work in 1945, it was known that insulin was a small protein consisting of two or four polypeptide chains linked by disulfide bonds. Sanger and his coworkers had developed a few simple methods for studying protein sequences.

**Treatment with FDNB.** FDNB (1-fluoro-2,4-dinitrobenzene) reacted with free amino (but not amido or guanidino) groups in proteins to produce dinitrophenyl (DNP) derivatives of amino acids:

\[
\text{R-NH}_2 + \text{F)-(ONO}_2 \rightarrow \text{R-N(NO}_2)_2 + \text{HF}
\]

**Amine** FDNB **DNP-amino**

**Acid Hydrolysis.** Boiling a protein with 10% HCl for several hours hydrolyzed all of its peptide and amide bonds. Short treatments produced short polypeptides; the longer the treatment, the more complete the breakdown of the protein into its amino acids.

**Oxidation of Cysteines.** Treatment of a protein with performic acid cleaved all the disulfide bonds and converted all Cys residues to cysteic acid residues (Fig. 3-26).

**Paper Chromatography.** This more primitive version of thin-layer chromatography (see Fig. 10-24) separated compounds based on their chemical properties, allowing identification of single amino acids and, in some cases, dipeptides. Thin-layer chromatography also separates larger peptides.

As reported in his first paper (1945), Sanger reacted insulin with FDNB and hydrolyzed the resulting protein. He found many free amino acids, but only three DNP-amino acids: \(\alpha\)-DNP-glycine (DNP group attached to the \(\alpha\)-amino group); \(\alpha\)-DNP-phenylalanine; and \(\epsilon\)-DNP-lysine (DNP attached to the \(\epsilon\)-amino group). Sanger interpreted these results as showing that insulin had two protein chains: one with Gly at its amino terminus and one with Phe at its amino terminus. One of the two chains also contained a Lys residue, not at the amino terminus. He named the chain beginning with a Gly residue “A” and the chain beginning with Phe “B.”

(a) Explain how Sanger’s results support his conclusions.

(b) Are the results consistent with the known structure of insulin (Fig. 3-24)? Explain any discrepancies.

In a later paper (1949), Sanger described how he used these techniques to determine the entire sequence of the A and B chains. Their sequence for the A chain was as follows (amino terminus on left):

\[
\text{Gly-Ile-Val-Glx-Glx-Cys-Ser-Leu-Tyr'-Glx-Leu-Glx-Asx-Tyr-Cys-Asx}
\]

Because acid hydrolysis had converted all Asn to Asp and all Gin to Glu, these residues had to be designated Asx and Glx, respectively (exact identity in the peptide unknown). Sanger solved this problem by using protease enzymes that cleave peptide bonds, but not the amide bonds in Asn and Gin residues, to prepare short peptides. He then determined the number of amide groups present in each peptide by measuring the \(\text{NH}_2\) released when the peptide was acid-hydrolyzed. Some of the results for the A chain are shown below. The peptides may not have been completely pure, so the numbers were approximate—but good enough for Sanger’s purposes.

(e) Based on these data, determine the amino acid sequence of the A chain. Explain how you reached your answer. Compare it with Figure 3-24.

**References**

Perhaps the more remarkable features of [myoglobin] are its complexity and its lack of symmetry. The arrangement seems to be almost totally lacking in the kind of regularities which one instinctively anticipates, and it is more complicated than has been predicted by any theory of protein structure.

—John Kendrew, article in Nature, 1958

The Three-Dimensional Structure of Proteins

4.1 Overview of Protein Structure 113
4.2 Protein Secondary Structure 117
4.3 Protein Tertiary and Quaternary Structures 123
4.4 Protein Denaturation and Folding 140

The covalent backbone of a typical protein contains hundreds of individual bonds. Because free rotation is possible around many of these bonds, the protein can assume a very large number of conformations. However, each protein has a specific chemical or structural function, strongly suggesting that each has a unique three-dimensional structure (Fig. 4-1). By the late 1920s, several proteins had been crystallized, including hemoglobin ($M_r$ 64,500) and the enzyme urease ($M_r$ 483,000). Given that, generally, the ordered array of molecules in a crystal can form only if the molecular units are identical, the finding that many proteins could be crystallized was evidence that even very large proteins are discrete chemical entities with unique structures. This conclusion revolutionized thinking about proteins and their functions.

In this chapter, we examine how a sequence of amino acids in a polypeptide chain is translated into a discrete, three-dimensional protein structure. We emphasize five themes. First, the three-dimensional structure of a protein is determined by its amino acid sequence. Second, the function of a protein depends on its structure. Third, an isolated protein usually exists in one or a small number of stable structural forms. Fourth, the most important forces stabilizing the specific structures maintained by a given protein are noncovalent interactions. Finally, amid the huge number of unique protein structures, we can recognize some common structural patterns that help to organize our understanding of protein architecture.

These themes should not be taken to imply that proteins have static, unchanging, three-dimensional structures. Protein function often entails an interconversion between two or more structural forms. The dynamic aspects of protein structure will be explored in Chapters 5 and 6. An understanding of all levels of protein structure is essential to the discussion of function in later chapters.

4.1 Overview of Protein Structure

The spatial arrangement of atoms in a protein is called its conformation. The possible conformations of a protein include any structural state it can achieve without breaking covalent bonds. A change in conformation could occur, for example, by rotation about single bonds. Of the many conformations that are theoretically possible in a protein containing hundreds of single
bonds, one or (more commonly) a few generally predominate under biological conditions. The need for multiple stable conformations reflects the changes that must take place in most proteins as they bind to other molecules or catalyze reactions. The conformations existing under a given set of conditions are usually the ones that are thermodynamically the most stable—that is, having the lowest Gibbs free energy (G). Proteins in any of their functional, folded conformations are called native proteins.

What principles determine the most stable conformations of a protein? An understanding of protein conformation can be built stepwise from the discussion of primary structure in Chapter 3 through a consideration of secondary, tertiary, and quaternary structures. To this traditional approach we must add the newer emphasis on common and classifiable folding patterns, called superfolding structures or motifs, which provide an important organizational context to this complex endeavor. We begin by introducing some guiding principles.

**A Protein's Conformation Is Stabilized Largely by Weak Interactions**

In the context of protein structure, the term stability can be defined as the tendency to maintain a native conformation. Native proteins are only marginally stable; the ΔG separating the folded and unfolded states in typical proteins under physiological conditions is in the range of 20 to 65 kJ/mol. A given polypeptide chain can theoretically assume countless conformations, and as a result the unfolded state of a protein is characterized by a high degree of conformational entropy. This entropy, and the hydrogen-bonding interactions of many groups in the polypeptide chain with the solvent (water), tend to maintain the unfolded state. The chemical interactions that counteract these effects and stabilize the native conformation include disulfide (covalent) bonds and the weak (noncovalent) interactions described in Chapter 2: hydrogen bonds and hydrophobic and ionic interactions.

Many proteins do not have disulfide bonds. The environment within most cells is highly reducing and thus precludes the formation of —S—S— bonds. In eukaryotes, disulfide bonds are found primarily in secreted, extracellular proteins (for example, the hormone insulin). Disulfide bonds are also uncommon in bacterial proteins. However, thermophilic bacteria, as well as the archaea, typically have many proteins with disulfide bonds, which stabilize proteins; this is presumably an adaptation to life at high temperatures.

For the intracellular proteins of most organisms, weak interactions are especially important in the folding of polypeptide chains into their secondary and tertiary structures. The association of multiple polypeptides to form quaternary structures also relies on these weak interactions.

About 200 to 460 kJ/mol are required to break a single covalent bond, whereas weak interactions can be disrupted by a mere 4 to 30 kJ/mol. Individual covalent bonds, such as disulfide bonds linking separate parts of a single polypeptide chain, are clearly much stronger than individual weak interactions. Yet, because they are so numerous, it is weak interactions that predominate as a stabilizing force in protein structure. In general, the protein conformation with the lowest free energy (that is, the most stable conformation) is the one with the maximum number of weak interactions.

The stability of a protein is not simply the sum of the free energies of formation of the many weak interactions within it. For every hydrogen bond formed in a protein during folding, a hydrogen bond (of similar strength) between the same group and water was broken. The net stability contributed by a given hydrogen bond, or the difference in free energies of the folded and unfolded states, may be close to zero. Ionic interactions may be either stabilizing or destabilizing. We must therefore look elsewhere to understand why a particular native conformation is favored.

On carefully examining the contribution of weak interactions to protein stability, we find that hydrophobic interactions generally predominate. Pure water contains a network of hydrogen-bonded H₂O molecules. No other molecule has the hydrogen-bonding potential of water, and the presence of other molecules in an aqueous solution disrupts the hydrogen bonding of water. When water surrounds a hydrophobic molecule, the optimal arrangement of hydrogen bonds results in a highly structured shell, or solvation layer, of water around the molecule (see Fig. 2-7). The increased order of the water molecules in the solvation layer correlates with an unfavorable decrease in the entropy of the water. However, when nonpolar groups cluster together, the extent of the solvation layer decreases because each group no longer presents its entire surface to the solution. The result is a favorable increase in entropy. As described in Chapter 2, this increase in entropy is the major thermodynamic driving force for the association of hydrophobic groups in aqueous solution. Hydrophobic amino acid side chains therefore tend to cluster in a protein's interior, away from water.

Under physiological conditions, the formation of hydrogen bonds in a protein is driven largely by this same entropic effect. Polar groups can generally form hydrogen bonds with water and hence are soluble in water. However, the number of hydrogen bonds per unit mass is generally greater for pure water than for any other liquid or solution, and there are limits to the solubility of even the most polar molecules as their presence causes a net decrease in hydrogen bonding per unit mass. Therefore, a solvation layer also forms to some extent around polar molecules. Even though the energy of formation of an intramolecular hydrogen bond between two polar groups in a macromolecule is...
largely canceled by the elimination of such interactions between these polar groups and water, the release of structured water as intramolecular interactions form provides an entropic driving force for folding. Most of the net change in free energy as weak interactions form within a protein is therefore derived from the increased entropy in the surrounding aqueous solution resulting from the burial of hydrophobic surfaces. This more than counterbalances the large loss of conformational entropy as a polypeptide is constrained into its folded conformation.

Hydrophobic interactions are clearly important in stabilizing conformation; the interior of a protein is generally a densely packed core of hydrophobic amino acid side chains. It is also important that any polar or charged groups in the protein interior have suitable partners for hydrogen bonding or ionic interactions. One hydrogen bond seems to contribute little to the stability of a native structure, but the presence of hydrogen-bonding groups without partners in the hydrophobic core of a protein can be so destabilizing that conformations containing these groups are often thermodynamically untenable. The favorable free-energy change resulting from the combination of several such groups with partners in the surrounding solution can be greater than the free-energy difference between the folded and unfolded states. In addition, hydrogen bonds between groups in a protein form cooperatively (formation of one makes the next one more likely) in repeating secondary structures that optimize hydrogen bonding, as described below. In this way, hydrogen bonds often have an important role in guiding the protein-folding process.

The interaction of oppositely charged groups that form an ion pair, or salt bridge, can have either a stabilizing or destabilizing effect on protein structure. As in the case of hydrogen bonds, charged amino acid side chains interact with water and salts when the protein is unfolded, and the loss of those interactions must be considered when evaluating the effect of a salt bridge on the overall stability of a folded protein. However, the strength of a salt bridge increases as it moves to an environment of lower dielectric constant, $\varepsilon$ (see p. 46): from the polar aqueous solvent ($\varepsilon$ near 80) to the nonpolar protein interior ($\varepsilon$ near 4). Salt bridges, especially those that are partly or entirely buried, can thus provide significant stabilization to a protein structure. This trend explains the increased occurrence of buried salt bridges in the proteins of thermophilic organisms. Ionic interactions also limit structural flexibility and confer a uniqueness to protein structure that nonspecific hydrophobic interactions cannot provide.

Most of the structural patterns outlined in this chapter reflect two simple rules: (1) hydrophobic residues are largely buried in the protein interior, away from water; and (2) the number of hydrogen bonds and ionic interactions within the protein is maximized, thus reducing the number of hydrogen-bonding and ionic groups that are not paired with a suitable partner. Insoluble proteins and proteins within membranes (which we examine in Chapter 11) follow somewhat different rules, because of their particular function or environment, but weak interactions are still critical structural elements.

The Peptide Bond Is Rigid and Planar

Linus Pauling, 1901–1994

Robert Corey, 1897–1971

The $\alpha$ carbons of adjacent amino acid residues are separated by three covalent bonds, arranged as $C_{\alpha} - C - N - C_{\alpha}$. X-ray diffraction studies of crystals of amino acids and of simple dipeptides and tripeptides showed that the peptide $C - N$ bond is somewhat shorter than the $C - N$ bond in a simple amine and that the atoms associated with the peptide bond are coplanar. This indicated a resonance or partial sharing of two pairs of electrons between the carbonyl oxygen and the amide nitrogen (Fig. 4-2a). The oxygen has a partial negative charge and the nitrogen a partial positive charge, setting up a small electric dipole. The six atoms of the peptide group lie in a single plane, with the oxygen atom of the carbonyl group trans to the hydrogen atom of the amide nitrogen. From these findings Pauling and Corey concluded that the peptide $C - N$ bonds, because of their partial double-bond character, cannot rotate freely. Rotation is permitted about the $N - C_{\alpha}$ and the $C_{\alpha} - C$ bonds. The backbone of a polypeptide chain can thus be pictured as a series of rigid planes, with consecutive planes sharing a common point of rotation at $C_{\alpha}$ (Fig. 4-2b). The rigid peptide bonds limit the range of conformations possible for a polypeptide chain.
Peptide conformation is defined by three dihedral angles (also known as torsion angles) called $\phi$ (phi), $\psi$ (psi), and $\omega$ (omega), reflecting rotation about each of the three repeating bonds in the peptide backbone. A dihedral angle is the angle at the intersection of two planes. In the case of peptides, the planes are defined by bond vectors in the peptide backbone. Two successive bond vectors describe a plane. Three successive bond vectors describe two planes (the central bond vector is common to both; Fig. 4-2c), and the angle between these two planes is what we measure to describe protein conformation.

**KEY CONVENTION:** The important dihedral angles in a peptide are defined by the three bond vectors connecting four consecutive main-chain (peptide backbone) atoms (Fig. 4-2c): $\phi$ involves the $\text{C} - \text{N} - \text{C} - \text{C}$ bonds (with the rotation occurring about the $\text{N} - \text{C}$ bond), and $\psi$ involves the $\text{N} - \text{C} - \text{C} - \text{N}$ bonds. Both $\phi$ and $\psi$ are defined as $\pm 180^\circ$ when the polypeptide is fully extended and all peptide groups are in the same plane (Fig. 4-2d). As one looks down the central bond vector in the direction of the vector arrow (as depicted in Fig. 4-2c for $\psi$), the dihedral angles increase as the distal (fourth) atom is rotated clockwise (Fig. 4-2d). From the $\pm 180^\circ$ position, the dihedral angle increases from $-180^\circ$ to $0^\circ$, at which point the first and fourth atoms are farthest apart and the peptide is fully extended. As the viewer looks out along the bond undergoing rotation (from either direction) the $\phi$ and $\psi$ angles increase as the fourth atom rotates clockwise relative to the first. In a protein, some of the conformations shown here (e.g., $0^\circ$) are prohibited by steric overlap of atoms. In (b) through (d), the balls representing atoms are smaller than the van der Waal's radii for this scale.

The carbonyl oxygen has a partial negative charge and the amide nitrogen a partial positive charge, setting up a small electric dipole. Virtually all peptide bonds in proteins occur in this trans configuration; an exception is noted in Figure 4-7b.
FIGURE 4-3 Ramachandran plot for L-Ala residues. Peptide conformations are defined by the values of $\phi$ and $\psi$. Conformations deemed possible are those that involve little or no steric interference, based on calculations using known van der Waals radii and dihedral angles. The areas shaded dark blue represent conformations that involve no steric overlap and thus are fully allowed; medium blue indicates conformations allowed at the extreme limits for unfavorable atomic contacts; the lightest blue indicates conformations that are permissible if a little flexibility is allowed in the dihedral angles. The yellow regions are conformations that are not allowed. The asymmetry of the plot results from the L stereochemistry of the amino acid residues. The plots for other L residues with unbranched side chains are nearly identical. Allowed ranges for branched residues such as Val, Ile, and Thr are somewhat smaller than for Ala. The Gly residue, which is less sterically hindered, has a much broader range of allowed conformations. The range for Pro residues is greatly restricted because $\psi$ is limited by the cyclic side chain to the range of $-35^\circ$ to $-85^\circ$.

for $\phi$ and $\psi$ become evident when $\psi$ is plotted versus $\phi$ in a Ramachandran plot (Fig. 4-3), introduced by G. N. Ramachandran.

SUMMARY 4.1 Overview of Protein Structure

- Every protein has a three-dimensional structure that reflects its function.
- Protein structure is stabilized by multiple weak interactions. Hydrophobic interactions are the major contributors to stabilizing the globular form of most soluble proteins; hydrogen bonds and ionic interactions are optimized in the thermodynamically most stable structures.
- The nature of the covalent bonds in the polypeptide backbone places constraints on structure. The peptide bond has a partial double-bond character that keeps the entire six-atom peptide group in a rigid planar configuration. The N-C$_\alpha$ and C$_\alpha$-C bonds can rotate to define the dihedral angles $\phi$ and $\psi$, respectively.

4.2 Protein Secondary Structure

The term secondary structure refers to any chosen segment of a polypeptide chain and describes the local spatial arrangement of its main-chain atoms, without regard to the conformation of its side chains or its relationship to other segments. A regular secondary structure occurs when each dihedral angle, $\phi$ and $\psi$, remains the same or nearly the same throughout the segment. There are a few types of secondary structure that are particularly stable and occur widely in proteins. The most prominent are the $\alpha$ helix and $\beta$ conformations; another common type is the $\beta$ turn. Where a regular pattern is not found, the secondary structure is sometimes referred to as undefined or as a random coil. This last designation, however, does not properly describe the structure of these segments. The path of the polypeptide backbone in almost any protein is not random; rather, it is typically unchanging and highly specific to the structure and function of that particular protein. Our discussion here focuses on the regular, common structures.

The $\alpha$ Helix Is a Common Protein Secondary Structure

Protein Architecture—$\alpha$ Helix Pauling and Corey were aware of the importance of hydrogen bonds in orienting polar chemical groups such as the C=O and N—H groups of the peptide bond. They also had the experimental results of William Astbury, who in the 1930s had conducted pioneering x-ray studies of proteins. Astbury demonstrated that the protein that makes up hair and porcupine quills (the fibrous protein $\alpha$-keratin) has a regular structure that repeats every 5.15 to 5.2 Å. (The angstrom, Å, named after the physicist Anders J. Ångström, is equal to 0.1 nm. Although not an SI unit, it is used universally by structural biologists to describe atomic distances—it is approximately the length of a typical C—H bond.) With this information and their data on the peptide bond, and with the help of precisely constructed models, Pauling and Corey set out to determine the likely conformations of protein molecules.

The simplest arrangement the polypeptide chain can assume, given its rigid peptide bonds (but free rotation around its other, single bonds), is a helical structure, which Pauling and Corey called the $\alpha$ helix (Fig. 4-4). In this structure the polypeptide backbone is tightly wound around an imaginary axis drawn longitudinally through the middle of the helix, and the R groups of the amino acid residues protrude outward from the helical backbone. The repeating unit is a single turn of the helix, which extends about 5.4 Å along the long axis, slightly greater than the periodicity Astbury observed on x-ray analysis of hair keratin. The amino acid residues in the prototypical $\alpha$ helix have conformations with $\phi = -57^\circ$ and $\psi = -47^\circ$, and each helical turn includes 3.6 amino acid residues. The $\alpha$-helical segments in proteins often
deviate slightly from these dihedral angles, and even vary somewhat within a single contiguous segment to produce subtle bends or kinks in the helical axis. In all proteins, the helical twist of the \( \alpha \) helix is right-handed (Box 4–1). The \( \alpha \) helix proved to be the predominant structure in \( \alpha \)-keratins. More generally, about one-fourth of all amino acid residues in proteins are found in \( \alpha \) helices, the exact fraction varying greatly from one protein to another.

Why does the \( \alpha \) helix form more readily than many other possible conformations? The answer is, in part, that an \( \alpha \) helix makes optimal use of internal hydrogen bonds. The repeat unit is a single turn of the helix, 3.6 residues. (a) Ball-and-stick model showing the intrachain hydrogen bonds. The \( \alpha \) helix viewed from one end, looking down the longitudinal axis (derived from PDB ID 4TNC). Note the positions of the R groups, represented by purple spheres. This ball-and-stick model, which emphasizes the helical arrangement, gives the false impression that the helix is hollow, because the balls do not represent the van der Waals radii of the individual atoms. (c) As this space-filling model shows, the atoms in the center of the \( \alpha \) helix are in very close contact. (d) Helical wheel projection of an \( \alpha \) helix. This representation can be colored to identify surfaces with particular properties. The yellow residues, for example, could be hydrophobic and conform to an interface between the helix shown here and another part of the same or another polypeptide. The red and blue residues illustrate the potential for interaction of negatively and positively charged side chains separated by two residues in the helix.

**BOX 4–1 METHODS Knowing the Right Hand from the Left**

There is a simple method for determining whether a helical structure is right-handed or left-handed. Make fists of your two hands with thumbs outstretched and pointing away from you. Looking at your right hand, think of a helix spiraling up your right thumb in the direction in which the other four fingers are curled as shown (clockwise). The resulting helix is right-handed. Your left hand will demonstrate a left-handed helix, which rotates in the counterclockwise direction as it spirals up your thumb.
bonds. The structure is stabilized by a hydrogen bond between the hydrogen atom attached to the electronegative nitrogen atom of a peptide linkage and the electronegative carbonyl oxygen atom of the fourth amino acid on the amino-terminal side of that peptide bond (Fig. 4–4a). Within the α helix, every peptide bond (except those close to each end of the helix) participates in such hydrogen bonding. Each successive turn of the α helix is held to adjacent turns by three to four hydrogen bonds, conferring significant stability on the overall structure.

Further model-building experiments have shown that an α helix can form in polypeptides consisting of either L- or D-amino acids. However, all residues must be of one stereoisomeric series; a D-amino acid will disrupt a regular structure consisting of L-amino acids, and vice versa. In principle, naturally occurring L-amino acids can form either right- or left-handed α helices, but extended left-handed α helices are theoretically less stable and have not been observed in proteins.

**WORKED EXAMPLE 4–1  Secondary Structure and Protein Dimensions**

What is the length of a polypeptide with 80 amino acid residues in a single contiguous α helix?

**Solution:** An idealized α helix has 3.6 residues per turn and the rise along the helical axis is 5.4 Å. Thus, the rise along the axis for each amino acid residue is 1.5 Å. The length of the polypeptide is therefore 80 residues × 1.5 Å/residue = 120 Å.

**Amino Acid Sequence Affects Stability of the α Helix**

Not all polypeptides can form a stable α helix. Each amino acid residue in a polypeptide has an intrinsic propensity to form an α helix (Table 4–1), reflecting the properties of the R group and how they affect the capacity of the adjoining main-chain atoms to take up the characteristic φ and ψ angles. Alanine shows the greatest tendency to form α helices in most experimental model systems.

The position of an amino acid residue relative to its neighbors is also important. Interactions between amino acid side chains can stabilize or destabilize the α-helical structure. For example, if a polypeptide chain has a long block of Glu residues, this segment of the chain will not form an α helix at pH 7.0. The negatively charged carboxyl groups of adjacent Glu residues repel each other so strongly that they prevent formation of the α helix. For the same reason, if there are many adjacent Lys and/or Arg residues, with positively charged R groups at pH 7.0, they also repel each other and prevent formation of the α helix. The bulk and shape of Asn, Ser, Thr, and Cys residues can also destabilize an α helix if they are close together in the chain.

*ΔΔG° is the difference in free-energy change, relative to that for alanine, required for the amino acid residue to take up the α-helical conformation. Larger numbers reflect greater difficulty taking up the α-helical structure. Data are a composite derived from multiple experiments and experimental systems.

The twist of an α helix ensures that critical interactions occur between an amino acid side chain and the side chain three (and sometimes four) residues away on either side of it. This is clear when the α helix is depicted as a helical wheel (Fig. 4–4d). Positively charged amino acids are often found three residues away from negatively charged amino acids, permitting the formation of an ion pair. Two aromatic amino acid residues are often similarly spaced, resulting in a hydrophobic interaction.

A constraint on the formation of the α helix is the presence of Pro or Gly residues, which have the least proclivity to form α helices. In proline, the nitrogen atom is part of a rigid ring (see Fig. 4–7b), and rotation about the N–Cα bond is not possible. Thus, a Pro residue introduces a destabilizing kink in an α helix. In addition, the nitrogen atom of a Pro residue in a peptide linkage has no substituent hydrogen to participate in hydrogen bonds with other residues. For these reasons, proline is only rarely found in an α helix. Glycine occurs infrequently in α helices for a different reason: it has more conformational flexibility than the other amino acid residues. Polymers of glycine tend to take up coiled structures quite different from an α helix.

A final factor affecting the stability of an α helix is the identity of the amino acid residues near the ends of the α-helical segment of the polypeptide. A small electric dipole exists in each peptide bond (Fig. 4–2a). These dipoles are aligned through the hydrogen bonds of the helix, resulting in a net dipole along the helical
The Three-Dimensional Structure of Proteins

Carboxyl terminus

\[ \delta^- \]

**FIGURE 4-5 Helix dipole.** The electric dipole of a peptide bond (see Fig. 4-2a) is transmitted along an \( \alpha \)-helical segment through the intrachain hydrogen bonds, resulting in an overall helix dipole. In this illustration, the amino and carbonyl constituents of each peptide bond are indicated by + and – symbols, respectively. Non-hydrogen-bonded amino and carbonyl constituents of the peptide bonds near each end of the \( \alpha \)-helical region are shown in red.

axis that increases with helix length (Fig. 4–5). The four amino acid residues at each end of the helix do not participate fully in the helix hydrogen bonds. The partial positive and negative charges of the helix dipole reside on the peptide amino and carbonyl groups near the amino-terminal and carboxyl-terminal ends, respectively. For this reason, negatively charged amino acids are often found near the amino terminus of the helical segment, where they have a stabilizing interaction with the positive charge of the helix dipole; a positively charged amino acid at the amino-terminal end is destabilizing. The opposite is true at the carboxyl-terminal end of the helical segment.

In summary, five types of constraints affect the stability of an \( \alpha \) helix: (1) the intrinsic propensity of an amino acid residue to form an \( \alpha \) helix; (2) the interactions between R groups, particularly those spaced three (or four) residues apart; (3) the bulkiness of adjacent R groups; (4) the occurrence of Pro and Gly residues; and (5) interactions between amino acid residues at the ends of the helical segment and the electric dipole inherent to the \( \alpha \) helix. The tendency of a given segment of a polypeptide chain to form an \( \alpha \) helix therefore depends on the identity and sequence of amino acid residues within the segment.

The \( \beta \) Conformation Organizes Polypeptide Chains into Sheets

**Protein Architecture—\( \beta \) Sheet** In 1951, Pauling and Corey predicted a second type of repetitive structure, the \( \beta \) conformation. This is a more extended conformation of polypeptide chains, and its structure has been confirmed by x-ray analysis. In the \( \beta \) conformation, the backbone of the polypeptide chain is extended into a zigzag rather than helical structure (Fig. 4-6). The zigzag polypeptide chains can be arranged side by side to form a structure resembling a series of pleats. In this arrangement, called a \( \beta \) sheet, hydrogen bonds form between adjacent segments of polypeptide chain. The individual segments that form a \( \beta \) sheet are usually nearby on the polypeptide chain, but can also be

**FIGURE 4-6 The \( \beta \) conformation of polypeptide chains.** These top and side views reveal the R groups extending out from the \( \beta \) sheet and emphasize the pleated shape described by the planes of the peptide bonds. (An alternative name for this structure is \( \beta \)-pleated sheet.) Hydrogen-bond cross-links between adjacent chains are also shown. The amino-terminal to carboxyl-terminal orientations of adjacent chains (arrows) can be the same or opposite, forming (a) an antiparallel \( \beta \) sheet or (b) a parallel \( \beta \) sheet.
quite distant from each other in the linear sequence of the polypeptide; they may even be in different polypeptide chains. The R groups of adjacent amino acids protrude from the zigzag structure in opposite directions, creating the alternating pattern seen in the side views in Figure 4–6.

The adjacent polypeptide chains in a β sheet can be either parallel or antiparallel (having the same or opposite amino-to-carboxyl orientations, respectively). The structures are somewhat similar, although the repeat period is shorter for the parallel conformation (6.5 Å, vs. 7 Å for antiparallel) and the hydrogen-bonding patterns are different. The idealized structures correspond to $\phi = -119^\circ$, $\psi = +113^\circ$ (parallel) and $\phi = -139^\circ$, $\psi = +135^\circ$ (antiparallel); these values vary somewhat in real proteins, resulting in structural variation, as seen above for α helices.

Some protein structures limit the kinds of amino acids that can occur in the β sheet. When two or more β sheets are layered close together within a protein, the R groups of the amino acid residues on the touching surfaces must be relatively small. β-Keratins such as silk fibroin and the fibroin of spider webs have a very high content of Gly and Ala residues, the two amino acids with the smallest R groups. Indeed, in silk fibroin Gly and Ala alternate over large parts of the sequence.

### β Turns Are Common in Proteins

**Protein Architecture—β Turn** In globular proteins, which have a compact folded structure, nearly one-third of the amino acid residues are in turns or loops where the polypeptide chain reverses direction (Fig. 4–7). These are the connecting elements that link successive runs of α helix or β conformation. Particularly common are β turns that connect the ends of two adjacent segments of an antiparallel β sheet. The structure is a 180° turn involving four amino acid residues, with the carbonyl oxygen of the first residue forming a hydrogen bond with the amino-group hydrogen of the fourth. The peptide groups of the central two residues do not participate in any inter-residue hydrogen bonding. Gly and Pro residues often occur in β turns, the former because it is small and flexible, the latter because peptide bonds involving the imino nitrogen of proline readily assume the cis configuration (Fig. 4–7b), a form that is particularly amenable to a tight turn. Of the several types of β turns, the two shown in Figure 4–7a are the most common. Beta turns are often found near the surface of a protein, where the peptide groups of the central two amino acid residues in the turn can hydrogen-bond with water. Considerably less common is the γ turn, a three-residue turn with a hydrogen bond between the first and third residues.

**Common Secondary Structures Have Characteristic Dihedral Angles**

The α helix and the β conformation are the major repetitive secondary structures in a wide variety of proteins, although other repetitive structures exist in some specialized proteins (an example is collagen; see Fig. 4–12). Every type of secondary structure can be completely described by the dihedral angles $\phi$ and $\psi$ associated with each residue. As shown by a Ramachandran plot, the α helix and β conformation fall within a relatively restricted range of sterically allowed
The Three-Dimensional Structure of Proteins

Structures (Fig. 4-8a). Most values of $\phi$ and $\psi$ taken from known protein structures fall into the expected regions, with high concentrations near the $\alpha$ helix and $\beta$ conformation values as predicted (Fig. 4-8b). The only amino acid residue often found in a conformation outside these regions is glycine. Because its side chain is small, a Gly residue can take part in many conformations that are sterically forbidden for other amino acids.

Common Secondary Structures Can Be Assessed by Circular Dichroism

Structural asymmetry in a molecule gives rise to differences in absorption of left-handed versus right-handed plane-polarized light. Measurement of this difference is called circular dichroism (CD) spectroscopy. An ordered structure, such as a folded protein, gives rise to an absorption spectrum that can have peaks or regions with both positive and negative values. For proteins, spectra are obtained in the far UV region (190 to 250 nm). The light-absorbing entity, or chromophore, in this region is the peptide bond; a signal is obtained when the peptide bond is in a folded environment. The difference in molar extinction coefficients (see Box 3-1) for left- and right-handed plane-polarized light ($\Delta\varepsilon$) is plotted as a function of wavelength. The $\alpha$ helix and $\beta$ conformations have characteristic CD spectra (Fig. 4-9). Using CD spectra, biochemists can determine whether proteins are properly folded, estimate the fraction of the protein that is folded in either of the common secondary structures, and monitor transitions between the folded and unfolded states.

SUMMARY 4.2 Protein Secondary Structure

- Secondary structure is the local spatial arrangement of the main-chain atoms in a selected segment of a polypeptide chain.
The most common regular secondary structures are the α helix, the β conformation, and β turns.

The secondary structure of a polypeptide segment can be completely defined if the φ and ψ angles are known for all amino acid residues in that segment.

Circular dichroism spectroscopy is a method for assessing common secondary structure and monitoring folding in proteins.

### 4.3 Protein Tertiary and Quaternary Structures

#### Protein Architecture—Introduction to Tertiary Structure

The overall three-dimensional arrangement of all atoms in a protein is referred to as the protein's tertiary structure. Whereas the term "secondary structure" refers to the spatial arrangement of amino acid residues that are adjacent in a segment of a polypeptide, tertiary structure includes longer-range aspects of amino acid sequence. Amino acids that are far apart in the polypeptide sequence and are in different types of secondary structure may interact within the completely folded structure of a protein. The location of bends (including β turns) in the polypeptide chain and the direction and angle of these bends are determined by the number and location of specific bend-producing residues, such as Pro, Thr, Ser, and Gly. Interacting segments of polypeptide chains are held in their characteristic tertiary positions by several kinds of weak interactions (and sometimes by covalent bonds such as disulfide cross-links) between the segments.

Some proteins contain two or more separate polypeptide chains, or subunits, which may be identical or different. The arrangement of these protein subunits in three-dimensional complexes constitutes quaternary structure.

In considering these higher levels of structure, it is useful to classify proteins into two major groups: fibrous proteins, with polypeptide chains arranged in long strands or sheets, and globular proteins, with polypeptide chains folded into a spherical or globular shape. The two groups are structurally distinct. Fibrous proteins usually consist largely of a single type of secondary structure, and their tertiary structure is relatively simple.

Globular proteins often contain several types of secondary structure. The two groups also differ functionally: the structures that provide support, shape, and external protection to vertebrates are made of fibrous proteins, whereas most enzymes and regulatory proteins are globular proteins.

#### Fibrous Proteins Are Adapted for a Structural Function

α-Keratin The α-keratins have evolved for strength. Found only in mammals, these proteins constitute almost the entire dry weight of hair, wool, nails, claws, quills, horns, hooves, and much of the outer layer of skin. The α-keratins are part of a broader family of proteins called intermediate filament (IF) proteins. Other IF proteins are found in the cytoskeletons of animal cells. All IF proteins have a structural function and share the structural features exemplified by the α-keratins.

The α-keratin helix is a right-handed α helix, the same helix found in many other proteins. Francis Crick and Linus Pauling in the early 1950s independently suggested that the α helices of keratin were arranged as a coiled coil. Two strands of α-keratin, oriented in parallel (with their amino termini at the same end), are wrapped about each other to form a supertwisted coiled coil. The supertwisting amplifies the strength of the overall structure, just as strands are twisted to make a strong

The twisting of the axis of an \( \alpha \) helix to form a coiled coil explains the discrepancy between the 5.4 Å per turn predicted for an \( \alpha \) helix by Pauling and Corey and the 5.15 to 5.2 Å repeating structure observed in the x-ray diffraction of hair (p. 117). The helical path of the supertwists is left-handed, opposite in sense to the \( \alpha \) helix. The surfaces where the two \( \alpha \) helices touch are made up of hydrophobic amino acid residues, their R groups meshed together in a regular interlocking pattern. This permits a close packing of the polypeptide chains within the left-handed supertwist. Not surprisingly, \( \alpha \)-keratin is rich in the hydrophobic residues Ala, Val, Leu, Ile, Met, and Phe.

An individual polypeptide in the \( \alpha \)-keratin coiled coil has a relatively simple tertiary structure, dominated by an \( \alpha \)-helical secondary structure with its helical axis twisted in a left-handed superhelix. The intertwining of the two \( \alpha \)-helical polypeptides is an example of quaternary structure. Coiled coils of this type are common structural elements in filamentous proteins and in the muscle protein myosin (see Fig. 5–27). The quaternary structure of \( \alpha \)-keratin can be quite complex. Many coiled coils can be assembled into large supramolecular complexes, such as the arrangement of \( \alpha \)-keratin to form the intermediate filament of hair (Fig. 4–10b).

The strength of fibrous proteins is enhanced by covalent cross-links between polypeptide chains in the multihelical "ropes" and between adjacent chains in a supramolecular assembly. In \( \alpha \)-keratins, the cross-links stabilizing quaternary structure are disulfide bonds (Box 4–2). In the hardest and toughest \( \alpha \)-keratins, such as those of rhinoceros horn, up to 18% of the residues are cysteines involved in disulfide bonds.

**Collagen** Like the \( \alpha \)-keratins, collagen has evolved to provide strength. It is found in connective tissue such as tendons, cartilage, the organic matrix of bone, and the cornea of the eye. The collagen helix is a unique secondary structure \( (\phi = -51^\circ, \psi = +153^\circ) \) quite distinct from the \( \alpha \) helix. It is left-handed and has three amino acid residues per turn (Fig. 4–11). Collagen is also a
When hair is exposed to moist heat, it can be stretched. At the molecular level, the α helices in the α-keratin of hair are stretched out until they arrive at the fully extended β conformation. On cooling they spontaneously revert to the α-helical conformation. The characteristic “stretchability” of α-keratins, and their numerous disulfide cross-linkages, are the basis of permanent waving. The hair to be waved or curled is first bent around a form of appropriate shape. A solution of a reducing agent, usually a compound containing a thiol or sulfhydryl group (—SH), is then applied with heat. The reducing agent cleaves the cross-linkages by reducing each disulfide bond to form two Cys residues. The moist heat breaks hydrogen bonds and causes the α-helical structure of the polypeptide chains to uncoil. After a time the reducing solution is removed, and an oxidizing agent is added to establish new disulfide bonds between pairs of Cys residues of adjacent polypeptide chains, but not the same pairs as before the treatment. After the hair is washed and cooled, the polypeptide chains revert to their α-helical conformation. The hair fibers now curl in the desired fashion because the new disulfide cross-linkages exert some torsion or twist on the bundles of α-helical coils in the hair fibers. The same process can be used to straighten hair that is naturally curly. A permanent wave (or hair straightening) is not truly permanent, because the hair grows; in the new hair replacing the old, the α-keratin has the natural pattern of disulfide bonds.

coiled coil, but one with distinct tertiary and quaternary structures: three separate polypeptides, called α chains (not to be confused with α helices), are supertwisted about each other (Fig. 4-11c). The superhelical twisting is right-handed in collagen, opposite in sense to the left-handed helix of the α chains.

There are many types of vertebrate collagen. Typically they contain about 35% Gly, 11% Ala, and 21% Pro and 4-Hyp (4-hydroxyproline, an uncommon amino acid; see Fig. 3-8a). The food product gelatin is derived from collagen; it has little nutritional value as a protein, because collagen is extremely low in many amino acids that are essential in the human diet. The unusual amino acid content of collagen is related to structural constraints unique to the collagen helix. The amino acid sequence in collagen is generally a repeating tripeptide unit, Gly–X–Y, where X is often Pro, and Y is often 4-Hyp. Only Gly residues can be accommodated at the very tight junctions between the individual α chains (Fig. 4-11d). The Pro and 4-Hyp residues permit the sharp twisting of the collagen helix. The amino acid sequence and the supertwisted quaternary structure of collagen allow a very close packing of its three polypeptides. 4-Hydroxyproline has a special role in the structure of collagen—and in human history (Box 4-3).

The tight wrapping of the α chains in the collagen triple helix provides tensile strength greater than that of a steel wire of equal cross section. Collagen fibrils (Fig. 4-12) are supramolecular assemblies consisting of triple-helical collagen molecules (sometimes referred to as tropocollagen molecules) associated in a variety of ways to provide different degrees of tensile strength.
... from this misfortune, together with the unhealthiness of the country, where there never falls a drop of rain, we were stricken with the "camp-sickness," which was such that the flesh of our limbs all shrivelled up, and the skin of our legs became all blotched with black, mouldy patches, like an old jack-boot, and proud flesh came upon the gums of those of us who had the sickness, and none escaped from this sickness save through the jaws of death. The signal was this: when the nose began to bleed, then death was at hand...

—The Memoirs of the Lord of Joinville, ca. 1300

This excerpt describes the plight of Louis IX's army toward the end of the Seventh Crusade (1248-1254), when the scurvy-weakened Crusader army was destroyed by the Egyptians. What was the nature of the malady afflicting these thirteenth-century soldiers?

Scurvy is caused by lack of vitamin C, or ascorbic acid (ascorbate). Vitamin C is required for, among other things, the hydroxylation of proline and lysine in collagen; scurvy is a deficiency disease characterized by general degeneration of connective tissue. Manifestations of advanced scurvy include numerous small hemorrhages caused by fragile blood vessels, tooth loss, poor wound healing and the reopening of old wounds, bone pain and degeneration, and eventually heart failure. Milder cases of vitamin C deficiency are accompanied by fatigue, irritability, and an increased severity of respiratory tract infections. Most animals make large amounts of vitamin C, converting glucose to ascorbate in four enzymatic steps. But in the course of evolution, humans and some other animals—gorillas, guinea pigs, and fruit bats—have lost the last enzyme in this pathway and must obtain ascorbate in their diet. Vitamin C is available in a wide range of fruits and vegetables. Until 1800, however, it was often absent in the dried foods and other food supplies stored for winter or extended travel.

Scurvy was recorded by the Egyptians in 1500 BCE, and it is described in the fifth century BCE writings of Hippocrates. Yet it did not come to wide public notice until the European voyages of discovery from 1500 to 1800. The first circumnavigation of the globe, led by Ferdinand Magellan (1520), was accomplished only with the loss of more than 80% of his crew to scurvy. During Jacques Cartier's second voyage to explore the St. Lawrence River (1535-1536), his band was threatened with complete disaster until the native Americans taught the men to make a cedar tea that cured and prevented scurvy (it contained vitamin C). Winter outbreaks of scurvy in Europe were gradually eliminated in the nineteenth century as the cultivation of the potato, introduced from South America, became widespread.

In 1747, James Lind, a Scottish surgeon in the Royal Navy, carried out the first controlled clinical study in recorded history. During an extended voyage on the 50-gun warship HMS Salisbury, Lind selected 12 sailors suffering from scurvy and separated them into groups of two. All 12 received the same diet, except that each group was given a different remedy for scurvy from among those recommended at the time. The sailors given lemons and oranges recovered and returned to duty. The sailors given boiled apple juice improved slightly. The remainder continued to deteriorate. Lind's Treatise on the Scurvy was published in 1753, but inaction persisted in the Royal Navy for another 40 years. In 1795 the British admiralty finally mandated a ration of concentrated lime or lemon juice for all British sailors (hence the name "limeys"). Scurvy continued to be a problem in some other parts of the world until 1932, when Hungarian scientist Albert Szent-Györgyi, and W. A. Waugh and C. G. King at the University of Pittsburgh, isolated and synthesized ascorbic acid.

L-Ascorbic acid (vitamin C) is a white, odorless, crystalline powder. It is freely soluble in water and relatively insoluble in organic solvents. In a dry state, away from light, it is stable for a considerable length of time. The appropriate daily intake of this vitamin is still in dispute. The recommended daily allowance in the United States is 60 mg (Australia and the United Kingdom recommend 30 to 40 mg; Russia recommends 100 mg). Along with citrus fruits and almost all other fresh fruits, other good sources of vitamin C include peppers, tomatoes, potatoes, and broccoli. The vitamin C of fruits and vegetables is destroyed by overcooking or prolonged storage.

So why is ascorbate so necessary to good health? Of particular interest to us here is its role in the formation of collagen. As noted in the text, collagen is constructed of the repeating tripeptide unit Gly-X-Y, where X and Y are generally Pro or 4-Hyp—the proline derivative (4R)-l-hydroxyproline, which plays an essential role in the folding of collagen and in maintaining its structure. The proline ring is normally found as a mixture of two puckered conformations, called C3-endo and C3-exo (Fig. 1). The collagen helix structure requires the Pro residue in...
the Y positions to be in the C$_{\gamma}$-exo conformation, and it is this conformation that is enforced by the hydroxyl substitution at C-4 in 4-Hyp. The collagen structure also requires that the Pro residue in the X positions have the C$_{\gamma}$-endo conformation, and introduction of 4-Hyp here can destabilize the helix. In the absence of vitamin C, cells cannot hydroxylate the Pro at the Y positions. This leads to collagen instability and the connective tissue problems seen in scurvy.

The hydroxylation of specific Pro residues in procollagen, the precursor of collagen, requires the action of the enzyme prolyl 4-hydroxylase. This enzyme ($M_r$ 240,000) is an $\alpha_2\beta_2$ tetramer in all vertebrate sources. The proline-hydroxylating activity is found in the $\alpha$ subunits. Each $\alpha$ subunit contains one atom of nonheme iron (Fe$^{2+}$), and the enzyme is one of a class of hydroxylases that require $\alpha$-ketoglutarate in their reactions.

In the normal prolyl 4-hydroxylase reaction (Fig. 2a), one molecule of $\alpha$-ketoglutarate and one of O$_2$ bind to the enzyme. The $\alpha$-ketoglutarate is oxidatively decarboxylated to form CO$_2$ and succinate. The remaining oxygen atom is then used to hydroxylate an appropriate Pro residue in procollagen. No ascorbate is needed in this reaction. However, prolyl 4-hydroxylase also catalyzes an oxidative decarboxylation of $\alpha$-ketoglutarate that is not coupled to proline hydroxylation (Fig. 2b). During this reaction the heme Fe$^{2+}$ becomes oxidized, inactivating the enzyme and preventing the proline hydroxylation. The ascorbate consumed in the reaction is needed to restore enzyme activity—by reducing the heme iron.

Scurvy remains a problem today, not only in remote regions where nutritious food is scarce but, surprisingly, on U.S. college campuses. The only vegetables consumed by some students are those in tossed salads, and days go by without these young adults consuming fruit. A 1998 study of 230 students at Arizona State University revealed that 10% had serious vitamin C deficiencies, and 2 students had vitamin C levels so low that they probably had scurvy. Only half the students in the study consumed the recommended daily allowance of vitamin C.

Eat your fresh fruit and vegetables.
The α chains of collagen molecules and the collagen molecules of fibrils are cross-linked by unusual types of covalent bonds involving Lys, HyLys (5-hydroxylysine; see Fig. 3–8a), or His residues that are present at a few of the X and Y positions. These links create uncommon amino acid residues such as dehydrohydroxylysinonorleucine. The increasingly rigid and brittle character of aging connective tissue results from accumulated covalent cross-links in collagen fibrils.

A typical mammal has more than 30 structural variants of collagen, particular to certain tissues and each somewhat different in sequence and function. Some human genetic defects in collagen structure illustrate the close relationship between amino acid sequence and three-dimensional structure in this protein. Osteogenesis imperfecta is characterized by abnormal bone formation in babies; Ehlers-Danlos syndrome is characterized by loose joints. Both conditions can be lethal, and both result from the substitution of an amino acid residue with a larger R group (such as Cys or Ser) for a single Gly residue in each α chain (a different Gly residue in each disorder). These single-residue substitutions have a catastrophic effect on collagen function because they disrupt the Gly-X-Y repeat that gives collagen its unique helical structure. Given its role in the collagen triple helix (Fig. 4–11d), Gly cannot be replaced by another amino acid residue without substantial deleterious effects on collagen structure.

Silk Fibroin Fibroin, the protein of silk, is produced by insects and spiders. Its polypeptide chains are predominantly in the β conformation. Fibroin is rich in Ala and Gly residues, permitting a close packing of β sheets and an interlocking arrangement of R groups (Fig. 4–13). The overall structure is stabilized by extensive hydrogen bonding between all peptide linkages in the polypeptides of each β sheet and by the optimization of van der Waals interactions between sheets. Silk does not stretch, because the β conformation is already highly extended (Fig. 4–6). However, the structure is flexible because the sheets are held together by numerous weak interactions rather than by covalent bonds such as the disulfide bonds in α-keratins.

**FIGURE 4–13 Structure of silk.** The fibers in silk cloth and in a spider web are made up of the protein fibroin. (a) Fibroin consists of layers of antiparallel β sheets rich in Ala and Gly residues. The small side chains interdigitate and allow close packing of the sheets, as shown in the ball and stick view. (b) Strands of fibroin (blue) emerge from the spinnerets of a spider in this colorized electron micrograph.
The number of known three-dimensional protein structures is now in the tens of thousands and more than doubles every couple of years. This wealth of information is revolutionizing our understanding of protein structure, the relation of structure to function, and the evolutionary paths by which proteins arrived at their present state, which can be seen in the family resemblances that come to light as protein databases are sifted and sorted. One of the most important resources available to biochemists is the Protein Data Bank (PDB; www.rcsb.org).

The PDB is an archive of experimentally determined three-dimensional structures of biological macromolecules, containing virtually all of the macromolecular structures (proteins, RNAs, DNAs, etc.) elucidated to date. Each structure is assigned an identifying label (a four-character identifier called the PDB ID). Such labels are provided in the figure legends for every PDB-derived structure illustrated in this text so that students and instructors can explore the same structures on their own. The data files in the PDB describe the spatial coordinates of each atom whose position has been determined (many of the cataloged structures are not complete). Additional data files provide information on how the structure was determined and its accuracy. The atomic coordinates can be converted into an image of the macromolecule using structure visualization software. Students are encouraged to access the PDB and explore structures using visualization software linked to the database. Macromolecular structure files can also be downloaded and explored on the desktop using free software such as RasMol, Protein Explorer, or FirstGlance in Jmol, available at www.umass.edu/microbio/rasmol.

Structural Diversity Reflects Functional Diversity in Globular Proteins

In a globular protein, different segments of the polypeptide chain (or multiple polypeptide chains) fold back on each other, generating a more compact shape than is seen in the fibrous proteins (Fig. 4-14). The folding also provides the structural diversity necessary for proteins to carry out a wide array of biological functions. Globular proteins include enzymes, transport proteins, motor proteins, regulatory proteins, immunoglobulins, and proteins with many other functions.

Our discussion of globular proteins begins with the principles gleaned from the first protein structures to be elucidated. This is followed by a detailed description of protein substructure and comparative categorization. Such discussions are possible only because of the vast amount of information available over the Internet from publicly accessible databases, particularly the Protein Data Bank (Box 4-4).

Myoglobin Provided Early Clues about the Complexity of Globular Protein Structure

Protein Architecture—Tertiary Structure of Small Globular Proteins, II. Myoglobin The first breakthrough in understanding the three-dimensional structure of a globular protein came from x-ray diffraction studies of myoglobin carried out by John Kendrew and his colleagues in the 1950s. Myoglobin is a relatively small (M, 16,700), oxygen-binding protein of muscle cells. It functions both to store oxygen and to facilitate oxygen diffusion in rapidly contracting muscle tissue. Myoglobin contains a single polypeptide chain of 153 amino acid residues of known sequence and a single iron protoporphyrin, or heme, group. The same heme group that is found in myoglobin is found in hemoglobin, the oxygen-binding protein of erythrocytes, and is responsible for the deep red-brown color of both myoglobin and hemoglobin. Myoglobin is particularly abundant in the muscles of diving mammals such as the whale, seal, and porpoise—so abundant that the muscles of these animals are brown. Storage and distribution of oxygen by muscle myoglobin permits diving mammals to remain submerged for long periods. The activities of myoglobin and other globin molecules are investigated in greater detail in Chapter 5.

Figure 4-15 shows several structural representations of myoglobin, illustrating how the polypeptide chain is folded in three dimensions—its tertiary structure. The red group surrounded by protein is heme. The
The Three-Dimensional Structure of Proteins

FIGURE 4-15 Tertiary structure of sperm whale myoglobin. (PDB ID 1MB0) Orientation of the protein is similar in (a) through (d); the heme group is shown in red. In addition to illustrating the myoglobin structure, this figure provides examples of several different ways to display protein structure. (a) The polypeptide backbone in a ribbon representation of a type introduced by Jane Richardson, which highlights regions of secondary structure. The α-helical regions are evident.

backbone of the myoglobin molecule consists of eight relatively straight segments of α helix interrupted by bends, some of which are β turns. The longest α helix has 23 amino acid residues and the shortest only 7; all helices are right-handed. More than 70% of the residues in myoglobin are in these α-helical regions. X-ray analysis has revealed the precise position of each of the R groups, which occupy nearly all the space within the folded chain.

Many important conclusions were drawn from the structure of myoglobin. The positioning of amino acid side chains reflects a structure that derives much of its stability from hydrophobic interactions. Most of the hydrophobic R groups are in the interior of the molecule, hidden from exposure to water. All but two of the polar R groups are located on the outer surface of the molecule, and all are hydrated. The myoglobin molecule is so compact that its interior has room for only four molecules of water. This dense hydrophobic core is typical of globular proteins. The fraction of space occupied by atoms in an organic liquid is 0.4 to 0.6. In a globular protein the fraction is about 0.75, comparable to that in a crystal (in a typical crystal the fraction is 0.70 to 0.78, near the theoretical maximum). In this packed environment, weak interactions strengthen and reinforce each other. For example, the nonpolar side chains in the core are so close together that short-range van der Waals interactions make a significant contribution to stabilizing hydrophobic interactions.

Deduction of the structure of myoglobin confirmed some expectations and introduced some new elements of secondary structure. As predicted by Pauling and Corey, all the peptide bonds are in the planar trans configuration. The α helices in myoglobin provided the first direct experimental evidence for the existence of this type of secondary structure. Three of the four Pro residues are found at bends. The fourth Pro residue occurs within an α helix, where it creates a kink necessary for tight helix packing.

The flat heme group rests in a crevice, or pocket, in the myoglobin molecule. The iron atom in the center of the heme group has two bonding (coordination) positions perpendicular to the plane of the heme (Fig. 4-16). One of these is bound to the R group of the His residue at position 93; the other is the site at which an O₂ molecule binds. Within this pocket, the accessibility of the heme group to solvent is highly restricted. This is important for function, because free heme groups in an oxygenated solution are rapidly oxidized from the ferrous (Fe²⁺) form, which is active in the reversible binding of O₂, to the ferric (Fe³⁺) form, which does not bind O₂.

FIGURE 4-16 The heme group. This group is present in myoglobin, hemoglobin, cytochromes, and many other proteins (the heme proteins). (a) Heme consists of a complex organic ring structure, protoporphyrin, which binds an iron atom in its ferrous (Fe²⁺) state. The iron atom has six coordination bonds, four in the plane of, and bonded to, the flat porphyrin molecule and two perpendicular to it. (b) In myoglobin and hemoglobin, one of the perpendicular coordination bonds is bound to a nitrogen atom of a His residue. The other is “open” and serves as the binding site for an O₂ molecule.
As many different myoglobin structures were resolved, investigators were able to observe the structural changes that accompany the binding of oxygen or other molecules and thus, for the first time, to understand the correlation between protein structure and function. Hundreds of proteins have now been subjected to similar analysis. Today, nuclear magnetic resonance (NMR) spectroscopy and other techniques supplement x-ray diffraction data, providing more information on a protein’s structure (Box 4-5, p. 132). In addition, the sequencing of the genomic DNA of many organisms (Chapter 9) has identified thousands of genes that encode proteins of known sequence but, as yet, unknown function; this work continues apace.

Globular Proteins Have a Variety of Tertiary Structures

From what we now know about the tertiary structures of hundreds of globular proteins, it is clear that myoglobin illustrates just one of many ways in which a polypeptide chain can be folded. Table 4-3 shows the proportions of α helix and β conformations (expressed as percentage of residues in each type) in several small, single-chain, globular proteins. Each of these proteins has a distinct structure, adapted for its particular biological function, but together they share several important properties with myoglobin. Each is folded compactly, and in each case the hydrophobic amino acid side chains are oriented toward the interior (away from water) and the hydrophilic side chains are on the surface. The structures are also stabilized by a multitude of hydrogen bonds and some ionic interactions.

For the beginning student, the very complex tertiary structures of globular proteins—some much larger than myoglobin—are best approached by focusing on common structural patterns, recurring in different and often unrelated proteins. The three-dimensional structure of a typical globular protein can be considered an assemblage of polypeptide segments in the α-helical and β-sheet conformations, linked by connecting segments. The structure can then be defined by how these segments stack on one another and how the segments that connect them are arranged.

To understand a complete three-dimensional structure, we need to analyze its folding patterns. We begin by defining two important terms that describe protein structural patterns or elements in a polypeptide chain, and then turn to the folding rules.

The first term is motif, also called a supersecondary structure or fold. A motif is simply a recognizable folding pattern involving two or more elements of secondary structure and the connection(s) between them. Although there is some confusing application of these three terms in the literature, they are generally used interchangeably. A motif can be very simple, such as two elements of secondary structure folded against each other, and represent only a small part of a protein. An example is a β-α-β loop (Fig. 4-17a). A motif can also be a very elaborate structure involving scores of protein segments folded together, such as the β barrel (Fig. 4-17b). In some cases, a single large motif may comprise the entire protein. The term encompasses any advantageous folding pattern and is useful for describing such patterns. The segment defined as a motif may or may not be independently stable. We have already encountered one well-studied motif, the coiled coil of α-keratin, which is also found in some other proteins. Note that a motif is not a hierarchical structural element falling between secondary and tertiary structure. It is a folding pattern that can describe a small part of a protein or an entire polypeptide chain. The synonymous term “supersecondary structure” is thus somewhat misleading because it suggests hierarchy.

*Portions of the polypeptide chains not accounted for by α helix or β conformation consist of bends and irregularly coiled or extended stretches. Segments of α helix and β conformation sometimes deviate slightly from their normal dimensions and geometry.

**FIGURE 4-17 Motifs.** (a) A simple motif, the β-α-β loop. (b) A more elaborate motif, the β barrel. This β barrel is a single domain of α-hemolysin (a toxin that kills a cell by creating a hole in its membrane) from the bacterium *Staphylococcus aureus* (derived from PDB ID 7AHL).
X-Ray Diffraction

The spacing of atoms in a crystal lattice can be determined by measuring the locations and intensities of spots produced on photographic film by a beam of x rays of given wavelength, after the beam has been diffracted by the electrons of the atoms. For example, x-ray analysis of sodium chloride crystals shows that Na\(^+\) and Cl\(^-\) ions are arranged in a simple cubic lattice. The spacing of the different kinds of atoms in complex organic molecules, even very large ones such as proteins, can also be analyzed by x-ray diffraction methods. However, the technique for analyzing crystals of complex molecules is far more laborious than for simple salt crystals. When the repeating pattern of the crystal is a molecule as large as, say, a protein, the numerous atoms in the molecule yield thousands of diffraction spots that must be analyzed by computer.

Consider how images are generated in a light microscope. Light from a point source is focused on an object. The object scatters the light waves, and these scattered waves are recombined by a series of lenses to generate an enlarged image of the object. The smallest object whose structure can be determined by such a system—that is, the resolving power of the microscope—is determined by the wavelength of the light, in this case visible light, with wavelengths in the range of 400 to 700 nm. Objects smaller than half the wavelength of the incident light cannot be resolved. To resolve objects as small as proteins we must use x rays, with wavelengths in the range of 0.7 to 1.5 Å (0.07 to 0.15 nm). However, there are no lenses that can recombine x rays to form an image; instead, the pattern of diffracted x rays is collected directly and an image is reconstructed by mathematical techniques.

The amount of information obtained from x-ray crystallography depends on the degree of structural order in the sample. Some important structural parameters were obtained from early studies of the diffraction patterns of the fibrous proteins arranged in regular arrays in hair and wool. However, the orderly bundles formed by fibrous proteins are not crystals—the molecules are aligned side by side, but not all are oriented in the same direction. More detailed three-dimensional structural information about proteins requires a highly ordered protein crystal. The structures of many proteins are not yet known, simply because they have proved difficult to crystallize. Practitioners have compared making protein crystals to holding together a stack of bowling balls with cellophane tape.

Operationally, there are several steps in x-ray structural analysis (Fig. 1). A crystal is placed in an x-ray beam between the x-ray source and a detector, and a regular array of spots called reflections is generated. The spots are created by the diffracted x-ray beam, and each atom in a molecule makes a contribution to each spot. An electron-density map of the protein is reconstructed from the overall diffraction pattern of spots by a mathematical technique called a Fourier transform. In effect, the computer acts as a “computational lens.” A model for the structure is then built that is consistent with the electron-density map.

John Kendrew found that the x-ray diffraction pattern of crystalline myoglobin (isolated from muscles of the sperm whale) is very complex, with nearly 25,000 reflections. Computer analysis of these reflections took place in stages. The resolution improved at each stage, until in 1959 the positions of virtually all the nonhydrogen atoms in the protein had been determined. The amino acid sequence of the protein, obtained by chemical analysis, was consistent with the molecular model. The structures of thousands of proteins, many of them much more complex than myoglobin, have since been determined to a similar level of resolution.
The physical environment in a crystal, of course, is not identical to that in solution or in a living cell. A crystal imposes a space and time average on the structure deduced from its analysis, and x-ray diffraction studies provide little information about molecular motion within the protein. The conformation of proteins in a crystal could in principle also be affected by nonphysiological factors such as incidental protein-protein contacts within the crystal. However, when structures derived from the analysis of crystals are compared with structural information obtained by other means (such as NMR, as described below), the crystal-derived structure almost always represents a functional conformation of the protein. X-ray crystallography can be applied successfully to proteins too large to be structurally analyzed by NMR.

**Nuclear Magnetic Resonance**

An advantage of nuclear magnetic resonance (NMR) studies is that they are carried out on macromolecules in solution, whereas x-ray crystallography is limited to molecules that can be crystallized. NMR can also illuminate the dynamic side of protein structure, including conformational changes, protein folding, and interactions with other molecules.

NMR is a manifestation of nuclear spin angular momentum, a quantum mechanical property of atomic nuclei. Only certain atoms, including $^1$H, $^{13}$C, $^{15}$N, $^{19}$F, and $^{31}$P, have the kind of nuclear spin that gives rise to an NMR signal. Nuclear spin generates a magnetic dipole. When a strong, static magnetic field is applied to a solution containing a single type of macromolecule, the magnetic dipoles are aligned in the field in one of two orientations, parallel (low energy) or antiparallel (high energy). A short (~10 μs) pulse of electromagnetic energy of suitable frequency (the resonant frequency, which is in the radio frequency range) is applied at right angles to the nuclei aligned in the magnetic field. Some energy is absorbed as nuclei switch to the high-energy state, and the absorption spectrum that results contains information about the identity of the nuclei and their immediate chemical environment. The data from many such experiments on a sample are averaged, increasing the signal-to-noise ratio, and an NMR spectrum such as that in Figure 2 is generated.

$^1$H is particularly important in NMR experiments because of its high sensitivity and natural abundance. For macromolecules, $^1$H NMR spectra can become quite complicated. Even a small protein has hundreds of $^1$H atoms, typically resulting in a one-dimensional NMR spectrum too complex for analysis. Structural analysis of proteins became possible with the advent of two-dimensional NMR techniques (Fig. 3). These methods allow measurement of distance-dependent coupling of nuclear spins in nearby atoms through space (the nuclear Overhauser effect (NOE), in a method dubbed NOESY) or the coupling of nuclear spins in atoms connected by covalent bonds (total correlation spectroscopy, or TOCSY).

(continued on next page)
Translating a two-dimensional NMR spectrum into a complete three-dimensional structure can be a laborious process. The NOE signals provide some information about the distances between individual atoms, but for these distance constraints to be useful, the atoms giving rise to each signal must be identified. Complementary TOCSY experiments can help identify which NOE signals reflect atoms that are linked by covalent bonds. Certain patterns of NOE signals have been associated with secondary structures such as α-helices. Modern genetic engineering (Chapter 9) can be used to prepare proteins that contain the rare isotopes $^{13}$C or $^{15}$N. The new NMR signals produced by these atoms, and the coupling with $^1$H signals resulting from these substitutions, help in the assignment of individual $^1$H NOE signals. The process is also aided by a knowledge of the amino acid sequence of the polypeptide.

To generate a three-dimensional structure, researchers feed the distance constraints into a computer along with known geometric constraints such as chirality, van der Waals radii, and bond lengths and angles. The computer generates a family of closely related structures that represent the range of conformations consistent with the NOE distance constraints (Fig. 3c). The uncertainty in structures generated by NMR is in part a reflection of the molecular vibrations (known as breathing) within a protein structure in solution, discussed in more detail in Chapter 5. Normal experimental uncertainty can also play a role.

Protein structures determined by both x-ray crystallography and NMR generally agree well. In some cases, the precise locations of particular amino acid side chains on the protein exterior are different, often because of effects related to the packing of adjacent protein molecules in a crystal. The two techniques together are at the heart of the rapid increase in the availability of structural information about the macromolecules of living cells.

**FIGURE 3** Use of two-dimensional NMR to generate a three-dimensional structure of a globin, the same protein used to generate the data in Figure 2. The diagonal in a two-dimensional NMR spectrum is equivalent to a one-dimensional spectrum. The off-diagonal peaks are NOE signals generated by close-range interactions of $^1$H atoms that may generate signals quite distant in the one-dimensional spectrum. Two such interactions are identified in (a), and their identities are shown with blue lines in (b) (PDB ID 1VRF). Three lines are drawn for interaction 2 between a methyl group in the protein and a hydrogen on the heme. The methyl group rotates rapidly such that each of its three hydrogens contributes equally to the interaction and the NMR signal. Such information is used to determine the complete three-dimensional structure (PDB ID 1VRE), as in (c). The multiple lines shown for the protein backbone in (c) represent the family of structures consistent with the distance constraints in the NMR data. The structural similarity with myoglobin (Fig. 1) is evident. The proteins are oriented in the same way in both figures.
The second term for describing structural patterns is domain. A domain, as defined by Jane Richardson in 1981, is a part of a polypeptide chain that is independently stable or could undergo movements as a single entity with respect to the entire protein. Polypeptides with more than a few hundred amino acid residues often fold into two or more domains, sometimes with different functions. In many cases, a domain from a large protein will retain its native three-dimensional structure even when separated (for example, by proteolytic cleavage) from the remainder of the polypeptide chain. In a protein with multiple domains, each domain may appear as a distinct globular lobe (Fig. 4-18); more commonly, extensive contacts between domains make individual domains hard to discern. Different domains often have distinct functions, such as the binding of small molecules or interaction with other proteins. Small proteins usually have only one domain (the domain is the protein).

Following these rules, complex motifs can be built up from simple ones. For example, a series of β-α-β loops arranged so that the β strands form a barrel creates a particularly stable and common motif, the α/β barrel. Hydrophobic interactions make a large contribution to the stability of protein structures. Burial of hydrophobic amino acid R groups so as to exclude water requires at least two layers of secondary structure. Simple motifs, such as the β-α-β loop (Fig. 4-17a), create two such layers.

1. Hydrophobic interactions make a large contribution to the stability of protein structures. Burial of hydrophobic amino acid R groups so as to exclude water requires at least two layers of secondary structure. Simple motifs, such as the β-α-β loop (Fig. 4-17a), create two such layers.

2. Where they occur together in a protein, α helices and β sheets generally are found in different structural layers. This is because the backbone of a polypeptide segment in the β conformation (Fig. 4-6) cannot readily hydrogen-bond to an α helix aligned with it.

3. Segments adjacent to each other in the amino acid sequence are usually stacked adjacent to each other in the folded structure. Distant segments of a polypeptide may come together in the tertiary structure, but this is not the norm.

4. Connections between common elements of secondary structure cannot cross or form knots (Fig. 4-19a).

5. The β conformation is most stable when the individual segments are twisted slightly in a right-handed sense. This influences both the arrangement of β sheets relative to one another and the path of the polypeptide connections between them. Two parallel β strands, for example, must be connected by a crossover strand (Fig. 4-19b). In principle, this crossover could have a right- or left-handed conformation, but in proteins it is almost always right-handed. Right-handed connections tend to be shorter than left-handed connections and tend to bend through smaller angles, making them easier to form. The twisting of β sheets also leads to a characteristic twisting of the structure formed by many such segments together, as seen in the β barrel (4-17b) and twisted β sheet (Fig. 4-19c), which form the core of many larger structures.
The Three-Dimensional Structure of Proteins

FIGURE 4-20 Constructing large motifs from smaller ones. The α/β barrel is a commonly occurring motif constructed from repetitions of the β-α-β loop motif. This α/β barrel is a domain of pyruvate kinase (a glycolytic enzyme) from rabbit (derived from PDB ID 1PNK).

(Fig. 4-20). In this structure, each parallel β segment is attached to its neighbor by an α-helical segment. All connections are right-handed. The α/β barrel is found in many enzymes, often with a binding site (for a cofactor or substrate) in the form of a pocket near one end of the barrel. Note that domains with similar folding patterns are said to have the same motif even though their constituent α helices and β sheets may differ in length.

Protein Motifs Are the Basis for Protein Structural Classification

Protein Architecture—Tertiary Structure of Large Globular Proteins, IV. Structural Classification of Proteins As we have seen, understanding the complexities of tertiary structure is made easier by considering substructures. Taking this idea further, researchers have organized the complete contents of protein databases according to hierarchical levels of structure. All of these databases rely on data and information deposited in the Protein Data Bank. The Structural Classification of Proteins (SCOP) database is a good example of this important trend in biochemistry. At the highest level of classification, the SCOP database (http://scop.mrc-lmb.cam.ac.uk/scop) borrows a scheme already in common use, with four classes of protein structure: all α, all β, α/β (with α and β segments interspersed or alternating), and α + β (with α and β regions somewhat segregated). Each class includes tens to hundreds of different folding arrangements (motifs), built up from increasingly identifiable substructures. Some of the substructure arrangements are very common, others have been found in just one protein. Figure 4-21 shows a variety of motifs arrayed among the four classes of protein structure; this is just a minute sample of the hundreds of known motifs. The number of folding patterns is not infinite, however. As the rate at which new protein structures are elucidated has increased, the fraction of those structures containing a new motif has steadily declined. Fewer than 1,000 different folds or motifs may exist in all. Figure 4-21 also shows how proteins can be organized based on the presence of the various motifs. The top two levels of organization, class and fold, are purely structural. Below the fold level (see color key in Fig. 4-21), categorization is based on evolutionary relationships.

Many examples of recurring domain or motif structures are available, and these reveal that protein tertiary structure is more reliably conserved than amino acid sequence. The comparison of protein structures can thus provide much information about evolution.

FIGURE 4-21 Organization of proteins based on motifs. Shown here are just a few of the hundreds of known stable motifs. They are divided into four classes: all α, all β, α/β, and α + β. Structural classification data from the SCOP (Structural Classification of Proteins) database (http://scop.mrc-lmb.cam.ac.uk/scop) are also provided (see the color key). The PDB identifier (listed first for each structure) is the unique accession code given to each structure archived in the Protein Data Bank (www.rcsb.org). The α/β barrel (see Fig. 4-20) is another particularly common α/β motif.

  - Green fluorescent protein, GFP
  - Jollyfish (Aequorea victoria)
Proteins with significant similarity in primary structure and/or with similar tertiary structure and function are said to be in the same **protein family**. A strong evolutionary relationship is usually evident within a protein family. For example, the globin family has many different proteins with both structural and sequence similarity to myoglobin (as seen in the proteins used as examples in Box 4–5 and in Chapter 5). Two or more families with little similarity in amino acid sequence sometimes make use of the same major structural motif and have functional similarities; these families are grouped as **superfamilies**. An evolutionary relationship among families in a superfamily is considered probable, even though time and functional distinctions—that is, different adaptive pressures—may have erased many of the telltale sequence relationships. A protein family may be widespread in all three domains of cellular life, the Bacteria, Archaea, and Eukarya, suggesting a very ancient origin. Other families may be present in only a small group of organisms, indicating that the structure arose more recently. Tracing the natural history of structural motifs, using structural classifications in databases such as SCOP, provides a powerful complement to sequence analyses in tracing evolutionary relationships. The SCOP database is curated manually, with the objective of placing proteins in the correct evolutionary framework based on conserved structural features.

Structural motifs become especially important in defining protein families and superfamilies. Improved classification and comparison systems for proteins lead inevitably to the elucidation of new functional relationships. Given the central role of proteins in living systems, these structural comparisons can help illuminate every aspect of biochemistry, from the evolution of individual proteins to the evolutionary history of complete metabolic pathways.

Several online databases and resources complement the SCOP database for analysis of protein structure. The CATH (Class, Architecture, Topology, and Homologous Superfamily) database arranges the proteins in the PDB in a four-level hierarchy. Other programs allow the user to input the structure of a protein of interest and then find all the proteins in the PDB that are structurally similar to this protein or some part of it. These programs include VAST (Vector Alignment Search Tool), CE (Combinatorial Extension of the Optimal Paths), and FSSP (Fold Classification Based on Structure-Structure Alignment of Proteins).

**Protein Quaternary Structures Range from Simple Dimers to Large Complexes**

**Protein Architecture—Quaternary Structure** Many proteins have multiple polypeptide subunits (from two to hundreds). The association of polypeptide chains can serve a variety of functions. Many multisubunit proteins have regulatory roles; the binding of small molecules may affect the interaction between subunits, causing large changes in the protein's activity in response to small changes in the concentration of substrate or regulatory molecules (Chapter 6). In other cases, separate subunits take on separate but related functions, such as catalysis and regulation. Some associations, such as the fibrous proteins considered earlier in this chapter and the coat proteins of viruses, serve primarily structural roles. Some very large protein assemblies are the site of complex, multistep reactions. For example, each ribosome, the site of protein synthesis, incorporates dozens of protein subunits along with a number of RNA molecules.

A multisubunit protein is also referred to as a **multimer**. A multimer with just a few subunits is often called an **oligomer**. If a multimer has nonidentical subunits, the overall structure of the protein can be asymmetric and quite complicated. However, most multimers have identical subunits or repeating groups of nonidentical subunits, usually in symmetric arrangements. As noted in Chapter 3, the repeating structural unit in such a multimeric protein, whether a single subunit or a group of subunits, is called a **protomer**. Greek letters are sometimes used to distinguish the individual subunits that make up a protomer.

The first oligomeric protein to have its three-dimensional structure determined was hemoglobin (M, 64,500), which contains four polypeptide chains and four heme prosthetic groups, in which the iron atoms are in the ferrous (Fe²⁺) state (Fig. 4–16). The protein portion, the globin, consists of two α chains (141 residues each) and two β chains (146 residues each). Note that in this case, α and β do not refer to secondary structures. Because hemoglobin is four times as large as myoglobin, much more time and effort were required to solve its three-dimensional structure by x-ray analysis, finally achieved by Max Perutz, John Kendrew, and their colleagues in 1959. The subunits of hemoglobin are arranged in symmetric pairs (Fig. 4–22), each pair having one α and one β subunit. Hemoglobin can therefore be described either as a tetramer or as a dimer of αβ protomers.

![Max Perutz, 1914–2002 (left) John Kendrew, 1917–1997 (right)](image-url)
Identical subunits of multimeric proteins are generally arranged in one or a limited set of symmetric patterns. A description of the structure of these proteins requires an introduction to conventions used to define symmetries. Oligomers can have either rotational symmetry or helical symmetry; that is, individual subunits can be superimposed on others (brought to coincidence) by rotation about one or more rotational axes or by a helical rotation. In proteins with rotational symmetry, the subunits pack about the rotational axes to form closed structures. Proteins with helical symmetry tend to form more open-ended structures, with subunits added in a spiraling array.

There are several forms of rotational symmetry. The simplest is cyclic symmetry, involving rotation about a single axis (Fig. 4-23a). If subunits can be superimposed by rotation about a single axis, the protein has a symmetry defined as \( C_n \) (C for cyclic, \( n \) for the number of subunits related by the axis). The axis itself is described as an \( n \)-fold rotational axis. The \( \alpha \beta \) protomers of hemoglobin (Fig. 4–22) are related by \( C_2 \) symmetry. A somewhat more complicated rotational symmetry is dihedral symmetry, in which a twofold rotational axis intersects an \( n \)-fold axis at right angles; this symmetry is defined as \( D_n \) (Fig. 4–23b). A protein with dihedral symmetry has \( 2n \) protomers.

Proteins with cyclic or dihedral symmetry are particularly common. More complex rotational symmetries are possible, but only a few are regularly encountered in proteins. One example is icosahedral symmetry. An icosahedron is a regular 12-cornered polyhedron with 20 equilateral triangular faces (Fig. 4–23c). Each face can be brought to coincidence with another face by rotation about one or more of three axes. This is a common structure in virus coats, or capsids. The human

**FIGURE 4-22 Quaternary structure of deoxyhemoglobin.** (PDB ID 2HHB) X-ray diffraction analysis of deoxyhemoglobin (hemoglobin without oxygen molecules bound to the heme groups) shows how the four polypeptide subunits are packed together. (a) A ribbon representation. (b) A surface contour model. The \( \alpha \) subunits are shown in shades of gray; the \( \beta \) subunits in shades of blue. Note that the heme groups (red) are relatively far apart.

**FIGURE 4-23 Rotational symmetry in proteins.** (a) In cyclic symmetry, subunits are related by rotation about a single \( n \)-fold axis, where \( n \) is the number of subunits so related. The axes are shown as black lines; the numbers are values of \( n \). Only two of many possible \( C_n \) arrangements are shown. (b) In dihedral symmetry, all subunits can be related by rotation about one or both of two axes, one of which is twofold. \( D_2 \) symmetry is most common. (c) Icosahedral symmetry. Relating all 20 triangular faces of an icosahedron requires rotation about one or more of three separate rotational axes: twofold, threefold, and fivefold. An end-on view of each of these axes is shown at the right.
The Three-Dimensional Structure of Proteins

**SUMMARY 4.3 Protein Tertiary and Quaternary Structures**

- Tertiary structure is the complete three-dimensional structure of a polypeptide chain. There are two general classes of proteins based on tertiary structure: fibrous and globular.
- Fibrous proteins, which serve mainly structural roles, have simple repeating elements of secondary structure.
- Globular proteins have more complicated tertiary structures, often containing several types of secondary structure in the same polypeptide chain. The first globular protein structure to be determined, by x-ray diffraction methods, was that of myoglobin.
- The complex structures of globular proteins can be analyzed by examining folding patterns called motifs, supersecondary structures, or folds. The thousands of known protein structures are generally assembled from a repertoire of only a few hundred motifs. Domains are regions of a polypeptide chain that can fold stably and independently.
- Quaternary structure results from interactions between the subunits of multisubunit (multimeric) proteins or large protein assemblies. Some multimeric proteins have a repeated unit consisting of a single subunit or a group of subunits, or protomer. Protomers are usually related by rotational or helical symmetry.

**4.4 Protein Denaturation and Folding**

All proteins begin their existence on a ribosome as a linear sequence of amino acid residues (Chapter 27). This polypeptide must fold during and following synthesis to take up its native conformation. As we have seen, a native protein conformation is only marginally stable. Modest changes in the protein’s environment can affect function. We now explore the transition that occurs between the folded and unfolded states.

**Loss of Protein Structure Results in Loss of Function**

Protein structures have evolved to function in particular cellular environments. Conditions different from those in the cell can result in protein structural changes, large and small. A loss of three-dimensional structure sufficient to cause loss of function is called denaturation. The denatured state does not necessarily equate with complete unfolding of the protein and randomization of conformation. Under most conditions, denatured proteins exist in a set of partially folded states, which as yet are poorly understood.

Most proteins can be denatured by heat, which has complex effects on the weak interactions in a protein (primarily hydrogen bonds). If the temperature is increased slowly, a protein’s conformation generally remains intact until an abrupt loss of structure (and function) occurs over a narrow temperature range (Fig. 4–25). The abruptness of the change suggests that unfolding is a cooperative process: loss of structure in one part of the protein destabilizes other parts. The effects of heat on proteins are not readily predictable. The very heat-stable proteins of thermophilic bacteria and archaea have evolved to function at the temperature of hot springs (∼100 °C). Yet the structures of these proteins often

**FIGURE 4–24 Viral capsids.** (a) Poliovirus (derived from PDB ID 2PLV) as rendered in the VIPER relational database for structural virology. The coat proteins of poliovirus assemble into an icosahedron 300 Å in diameter. Icosahedral symmetry is a type of rotational symmetry (see Fig. 4–23c). On the left is a surface contour image of the poliovirus capsid. The image at right was rendered at lower resolution, and the coat protein subunits were colored to show the icosahedral symmetry. (b) Tobacco mosaic virus (derived from PDB ID 1VTM). This rod-shaped virus (as shown in the electron micrograph) is 3,000 Å long and 180 Å in diameter; it has helical symmetry.

Poliovirus has an icosahedral capsid (Fig. 4–24a). Each triangular face is made up of three protomers, each containing single copies of four different polypeptide chains, three of which are accessible at the outer surface. Sixty protomers form the 20 faces of the icosahedral shell, which encloses the genetic material (RNA).

The other major type of symmetry found in oligomers, helical symmetry, also occurs in capsids. Tobacco mosaic virus is a right-handed helical filament made up of 2,130 identical subunits (Fig. 4–24b). This cylindrical structure encloses the viral RNA. Proteins with subunits arranged in helical filaments can also form long, fibrous structures such as the actin filaments of muscle (see Fig. 5–28).

---
Amino Acid Sequence Determines Tertiary Structure

The tertiary structure of a globular protein is determined by its amino acid sequence. The most important proof of this came from experiments showing that denaturation of some proteins is reversible. Certain globular proteins denatured by heat, extremes of pH, or denaturing reagents will regain their native structure and their biological activity if returned to conditions in which the native conformation is stable. This process is called renaturation.

A classic example is the denaturation and renaturation of ribonuclease A, demonstrated by Christian Anfinsen in the 1950s. Purified ribonuclease A denatures completely in a concentrated urea solution in the presence of a reducing agent. The reducing agent cleaves the four disulfide bonds to yield eight Cys residues, and the urea disrupts the stabilizing hydrophobic interactions, thus freeing the entire polypeptide from its folded conformation. Denaturation of ribonuclease is accompanied by a complete loss of catalytic activity. When the urea and the reducing agent are removed, the randomly coiled, denatured ribonuclease spontaneously refolds into its correct tertiary structure, with full restoration of its catalytic activity (Fig. 4-26). The refolding of ribonuclease is so
accurate that the four intrachain disulfide bonds are re-formed in the same positions in the renatured molecule as in the native ribonuclease. Calculated mathematically, the eight Cys residues could recombine at random to form up to four disulfide bonds in 10^5 different ways. In fact, an essentially random distribution of disulfide bonds is obtained when the disulfides are allowed to re-form in the presence of denaturant (without reducing agent), indicating that weak bonding interactions are required for correct positioning of disulfide bonds and restoration of the native conformation. Later, similar results were obtained using chemically synthesized, catalytically active ribonuclease A. This eliminated the possibility that some minor contaminant in Anfinsen’s purified ribonuclease preparation might have contributed to the renaturation of the enzyme, thus dispelling any remaining doubt that this enzyme folds spontaneously.

The Anfinsen experiment provided the first evidence that the amino acid sequence of a polypeptide chain contains all the information required to fold the chain into its native, three-dimensional structure. Subsequent work has shown that this is true only for a minority of proteins, many of them small and inherently stable. Even though all proteins have the potential to fold into their native structure, many require some assistance, as we shall see.

**Polypeptides Fold Rapidly by a Stepwise Process**

In living cells, proteins are assembled from amino acids at a very high rate. For example, E. coli cells can make a complete, biologically active protein molecule containing 100 amino acid residues in about 5 seconds at 37 °C. How does the polypeptide chain arrive at its native conformation? Let’s assume conservatively that each of the amino acid residues could take up 10 different conformations on average, giving 10^{100} different conformations for the polypeptide. Let’s also assume that the protein folds spontaneously by a random process in which it tries out all possible conformations around every single bond in its backbone until it finds its native, biologically active form. If each conformation were sampled in the shortest possible time (~10^{-12} second, or the time required for a single molecular vibration), it would take about 10^{77} years to sample all possible conformations. Clearly, protein folding is not a completely random, trial-and-error process. There must be shortcuts. This problem was first pointed out by Cyrus Levinthal in 1968 and is sometimes called Levinthal’s paradox.

The folding pathway of a large polypeptide chain is unquestionably complicated, and not all the principles that guide the process have been worked out. However, there are several plausible models. In one, the folding process is hierarchical. Local secondary structures form first. Certain amino acid sequences fold readily into α helices or β sheets, guided by constraints such as those reviewed in our discussion of secondary structure. Ionic interactions, involving charged groups that are often near one another in the linear sequence of the polypeptide chain, can play an important role in guiding these early folding steps. Assembly of local structures is followed by longer-range interactions between, say, two α helices that come together to form stable supersecondary structures. The process continues until complete domains form and the entire polypeptide is folded (Fig. 4-27). Notably, proteins dominated by close-range interactions (between pairs of residues generally located near each other in the polypeptide sequence) tend to fold faster than proteins with more complex folding patterns and many long-range interactions between different segments.

In an alternative model, folding is initiated by a spontaneous collapse of the polypeptide into a compact
state, mediated by hydrophobic interactions among nonpolar residues. The state resulting from this "hydrophobic collapse" may have a high content of secondary structure, but many amino acid side chains are not entirely fixed. The collapsed state is often referred to as a **molten globule**. Most proteins probably fold by a process that incorporates features of both models. Instead of following a single pathway, a population of peptide molecules may take a variety of routes to the same end point, with the number of different partly folded conformational species decreasing as folding nears completion.

Thermodynamically, the folding process can be viewed as a kind of free-energy funnel (Fig. 4–28). The unfolded states are characterized by a high degree of conformational entropy and relatively high free energy. As folding proceeds, the narrowing of the funnel represents a decrease in the number of conformational species present. Small depressions along the sides of the free-energy funnel represent semistable intermediates that can briefly slow the folding process. At the bottom of the funnel, an ensemble of folding intermediates has been reduced to a single native conformation (or one of a small set of native conformations).

Thermodynamic stability is not evenly distributed over the structure of a protein—the molecule has regions of high and low stability. For example, a protein may have two stable domains joined by a segment with lower structural stability, or one small part of a domain may have a lower stability than the remainder. The regions of low stability allow a protein to alter its conformation between two or more states. As we shall see in the next two chapters, variations in the stability of regions within a protein are often essential to protein function.

As our understanding of protein folding and protein structure improves, increasingly sophisticated computer programs for predicting the structure of proteins from their amino acid sequence are being developed. Prediction of protein structure is a specialty field of bioinformatics, and progress in this area is monitored with a biennial test called the CASP (Critical Assessment of Structural Prediction) competition. Entrants from around the world vie to predict the structure of an assigned protein (whose structure has been determined but not yet published). The most successful teams are invited to present their results at a CASP conference. Completely reliable solutions to the complex problem of predicting protein structure are not yet available, but the success and rigor of new approaches is being enriched by CASP.

**Some Proteins Undergo Assisted Folding**

Not all proteins fold spontaneously as they are synthesized in the cell. Folding for many proteins requires **molecular chaperones**, proteins that interact with partially folded or improperly folded polypeptides, facilitating correct folding pathways or providing microenvironments in which folding can occur. Two classes of molecular chaperones have been well studied. Both are found in organisms ranging from bacteria to humans. The first class is a family of proteins called **Hsp70** (see Fig. 3–30), which generally have a molecular weight near 70,000 and are more abundant in cells stressed by elevated temperatures (hence, heat shock proteins of M, 70,000, or Hsp70). Hsp70 proteins bind to regions of unfolded polypeptides that are rich in hydrophobic residues, preventing inappropriate aggregation. These chaperones thus "protect" both proteins subject to denaturation by heat and new peptide molecules being synthesized (and not yet folded). Hsp70 proteins also block the folding of certain proteins that must remain unfolded until they have been translocated across a membrane (as described in Chapter 27). Some chaperones also

**FIGURE 4–28** The thermodynamics of protein folding depicted as a free-energy funnel. At the top, the number of conformations, and hence the conformational entropy, is large. Only a small fraction of the intramolecular interactions that will exist in the native conformation are present. As folding progresses, the thermodynamic path down the funnel reduces the number of states present (decreases entropy), increases the amount of protein in the native conformation, and decreases the free energy. Depressions on the sides of the funnel represent semistable folding intermediates, which in some cases may slow the folding process.
1. DnaJ binds to the unfolded or partially folded protein and then to DnaK.

2. DnaJ stimulates ATP hydrolysis by DnaK. DnaK-ADP binds tightly to the unfolded protein.

3. In bacteria, the nucleotide-exchange factor GrpE stimulates release of ADP.

4. ATP binds to DnaK and the protein dissociates.

FIGURE 4-29 Chaperones in protein folding. The cyclic pathway by which chaperones bind and release polypeptides is illustrated for the E. coli chaperone proteins DnaK and DnaJ, homologs of the eukaryotic chaperones Hsp70 and Hsp40. The chaperones do not actively promote the folding of the substrate protein, but instead prevent aggregation of unfolded peptides. For a population of polypeptide molecules, some fraction of the molecules released at the end of the cycle are in the native conformation. The remainder are rebound by DnaK or diverted to the chaperonin system (GroEL; see Fig. 4-30). In bacteria, a protein called GrpE interacts transiently with DnaK late in the cycle (step 3), promoting dissociation of ADP and possibly DnaJ. No eukaryotic analog of GrpE is known.

facilitate the quaternary assembly of oligomeric proteins. The Hsp70 proteins bind to and release polypeptides in a cycle that uses energy from ATP hydrolysis and involves several other proteins (including a class called Hsp40). Figure 4-29 illustrates chaperone-assisted folding as elucidated for the chaperones DnaK and DnaJ in E. coli, homologs of the eukaryotic Hsp70 and Hsp40 chaperones. DnaK and DnaJ were first identified as proteins required for in vitro replication of certain viral DNA molecules (hence the “Dna” designation).

The second class of chaperones is the chaperonins. These are elaborate protein complexes required for the folding of some cellular proteins that do not fold spontaneously. In E. coli an estimated 10% to 15% of cellular proteins require the resident chaperonin system, called GroEL/GroES, for folding under normal conditions (up to 30% require this assistance when the cells are heat stressed). The chaperonins first became known when they were found to be necessary for the growth of certain bacterial viruses (hence the designation “Gro”). Unfolded proteins are bound within pockets in the GroEL complex, and the pockets are capped transiently by the GroES “lid” (Fig. 4-30). GroEL undergoes substantial conformational changes, coupled to ATP hydrolysis and the binding and release of GroES, which promote folding of the bound polypeptide. The mechanism by which the GroEL/GroES chaperonin facilitates folding is not known in detail, but it depends on the size and interior surface properties of the cavity where folding occurs.

Finally, the folding pathways of some proteins require two enzymes that catalyze isomerization reactions. Protein disulfide isomerase (PDI) is a widely distributed enzyme that catalyzes the interchange, or shuffling, of disulfide bonds until the bonds of the native conformation are formed. Among its functions, PDI catalyzes the elimination of folding intermediates with inappropriate disulfide cross-links. Peptide prolyl cis-trans isomerase (PPI) catalyzes the interconversion of the cis and trans isomers of Pro residue peptide bonds (Fig. 4-7b), which can be a slow step in the folding of proteins that contain some Pro peptide bonds in the cis conformation.
Protein Denaturation and Folding

Unfolded protein binds to the GroEL pocket not blocked by GroES.

ATP binds to each subunit of the GroEL heptamer.

ATP hydrolysis leads to release of 14 ADP and GroES.

Proteins not folded when released are rapidly bound again.

The released protein is fully folded or in a partially folded state that is committed to adopt the native conformation.

Protein folds inside the enclosure.

7 ATP and GroES bind to GroEL with a filled pocket.

---

**FIGURE 4-30 Chaperonins in protein folding.** (a) A proposed pathway for the action of the *E. coli* chaperonins GroEL (a member of the Hsp60 protein family) and GroES. Each GroEL complex consists of two large pockets formed by two heptameric rings (each subunit M, 57,000); GroES, also a heptamer (subunit M, 10,000), blocks one of the GroEL pockets. (b) Surface and cut-away images of the GroEL/GroES complex (PDB ID 1AON). The cut-away (right) illustrates the large interior space within which other proteins are bound.

Protein folding is likely to be a more complex process in the densely packed cellular environment than in the test tube. More classes of proteins that facilitate protein folding may well be discovered.

**Defects in Protein Folding May Be the Molecular Basis for a Wide Range of Human Genetic Disorders**

Despite the many processes that assist in protein folding, misfolding does occur. In fact, protein misfolding is a substantial problem in all cells, and a quarter or more of all polypeptides synthesized may be destroyed because they do not fold correctly. In some cases, the misfolding causes or contributes to the development of serious disease.

Many conditions, including type 2 diabetes, Alzheimer's disease, Huntington's disease, and Parkinson's disease, arise from a common misfolding mechanism. In most cases, a soluble protein that is normally secreted from the cell is secreted in a misfolded state and converted into an insoluble extracellular amyloid fiber. The diseases are collectively referred to as amyloidoses. The fibers are highly ordered and unbranched, with a diameter of 7 to 10 nm and a high
degree of β-sheet structure. The β strands are oriented perpendicular to the axis of the fiber. In some amyloid fibers the overall structure forms a long, two-layered β sheet such as that shown for amyloid-β peptide in Figure 4–31.

Many proteins can take on the amyloid fibril structure as an alternative to their normal folded conformations, and most of these proteins have a concentration of aromatic amino acid residues in a core region of β sheet. The proteins are secreted in an incompletely folded conformation. The core β sheet (or some part of it) forms before the rest of the protein folds correctly, and the β sheets from two or more incompletely folded protein molecules associate to begin forming an amyloid fibril. The fibril grows in the extracellular space. Other parts of the protein then fold differently, remaining on the outside of the β-sheet core in the growing fibril (Fig. 4–31a); the effect of aromatic residues in stabilizing the structure is shown in Fig. 4–31c). Because most of the protein molecules fold normally, the onset of symptoms in the amyloidoses is often very slow. If a person inherits a mutation such as substitution with an aromatic residue at a position that favors formation of amyloid fibrils, disease symptoms may begin at an earlier age. A decreased capacity for removing misfolded proteins may also contribute to these diseases.

Some amyloidoses are systemic, involving many tissues. Primary systemic amyloidosis is caused by deposition of fibrils consisting of misfolded immunoglobulin light chains (described in Chapter 5), or fragments of light chains derived from proteolytic degradation. The mean age of onset is about 65 years. Patients have symptoms including fatigue, hoarseness, swelling, and weight loss, and many die within the first year after diagnosis. The kidneys or heart are often most affected. Some amyloidoses are associated with other types of disease. Patients with certain chronic infectious or inflammatory diseases such as rheumatoid arthritis, tuberculosis, cystic fibrosis, and some cancers can experience a sharp increase in secretion of an amyloid-prone polypeptide called serum amyloid A (SAA) protein. This protein, or fragments of it, deposits in the connective tissue of the

**FIGURE 4–31** Formation of disease-causing amyloid fibrils. (a) Protein molecules whose normal structure includes regions of β sheet undergo partial folding. In a small number of the molecules, before folding is complete, the β-sheet regions of one polypeptide associate with the same region in another polypeptide, forming the nucleus of an amyloid. Additional protein molecules slowly associate with the amyloid and extend it to form a fibril. (b) The amyloid-β peptide, which plays a major role in Alzheimer's disease, is derived from a larger transmembrane protein called amyloid-β precursor protein or APP. This protein is found in most human tissues. When it is part of the larger protein, the peptide is composed of two α-helical segments spanning the membrane. When the external and internal domains (each of which have independent functions) are cleaved off by dedicated proteases, the remaining and relatively unstable amyloid-β peptide leaves the membrane and loses its α-helical structure. It can then assemble slowly into amyloid fibrils (c), which contribute to the characteristic plaques on the exterior of nervous tissue in people with Alzheimer's. Amyloid is rich in β-sheet structure, with the β strands arranged perpendicular to the axis of the amyloid fibril. In amyloid-β peptide, the structure takes the form of an extended two-layer parallel β sheet. Others may take the form of left-handed β-helices (see Fig. 4–21).
spleen, kidney, and liver, and around the heart. People with this condition, known as secondary systemic amyloidosis, have a wide range of symptoms, depending on the organs initially affected. The disease is generally fatal within a few years. More than 80 amyloidoses are associated with mutations in transthyretin (a protein that binds to and transports thyroid hormones, distributing them throughout the body and brain). A variety of mutations in this protein lead to amyloid deposition concentrated around different tissues, thus producing different symptoms. Amyloidoses are also associated with inherited mutations in the proteins lysozyme, fibrinogen A α-chain, and apolipoproteins A-I and A-II; all of these proteins are described in later chapters.

Some amyloid diseases are associated with particular organs. The amyloid-prone protein is generally secreted only by the affected tissue, and its locally high concentration leads to amyloid deposition around that tissue (although some of the protein may be distributed systemically). One common site of amyloid deposition is near the pancreatic islet β cells, responsible for insulin secretion and regulation of glucose metabolism (p. 924). Secretion by β cells of a small (37 amino acids) peptide called islet amyloid polypeptide (IAPP), or amylin, can lead to amyloid deposits around the islets, gradually destroying the cells. A healthy human adult has 1 to 1.5 million pancreatic β cells. With progressive loss of these cells, glucose homeostasis is affected and eventually, when 50% or more of the cells are lost, the condition matures into type 2 (adult onset) diabetes mellitus.

The amyloid deposition diseases that trigger neurodegeneration, particularly in older adults, are a special class of localized amyloidoses. Alzheimer’s disease is associated with extracellular amyloid deposition by neurons, involving a protein called amyloid β-peptide. These amyloid deposits seem to be the primary cause of Alzheimer’s, but a second type of amyloid-like aggregation, involving a protein called tau, also occurs intracellularly (in neurons) in patients with Alzheimer’s. Inherited mutations in the tau protein do not result in Alzheimer’s, but they cause a frontotemporal dementia and Parkinsonism (a condition with symptoms resembling Parkinson’s disease) that can be equally devastating.

Several other neurodegenerative conditions involve intracellular aggregation of misfolded proteins. In Parkinson’s disease, the misfolded form of the protein α-synuclein aggregates into spherical filamentous masses called Lewy bodies. Huntington’s disease involves the protein huntingtin, which has a long polyglutamine repeat. In some individuals, the polyglutamine repeat is longer than normal and a more subtle type of intracellular aggregation occurs. The relationship of some of these neurodegenerative conditions to amyloidoses has been debated, but the aggregates are known to have high degrees of β structure and insolubility that suggest some common structures and mechanisms of formation.

Protein misfolding need not lead to amyloid formation to cause serious disease. For example, cystic fibrosis is caused by defects in a membrane-bound protein called cystic fibrosis transmembrane conductance regulator (CFTR), which acts as a channel for chloride ions. The most common cystic fibrosis-causing mutation is the deletion of a Phe residue at position 508 in CFTR, which causes improper protein folding. Most of this protein is then degraded and its normal function is lost (see Box 11–3). Many of the disease-related mutations in collagen (p. 128) also cause defective folding. A particularly remarkable type of protein misfolding is seen in the prion diseases (Box 4–6).
Death by Misfolding: The Prion Diseases
(continued from previous page)

heretical. All disease-causing agents known up to that time—viruses, bacteria, fungi, and so on—contained nucleic acids, and their virulence was related to genetic reproduction and propagation. However, four decades of investigations, pursued most notably by Stanley Prusiner, have provided evidence that spongiform encephalopathies are different.

The infectious agent has been traced to a single protein ($M_r 28,000$), which Prusiner dubbed prion (proteinaceous infectious only) protein (PrP). Prion protein is a normal constituent of brain tissue in all mammals. Its role is not known in detail, but it may have a molecular signaling function. Strains of mice lacking the gene for PrP (and thus the protein itself) suffer no obvious ill effects. Illness occurs only when the normal cellular PrP, or PrP$^C$, occurs in an altered conformation called PrP$^Sc$ ($Sc$ denotes scrapie). The interaction of PrP$^Sc$ with PrP$^C$ converts the latter to PrP$^Sc$, initiating a domino effect in which more and more of the brain protein converts to the disease-causing form. The mechanism by which the presence of PrP$^Sc$ leads to spongiform encephalopathy is not understood.

In inherited forms of prion diseases, a mutation in the gene encoding PrP produces a change in one amino acid residue that is believed to make the conversion of PrP$^C$ to PrP$^Sc$ more likely. A complete understanding of prion diseases awaits new information on how prion protein affects brain function. Structural information about PrP is beginning to provide insights into the molecular process that allows the prion proteins to interact so as to alter their conformation (Fig. 2).

**SUMMARY 4.4 Protein Denaturation and Folding**

- The three-dimensional structure and the function of proteins can be destroyed by denaturation, demonstrating a relationship between structure and function. Some denatured proteins can renature spontaneously to form biologically active protein, showing that tertiary structure is determined by amino acid sequence.

- Protein folding in cells probably involves multiple pathways. Initially, regions of secondary structure may form, followed by folding into supersecondary structures. Large ensembles of folding intermediates are rapidly brought to a single native conformation.

- For many proteins, folding is facilitated by Hsp70 chaperones and by chaperonins. Disulfide bond formation and the cis-trans isomerization of Pro peptide bonds are catalyzed by specific enzymes.

- Protein misfolding is the molecular basis of a wide range of human diseases, including the amyloidoses.

Further Reading

General

The author reviews his classic work on ribonuclease.

A comprehensive and authoritative source.

A collection of excellent articles on many topics, including protein structure, folding, and function.

Describes how the structure of myoglobin was determined and what was learned from it.

An outstanding summary of protein structural patterns and principles; the author originated the very useful "ribbon" representation of protein structure.

Secondary, Tertiary, and Quaternary Structures

A broad summary of the different approaches being used to catalog protein structures.

A description of how macromolecules such as proteins are crystallized.

An explanation of how structural databases can be used to explore evolution.

A good summary of the evidence leading to the prion hypothesis.

A good, approachable summary of the major ideas in the field, and some interesting speculation thrown in.

A good summary of amyloidoses.

A good review.

Problems

1. Properties of the Peptide Bond In x-ray studies of crystalline peptides, Linus Pauling and Robert Corey found that the C—N bond in the peptide link is intermediate in length (1.32 Å) between a typical C—N single bond (1.49 Å) and a C≡N double bond (1.27 Å). They also found that the peptide bond is planar (all four atoms attached to the C—N group are located in the same plane) and that the two α-carbon atoms attached to the C—N are always trans to each other (on opposite sides of the peptide bond):

(a) What does the length of the C—N bond in the peptide linkage indicate about its strength and its bond order (i.e., whether it is single, double, or triple)?

(b) What do the observations of Pauling and Corey tell us about the ease of rotation about the C—N peptide bond?

2. Structural and Functional Relationships in Fibrous Proteins William Astbury discovered that the x-ray diffraction pattern of wool shows a repeating structural unit spaced about 5.2 Å along the length of the wool fiber. When he steamed and stretched the wool, the x-ray pattern showed a new repeating structural unit at a spacing of 7.0 Å. Steaming and stretching the wool and then letting it shrink gave an x-ray pattern consistent with the original spacing of about 5.2 Å. Although these observations provided important clues to the molecular structure of wool, Astbury was unable to interpret them at the time.

A review of how variations in structural stability in one protein contribute to function.

A good summary of the evidence leading to the prion hypothesis.

A good, approachable summary of the major ideas in the field, and some interesting speculation thrown in.

A good summary of amyloidoses.

A good review.
The Three-Dimensional Structure of Proteins

(a) Given our current understanding of the structure of wool, interpret Astbury’s observations.

(b) When wool sweaters or socks are washed in hot water or heated in a dryer, they shrink. Silk, on the other hand, does not shrink under the same conditions. Explain.

3. Rate of Synthesis of Hair α-Keratin Hair grows at a rate of 15 to 20 cm/yr. All this growth is concentrated at the base of the hair fiber, where α-keratin filaments are synthesized inside living epidermal cells and assembled into ropelike structures (see Fig. 4-10). The fundamental structural element of α-keratin is the α helix, which has 3.6 amino acid residues per turn and a rise of 5.4 Å per turn (see Fig. 4-4a).
Assuming that the biosynthesis of α-helical keratin chains is the rate-limiting factor in the growth of hair, calculate the rate at which peptide bonds of α-keratin chains must be synthesized (peptide bonds per second) to account for the observed yearly growth of hair.

4. Effect of pH on the Conformation of α-Helical Secondary Structures The unfolding of the α helix of a polypeptide to a randomly coiled conformation is accompanied by a large decrease in a property called specific rotation, a measure of a solution’s capacity to rotate plane-polarized light. Polypeptide made up of only 1-Glu residues, has the α-helical conformation at pH 3.
When the pH is raised to 7, there is a large decrease in the specific rotation of the solution. Similarly, polylysine (1-Lys residues) is an α helix at pH 10, but when the pH is lowered to 7 the specific rotation also decreases, as shown by the following graph.

What is the explanation for the effect of the pH changes on the conformations of poly(Glu) and poly(Lys)? Why does the transition occur over such a narrow range of pH?

5. Disulfide Bonds Determine the Properties of Many Proteins Some natural proteins are rich in disulfide bonds, and their mechanical properties (tensile strength, viscosity, hardness, etc.) are correlated with the degree of disulfide bonding.
(a) Glutenin, a wheat protein rich in disulfide bonds, is responsible for the cohesive and elastic character of dough made from wheat flour. Similarly, the hard, tough nature of tortoise shell is due to the extensive disulfide bonding in its α-keratin. What is the molecular basis for the correlation between disulfide-bond content and mechanical properties of the protein?
(b) Most globular proteins are denatured and lose their activity when briefly heated to 65 °C. However, globular proteins that contain multiple disulfide bonds often must be heated longer at higher temperatures to denature them. One such protein is bovine pancreatic trypsin inhibitor (BPTI), which has 58 amino acid residues in a single chain and contains three disulfide bonds. On cooling a solution of denatured BPTI, the activity of the protein is restored. What is the molecular basis for this property?

6. Amino Acid Sequence and Protein Structure Our growing understanding of how proteins fold allows researchers to make predictions about protein structure based on primary amino acid sequence data. Consider the following amino acid sequence.

(a) Where might bends or β turns occur?
(b) Where might intrachain disulfide cross-links be formed?
(c) Assuming that this sequence is part of a larger globular protein, indicate the probable location (the external surface or interior of the protein) of the following amino acid residues: Asp, Ile, Thr, Ala, Gln, Lys. Explain your reasoning. (Hint: See the hydropathy index in Table 3–1.)

7. Bacteriorhodopsin in Purple Membrane Proteins Under the proper environmental conditions, the salt-loving archaean Halobacterium halobium synthesizes a membrane protein (M, 28,000) known as bacteriorhodopsin, which is purple because it contains retinal (see Fig. 10–21). Molecules of this protein aggregate into “purple patches” in the cell membrane. Bacteriorhodopsin acts as a light-activated proton pump that provides energy for cell functions. X-ray analysis of this protein reveals that it consists of seven parallel α-helical segments, each of which traverses the bacterial cell membrane (thickness 45 Å). Calculate the minimum number of amino acid residues necessary for one segment of α helix to traverse the membrane completely. Estimate the fraction of the bacteriorhodopsin protein that is involved in membrane-spanning helices. (Use an average amino acid residue weight of 110.)

8. Protein Structure Terminology Is myoglobin a motif, a domain, or a complete three-dimensional structure?

9. Pathogenic Action of Bacteria That Cause Gas Gangrene The highly pathogenic anaerobic bacterium Clostridium perfringens is responsible for gas gangrene, a condition in which animal tissue structure is destroyed. This
bacterium secretes an enzyme that efficiently catalyzes the hydrolysis of the peptide bond indicated in red:

\[
-X\rightarrow\text{Gly-Pro-Y}\rightarrow H_2O
\]

\[
-X\rightarrow\text{COO}^- + H_2N\rightarrow\text{Gly-Pro-Y}\rightarrow
\]

where X and Y are any of the 20 common amino acids. How does the secretion of this enzyme contribute to the invasiveness of this bacterium in human tissues? Why does this enzyme not affect the bacterium itself?

10. Number of Polypeptide Chains in a Multisubunit Protein
A sample (660 mg) of an oligomeric protein of Mr 132,000 was treated with an excess of 1-fluoro-2,4-dinitrobenzene (Sanger's reagent) under slightly alkaline conditions until the chemical reaction was complete. The peptide bonds of the protein were then completely hydrolyzed by heating it with concentrated HCl. The hydrolysate was found to contain 5.5 mg of the following compound:

\[
\begin{align*}
\text{O}_2\text{N} & - \text{CH}_3 \text{CH}_3 \\
\text{C}_6\text{H}_4 & - \text{NH} - \text{C}_6\text{H}_4\text{COOH}
\end{align*}
\]

2,4-Dinitrophenyl derivatives of the α-amino groups of other amino acids could not be found.

(a) Explain how this information can be used to determine the number of polypeptide chains in an oligomeric protein.
(b) Calculate the number of polypeptide chains in this protein.
(c) What other protein analysis technique could you employ to determine whether the polypeptide chains in this protein are similar or different?

11. Predicting Secondary Structure Which of the following peptides is more likely to take up an α-helical structure, and why?

(a) LKAENDEAARAMSEA
(b) CRAGGFPWDQPGTSN

12. Amyloid Fibers in Disease Several small aromatic molecules, such as phenol red (used as a nontoxic drug model), have been shown to inhibit the formation of amyloid in laboratory model systems. A goal of the research on these small aromatic compounds is to find a drug that would efficiently inhibit the formation of amyloid in the brain in people with incipient Alzheimer's disease.

(a) Suggest why molecules with aromatic substituents would disrupt the formation of amyloid.
(b) Some researchers have suggested that a drug used to treat Alzheimer's disease may also be effective in treating type 2 (adult onset) diabetes mellitus. Why might a single drug be effective in treating these two different conditions?

Biochemistry on the Internet

13. Protein Modeling on the Internet A group of patients with Crohn's disease (an inflammatory bowel disease) under-went biopsies of their intestinal mucosa in an attempt to identify the causative agent. Researchers identified a protein that was present at higher levels in patients with Crohn's disease than in patients with an unrelated inflammatory bowel disease or in unaffected controls. The protein was isolated, and the following partial amino acid sequence was obtained (reads left to right):

\[
\begin{align*}
\text{EAELCPDRCI} & \quad \text{HSFQNLIGQC} \\
\text{SQRIQTNNNP} & \quad \text{FQVP1EEQRG} \\
\text{FQVTVRDPSG} & \quad \text{RPLRPPVPCL} \\
\text{TAELKICRVPN} & \quad \text{RNSGSCLGGD} \\
\text{KEDIEYFTTG} & \quad \text{PGWEARGFSFS} \\
\text{VFRTPPYADF} & \quad \text{SLAQAPVRVSM} \\
\text{SEPMEFQYLP} & \quad \text{DITDHRRIEEMU} \\
\text{SIMKKSFPFSG} & \quad \text{PITDRPPPPRR} \\
\text{VPKPAPQYP} & \quad \text{IVAPSRSSSAS}
\end{align*}
\]

(a) You can identify this protein using a protein database on the Internet. Some good places to start include Protein Information Resource (PIR; pir.georgetown.edu), Structural Classification of Proteins (SCOP; http://scop.mrc-lmb.cam.ac.uk/scop), and Prosite (http://expasy.org/prosite).

At your selected database site, follow links to the sequence comparison engine. Enter about 30 residues from the protein sequence in the appropriate search field and submit it for analysis. What does this analysis tell you about the identity of the protein?

(b) Try using different portions of the amino acid sequence. Do you always get the same result?

(c) A variety of websites provide information about the three-dimensional structure of proteins. Find information about the protein's secondary, tertiary, and quaternary structure using database sites such as the Protein Data Bank (PDB; www.rcsb.org) or SCOP.

(d) In the course of your Web searches, what did you learn about the cellular function of the protein?

Data Analysis Problem

14. Mirror-Image Proteins As noted in Chapter 3, "The amino acid residues in protein molecules are exclusively L stereoisomers." It is not clear whether this selectivity is necessary for proper protein function or is an accident of evolution. To explore this question, Milton and colleagues (1992) published a study of an enzyme made entirely of D stereoisomers. The enzyme they chose was HIV protease, a proteolytic enzyme made by HIV that converts inactive viral pre-proteins to their active forms.

Previously, Wodawer and coworkers (1989) had reported the complete chemical synthesis of HIV protease from L-amino acids (the L-enzyme), using the process shown in Figure 3-29. Normal HIV protease contains two Cys residues at positions 67 and 95. Because chemical synthesis of proteins containing Cys is technically difficult, Wodawer and colleagues substituted the synthetic amino acid L-α-amino-n-butyric acid (Ab) for the two Cys residues in the protein. In the authors' words, this was done so as to "reduce synthetic difficulties associated with Cys protection and ease product handling."
(a) The structure of Aba is shown below. Why was this a suitable substitution for a Cys residue? Under what circumstances would it not be suitable?

\[
\begin{align*}
\text{O} & \text{C} = \text{O} \\
\text{H} & \text{C} \text{CH}_2 \text{CH}_3 \\
\text{NH}_3
\end{align*}
\]

1-α-Amino-n-butyric acid

Wlodawer and coworkers denatured the newly synthesized protein by dissolving it in 6 M guanidine HCl, and then allowed it to fold slowly by dialyzing away the guanidine against a neutral buffer (10% glycerol, 25 mM NaPO₄, pH 7).

(b) There are many reasons to predict that a protein synthesized, denatured, and folded in this manner would not be active. Give three such reasons.

(c) Interestingly, the resulting L-protease was active. What does this finding tell you about the role of disulfide bonds in the native HIV protease molecule?

In their new study, Milton and coworkers synthesized HIV protease from D-amino acids, using the same protocol as the earlier study (Wlodawer et al.). Formally, there are three possibilities for the folding of the D-protease: it would give (1) the same shape as the L-protease; (2) the mirror image of the L-protease, or (3) something else, possibly inactive.

(d) For each possibility, decide whether or not it is a likely outcome and defend your position.

In fact, the D-protease was active: it cleaved a particular synthetic substrate and was inhibited by specific inhibitors. To examine the structure of the D- and L-enzymes, Milton and coworkers tested both forms for activity with D and L forms of a chiral peptide substrate and for inhibition by D and L forms of a chiral peptide-analog inhibitor. Both forms were also tested for inhibition by the achiral inhibitor Evans blue. The findings are given in the table.

<table>

# Protein Function

## 5.1 Reversible Binding of a Protein to a Ligand: Oxygen-Binding Proteins

## 5.2 Complementary Interactions between Proteins and Ligands: The Immune System and Immunoglobulins

## 5.3 Protein Interactions Modulated by Chemical Energy: Actin, Myosin, and Molecular Motors

Knowing the three-dimensional structure of a protein is an important part of understanding how the protein functions. However, the structure shown in two dimensions on a page is deceptively static. Proteins are dynamic molecules whose functions almost invariably depend on interactions with other molecules, and these interactions are affected in physiologically important ways by sometimes subtle, sometimes striking changes in protein conformation. In this chapter, we explore how proteins interact with other molecules and how their interactions are related to dynamic protein structure. The importance of molecular interactions to a protein’s function can hardly be overemphasized. In Chapter 4, we saw that the function of fibrous proteins as structural elements of cells and tissues depends on stable, long-term quaternary interactions between identical polypeptide chains. As we shall see in this chapter, the functions of many other proteins involve interactions with a variety of different molecules. Most of these interactions are fleeting, though they may be the basis of complex physiological processes such as oxygen transport, immune function, and muscle contraction—the topics we examine in this chapter. The proteins that carry out these processes illustrate the following key principles of protein function, some of which will be familiar from the previous chapter:

The functions of many proteins involve the reversible binding of other molecules. A molecule bound reversibly by a protein is called a ligand. A ligand may be any kind of molecule, including another protein. The transient nature of protein-ligand interactions is critical to life, allowing an organism to respond rapidly and reversibly to changing environmental and metabolic circumstances.

A ligand binds at a site on the protein called the binding site, which is complementary to the ligand in size, shape, charge, and hydrophobic or hydrophilic character. Furthermore, the interaction is specific: the protein can discriminate among the thousands of different molecules in its environment and selectively bind only one or a few. A given protein may have separate binding sites for several different ligands. These specific molecular interactions are crucial in maintaining the high degree of order in a living system. (This discussion excludes the binding of water, which may interact weakly and nonspecifically with many parts of a protein. In Chapter 6, we consider water as a specific ligand for many enzymes.)

Proteins are flexible. Changes in conformation may be subtle, reflecting molecular vibrations and small movements of amino acid residues throughout the protein. A protein flexing in this way is sometimes said to “breathe.” Changes in conformation may also be quite dramatic, with major segments of the protein structure moving as much as several nanometers. Specific conformational changes are frequently essential to a protein’s function.

The binding of a protein and ligand is often coupled to a conformational change in the protein that makes the binding site more complementary to the ligand, permitting tighter binding. The structural adaptation that occurs between protein and ligand is called induced fit.

In a multisubunit protein, a conformational change in one subunit often affects the conformation of other subunits.

Interactions between ligands and proteins may be regulated, usually through specific interactions with one or more additional ligands. These other ligands may cause conformational changes in the protein that affect the binding of the first ligand.
Enzymes represent a special case of protein function. Enzymes bind and chemically transform other molecules—they catalyze reactions. The molecules acted upon by enzymes are called reaction *substrates* rather than ligands, and the ligand-binding site is called the *catalytic site* or *active site*. In this chapter, we emphasize the noncatalytic functions of proteins. In Chapter 6, we consider catalysis by enzymes, a central topic in biochemistry. You will see that the themes of this chapter—binding, specificity, and conformational change—are continued in the next chapter, with the added element of proteins participating in chemical transformations.

### 5.1 Reversible Binding of a Protein to a Ligand: Oxygen-Binding Proteins

Myoglobin and hemoglobin may be the most-studied and best-understood proteins. They were the first proteins for which three-dimensional structures were determined, and these two molecules illustrate almost every aspect of that most central of biochemical processes: the reversible binding of a ligand to a protein. This classic model of protein function tells us a great deal about how proteins work.

**Oxygen-Binding Proteins—Myoglobin:**

**Oxygen Storage**

Oxygen can bind to a heme prosthetic group. Oxygen is poorly soluble in aqueous solutions (see Table 2-3) and cannot be carried to tissues in sufficient quantity if it is simply dissolved in blood serum. Diffusion of oxygen through tissues is also ineffective over distances greater than a few millimeters. The evolution of larger, multicellular animals depended on the evolution of proteins that could transport and store oxygen. However, none of the amino acid side chains in proteins are suited for the reversible binding of oxygen molecules. This role is filled by certain transition metals, among them iron and copper, that have a strong tendency to bind oxygen. Multicellular organisms exploit the properties of metals, most commonly iron, for oxygen transport. However, free iron promotes the formation of highly reactive oxygen species such as hydroxyl radicals that can damage DNA and other macromolecules. Iron used in cells is therefore bound in forms that sequester it and/or make it less reactive. In multicellular organisms—especially those in which iron, in its oxygen-carrying capacity, must be transported over large distances—iron is often incorporated into a protein-bound prosthetic group called heme (or haem). (Recall from Chapter 3 that a prosthetic group is a compound permanently associated with a protein that contributes to the protein’s function.)

Heme consists of a complex organic ring structure, protoporphyrin, to which is bound a single iron atom in its ferrous (Fe$^{2+}$) state (Fig. 5-1). The iron atom has six coordination bonds, four to nitrogen atoms that are part of the flat porphyrin ring system and two perpendicular to it. The coordinated nitrogen atoms (which have an electron-donating character) help prevent conversion of the heme iron to the ferric (Fe$^{3+}$) state. Iron in the Fe$^{3+}$ state binds oxygen reversibly; in the Fe$^{2+}$ state it does not bind oxygen. Heme is found in many oxygen-transporting proteins, as well as in some proteins, such as the cytochromes, that participate in oxidation-reduction (electron-transfer) reactions (Chapter 19).

Free heme molecules (heme not bound to protein) leave Fe$^{2+}$ with two “open” coordination bonds. Simultaneous reaction of one O$_2$ molecule with two free heme molecules (or two free Fe$^{2+}$) can result in irreversible conversion of Fe$^{2+}$ to Fe$^{3+}$. In heme-containing proteins, this reaction is prevented by sequestering each heme deep within the protein structure. Thus, access to

**FIGURE 5-1 Heme.** The heme group is present in myoglobin, hemoglobin, and many other proteins, designated heme proteins. Heme consists of a complex organic ring structure, protoporphyrin IX, with a bound iron atom in its ferrous (Fe$^{2+}$) state. (a) Porphyrins, of which protoporphyrin IX is only one example, consist of four pyrrole rings linked by methene bridges, with substitutions at one or more of the positions denoted X. (b, c) Two representations of heme (derived from PDB ID 1CCR). The iron atom of heme has six coordination bonds: four in the plane of, and bonded to, the flat porphyrin ring system, and (d) two perpendicular to it.
5.1 Reversible Binding of a Protein to a Ligand: Oxygen-Binding Proteins

The heme group viewed from the side. This view shows the two coordination bonds to Fe²⁺ that are perpendicular to the porphyrin ring system. One is occupied by a His residue, sometimes called the proximal His; the other is the binding site for oxygen. The remaining four coordination bonds are in the plane of, and bonded to, the flat porphyrin ring system.

the two open coordination bonds is restricted. One of these two coordination bonds is occupied by a side-chain nitrogen of a His residue. The other is the binding site for molecular oxygen (O₂) (Fig. 5-2). When oxygen binds, the electronic properties of heme iron change; this accounts for the change in color from the dark purple of oxygen-depleted venous blood to the bright red of oxygen-rich arterial blood. Some small molecules, such as carbon monoxide (CO) and nitric oxide (NO), coordinate to heme iron with greater affinity than does O₂. When a molecule of CO is bound to heme, O₂ is excluded, which is why CO is highly toxic to aerobic organisms (a topic explored later, in Box 5-1). By surrounding and sequestering heme, oxygen-binding proteins regulate the access of CO and other small molecules to the heme iron.

Myoglobin Has a Single Binding Site for Oxygen

Myoglobin (Mr 16,700; abbreviated Mb) is a relatively simple oxygen-binding protein found in almost all mammals, primarily in muscle tissue. As a transport protein, it facilitates oxygen diffusion in muscle. Myoglobin is particularly abundant in the muscles of diving mammals such as seals and whales, where it also has an oxygen-storage function for prolonged excursions undersea. Proteins very similar to myoglobin are widely distributed, occurring even in some single-celled organisms.

Myoglobin is a single polypeptide of 153 amino acid residues with one molecule of heme. It is typical of the family of proteins called globins, all of which have similar primary and tertiary structures. The polypeptide is made up of eight α-helical segments connected by bends (Fig. 5-3). About 78% of the amino acid residues in the protein are found in these α helices.

Any detailed discussion of protein function inevitably involves protein structure. In the case of myoglobin, we first introduce some structural conventions peculiar to globins. As seen in Figure 5-3, the helical segments are named A through H. An individual amino acid residue is designated either by its position in the amino acid sequence or by its location in the sequence of a particular α-helical segment. For example, the His residue coordinated to the heme in myoglobin, His93 (the 93rd residue from the amino-terminal end of the myoglobin polypeptide sequence), is also called His F8 (the 8th residue in α helix F).

Protein-Ligand Interactions Can Be Described Quantitatively

The function of myoglobin depends on the protein’s ability not only to bind oxygen but also to release it when and where it is needed. Function in biochemistry often revolves around a reversible protein-ligand interaction of this type. A quantitative description of this interaction is therefore a central part of many biochemical investigations.

In general, the reversible binding of a protein (P) to a ligand (L) can be described by a simple equilibrium expression:

\[ P + L \rightleftharpoons PL \]  

The reaction is characterized by an equilibrium constant, \( K_a \), such that

\[ K_a = \frac{[PL]}{[P][L]} = \frac{k_a}{k_d} \]
where $k_a$ and $k_d$ are rate constants (more on these below). The term $K_a$ is an association constant (not to be confused with the $K_a$ that denotes an acid dissociation constant; p. 58) that describes the equilibrium between the complex and the unbound components of the complex. The association constant provides a measure of the affinity of the ligand $L$ for the protein. $K_a$ has units of $M^{-1}$; a higher value of $K_a$ corresponds to a higher affinity of the ligand for the protein.

The equilibrium term $K_a$ is also equivalent to the ratio of the rates of the forward (association) and reverse (dissociation) reactions that form the PL complex. The association rate is described by a rate constant $k_a$, and dissociation by the rate constant $k_d$. As discussed further in the next chapter, rate constants are proportionality constants, describing the fraction of a pool of reactant that reacts in a given amount of time. When the reaction involves one molecule, such as the dissociation reaction $PL \rightarrow P + L$, the reaction is first order and the rate constant ($k_d$) has units of reciprocal time ($s^{-1}$). When the reaction involves two molecules, such as the association reaction $P + L \rightarrow PL$, it is called second order, and its rate constant ($k_a$) has units of $M^{-1} s^{-1}$.

**KEY CONVENTION:** Equilibrium constants are denoted with a capital $K$ and rate constants with a lower case $k$.

A rearrangement of the first part of Equation 5-2 shows that the ratio of bound to free protein is directly proportional to the concentration of free ligand:

$$K_a[L] = \frac{[PL]}{[P]}$$

(5-3)

When the concentration of the ligand is much greater than the concentration of ligand-binding sites, the binding of the ligand by the protein does not appreciably change the concentration of free (unbound) ligand—that is, $[L]$ remains constant. This condition is broadly applicable to most ligands that bind to proteins in cells and simplifies our description of the binding equilibrium.

We can now consider the binding equilibrium from the standpoint of the fraction, $\theta$ (theta), of ligand-binding sites on the protein that are occupied by ligand:

$$\theta = \frac{\text{binding sites occupied}}{\text{total binding sites}} = \frac{[PL]}{[PL] + [P]}$$

(5-4)

Substituting $K_a[L][P]$ for $[PL]$ (see Eqn 5-3) and rearranging terms gives

$$\theta = \frac{K_a[L][P]}{K_a[L][P] + [P]} = K_a[L][P] + 1 = \frac{[L]}{[L] + \frac{1}{K_a}}$$

(5-5)

The value of $K_a$ can be determined from a plot of $\theta$ versus the concentration of free ligand, $[L]$ (Fig. 5-4a). Any equation of the form $x = y/(y + z)$ describes a hyperbola, and $\theta$ is thus found to be a hyperbolic function of $[L]$. The fraction of ligand-binding sites occupied approaches saturation asymptotically as $[L]$ increases. The

![Figure 5-4 Graphical representations of ligand binding.](image)

**FIGURE 5-4** Graphical representations of ligand binding. The fraction of ligand-binding sites occupied, $\theta$, is plotted against the concentration of free ligand. Both curves are rectangular hyperbolas. (a) A hypothetical binding curve for a ligand $L$. The $[L]$ at which half of the available ligand-binding sites are occupied is equivalent to $1/K_a$ or $K_d$. The curve has a horizontal asymptote at $\theta = 1$ and a vertical asymptote (not shown) at $[L] = -1/K_a$. (b) A curve describing the binding of oxygen to myoglobin. The partial pressure of $O_2$ in the air above the solution is expressed in kilopascals (kPa). Oxygen binds tightly to myoglobin, with a $P_{50}$ of only 0.26 kPa.

When $[L]$ equals $K_a$, half of the available ligand-binding sites are occupied (that is, $\theta = 0.5$) corresponds to $1/K_a$.

It is more common (and intuitively simpler), however, to consider the dissociation constant, $K_d$, which is the reciprocal of $K_a$ ($K_d = 1/K_a$) and is given in units of molar concentration (M). $K_d$ is the equilibrium constant for the release of ligand. The relevant expressions change to

$$K_d = \frac{[P][L]}{[PL]} = \frac{k_d}{k_a}$$

(5-6)

$$[PL] = \frac{[P][L]}{K_d}$$

(5-7)

$$\theta = \frac{[L]}{[L] + K_d}$$

(5-8)

When $[L]$ equals $K_d$, half of the ligand-binding sites are occupied. As $[L]$ falls below $K_d$, progressively less of the protein has ligand bound to it. In order for 90% of the available ligand-binding sites to be occupied, $[L]$ must be nine times greater than $K_d$.

In practice, $K_d$ is used much more often than $K_a$ to express the affinity of a protein for a ligand. Note that a lower value of $K_d$ corresponds to a higher affinity of ligand for the protein. The mathematics can be reduced to simple statements: $K_d$ is equivalent to the molar

- Biotin-avidin
- Antibody-antigen
- Enzyme-substrate

Color bars indicate the range of dissociation constants typical of various classes of interactions in biological systems. A few interactions, such as that between the protein avidin and the enzyme cofactor biotin, fall outside the normal ranges. The avidin-biotin interaction is so tight it may be considered irreversible.

Sequence-specific protein-DNA interactions reflect proteins that bind to a particular sequence of nucleotides in DNA, as opposed to general binding to any DNA site.

Some representative dissociation constants are given in Table 5-1; the scale shows typical ranges for dissociation constants found in biological systems.

Concentration of ligand at which half of the available ligand-binding sites are occupied. At this point, the protein is said to have reached half-saturation with respect to ligand binding. The more tightly a protein binds a ligand, the lower the concentration of ligand required for half the binding sites to be occupied, and thus the lower the value of $K_d$. Some representative dissociation constants are given in Table 5-1; the scale shows typical ranges for dissociation constants found in biological systems.

**Worked Example 5-1: Receptor-Ligand Dissociation Constants**

Two proteins, X and Y, bind to the same ligand, A, with the binding curves shown below.

What is the dissociation constant, $K_d$, for each protein? Which protein (X or Y) has a greater affinity for ligand A?

**Solution:** We can determine the dissociation constants by inspecting the graph. Since $\theta$ represents the fraction of binding sites occupied by ligand, the concentration of ligand at which half the binding sites are occupied—that is, the point where the binding curve crosses the line where $\theta = 0.5$—is the dissociation constant. For X, $K_d = 2 \mu M$; for Y, $K_d = 6 \mu M$. Because X is half-saturated at a lower [A], it has a higher affinity for the ligand.

The binding of oxygen to myoglobin follows the patterns discussed above. However, because oxygen is a gas, we must make some minor adjustments to the equations so that laboratory experiments can be carried out more conveniently. We first substitute the concentration of dissolved oxygen for [L] in Equation 5-8 to give

$$\theta = \frac{[O_2]}{[O_2] + K_d}$$

As for any ligand, $K_d$ equals the [O$_2$] at which half of the available ligand-binding sites are occupied, or [O$_2$]$_{0.5}$. Equation 5-9 thus becomes

$$\theta = \frac{[O_2]}{[O_2] + [O_2]_{0.5}}$$  

(5-10)
In experiments using oxygen as a ligand, it is the partial pressure of oxygen \( (pO_2) \) in the gas phase above the solution that is varied, because this is easier to measure than the concentration of oxygen dissolved in the solution. The concentration of a volatile substance in solution is always proportional to the local partial pressure of the gas. So, if we define the partial pressure of oxygen at \( [O_2]_{1/2} \) as \( P_{50} \), substitution in Equation 5-10 gives

\[
\theta = \frac{pO_2}{pO_2 + P_{50}}
\]

(5-11)

A binding curve for myoglobin that relates \( \theta \) to \( pO_2 \) is shown in Figure 5-4b.

Protein Structure Affects How Ligands Bind

The binding of a ligand to a protein is rarely as simple as the above equations would suggest. The interaction is greatly affected by protein structure and is often accompanied by conformational changes. For example, the specificity with which heme binds its various ligands is altered when the heme is a component of myoglobin. Carbon monoxide binds to free heme molecules more than 20,000 times better than does \( O_2 \) (that is, the \( K_d \) or \( P_{50} \) for CO binding to free heme is more than 20,000 times lower than that for \( O_2 \)), but it binds only about 200 times better than \( O_2 \) when the heme is bound in myoglobin. The difference may be partly explained by steric hindrance. When \( O_2 \) binds to free heme, the axis of the oxygen molecule is positioned at an angle to the Fe-O bond (Fig. 5-5a). In contrast, when CO binds to free heme, the Fe, C, and O atoms lie in a straight line (Fig. 5-5b). In both cases, the binding reflects the geometry of hybrid orbitals in each ligand. In myoglobin, His\(^{64} \) (His E7), on the \( O_2 \)-binding side of the heme, is too far away to coordinate with the heme iron, but it does interact with a ligand bound to heme. This residue, called the distal His (as distinct from the proximal His, His F8), forms a hydrogen bond with \( O_2 \) (Fig. 5-5c) but may preclude the linear binding of CO, providing one explanation for the selectively diminished binding of CO to heme in myoglobin (and hemoglobin). A reduction in CO binding is physiologically important, because CO is a low-level byproduct of cellular metabolism. Other factors, not yet well-defined, also may modulate the interaction of heme with CO in these proteins.

The binding of \( O_2 \) to the heme in myoglobin also depends on molecular motions, or “breathing,” in the protein structure. The heme molecule is deeply buried in the folded polypeptide, with no direct path for oxygen to move from the surrounding solution to the ligand-binding site. If the protein were rigid, \( O_2 \) could not enter or leave the heme pocket at a measurable rate. However, rapid molecular flexing of the amino acid side chains produces transient cavities in the protein structure, and \( O_2 \) makes its way in and out by moving through these cavities. Computer simulations of rapid structural fluctuations in myoglobin suggest that there are many such pathways.

One major route is provided by rotation of the side chain of the distal His (His\(^{64} \)), which occurs on a nanosecond \( (10^{-9} \) s) time scale. Even subtle conformational changes can be critical for protein activity.

Hemoglobin Transports Oxygen in Blood

Nearly all the oxygen carried by whole blood in animals is bound and transported by hemoglobin in erythrocytes (red blood cells). Normal human erythrocytes are small (6 to 9 \( \mu \)m in diameter), biconcave disks. They are formed from precursor stem cells called hemocytoblasts. In the maturation process, the stem cell produces daughter cells that form large amounts of hemoglobin and then lose their intracellular organelles—nucleus, mitochondria, and endoplasmic reticulum. Erythrocytes are thus incomplete, vestigial cells, unable to reproduce and, in humans, destined to survive for
only about 120 days. Their main function is to carry hemoglobin, which is dissolved in the cytosol at a very high concentration (~34% by weight).

In arterial blood passing from the lungs through the heart to the peripheral tissues, hemoglobin is about 96% saturated with oxygen. In the venous blood returning to the heart, hemoglobin is only about 64% saturated. Thus, each 100 mL of blood passing through a tissue releases about one-third of the oxygen it carries, or 6.5 mL of O2 gas at atmospheric pressure and body temperature.

Myoglobin, with its hyperbolic binding curve for oxygen (Fig. 5–4b), is relatively insensitive to small changes in the concentration of dissolved oxygen and so functions well as an oxygen-storage protein. Hemoglobin, with its multiple subunits and O2-binding sites, is better suited to oxygen transport. As we shall see, interactions between the subunits of a multimeric protein can permit a highly sensitive response to small changes in ligand concentration. Interactions among the subunits in hemoglobin cause conformational changes that alter the affinity of the protein for oxygen. The modulation of oxygen binding allows the O2-transport protein to respond to changes in oxygen demand by tissues.

Hemoglobin Subunits Are Structurally Similar to Myoglobin

Hemoglobin (Mr 64,500; abbreviated Hb) is roughly spherical, with a diameter of nearly 5.5 nm. It is a tetrameric protein containing four heme prosthetic groups, one associated with each polypeptide chain. Adult hemoglobin contains two types of globin, two α chains (141 residues each) and two β chains (146 residues each). Although fewer than half of the amino acid residues are identical in the polypeptide sequences of the α and β subunits, the three-dimensional structures of the two types of subunits are very similar. Furthermore, their structures are very similar to that of myoglobin (Fig. 5–6), even though the amino acid sequences of the three polypeptides are identical at only 27 positions (Fig. 5–7). All three polypeptides are

![Heme group](image)

**FIGURE 5–6** Comparison of the structures of myoglobin (PDB ID 1MB0) and the β subunit of hemoglobin (derived from PDB ID 1HGA).

![Myoglobin](image)

**FIGURE 5–7** The amino acid sequences of whale myoglobin and the α and β chains of human hemoglobin. Dashed lines mark helix boundaries. To align the sequences optimally, short gaps must be introduced into both Hb sequences where a few amino acids are present in the other, compared sequences. With the exception of the missing D helix in Hb β, this alignment permits the use of the helix lettering convention that emphasizes the common positioning of amino acid residues that are identical in all three structures (shaded). Residues shaded in pink are conserved in all known globins. Note that the common helix-letter-and-number designation for amino acids does not necessarily correspond to a common position in the linear sequence of amino acids in the polypeptides. For example, the distal His residue is His E7 in all three structures, but corresponds to His 15′, His 15′′, and His 15′ in the linear sequences of Mb, Hbα, and Hbβ, respectively. Nonhelical residues at the amino and carboxyl termini, beyond the first (A) and last (H) α-helical segments, are labeled NA and HC, respectively.
Protein Function

Figure 5-8 Dominant interactions between hemoglobin subunits.

In this representation, α subunits are light and β subunits are dark. The strongest subunit interactions (highlighted) occur between unlike subunits. When oxygen binds, the α1β1 contact changes little, but there is a large change at the α1β2 contact, with several ion pairs broken (PDB ID 1HCA).

Members of the globin family of proteins. The helix-naming convention described for myoglobin is also applied to the hemoglobin polypeptides, except that the α subunit lacks the short D helix. The heme-binding pocket is made up largely of the E and F helices in each of the subunits.

The quaternary structure of hemoglobin features strong interactions between unlike subunits. The α1β1 interface (and its α2β2 counterpart) involves more than 30 residues, and its interaction is sufficiently strong that although mild treatment of hemoglobin with urea tends to disassemble the tetramer into αβ dimers, these dimers remain intact. The α1β2 (and α2β1) interface involves 19 residues (Fig. 5-8). Hydrophobic interactions predominate at all the interfaces, but there are also many hydrogen bonds and a few ion pairs (or salt bridges), whose importance is discussed below.

Hemoglobin Undergoes a Structural Change on Binding Oxygen

X-ray analysis has revealed two major conformations of hemoglobin: the R state and the T state. Although oxygen binds to hemoglobin in either state, it has a significantly higher affinity for hemoglobin in the R state. Oxygen binding stabilizes the R state. When oxygen is absent experimentally, the T state is more stable and is thus the predominant conformation of deoxyhemoglobin. T and R originally denoted "tense" and "relaxed," respectively, because the T state is stabilized by a greater number of ion pairs, many of which lie at the α1β2 (and α2β1) interface (Fig. 5-9). The binding of O2 to a hemoglobin subunit in the T state triggers a change in conformation to the R state. When the entire protein undergoes this transition, the structures of the individual subunits change little, but the αβ subunit pairs slide past each other and rotate, narrowing the pocket between the β subunits (Fig. 5-10). In this process, some of the ion pairs that stabilize the T state are broken and some new ones are formed.

Max Perutz proposed that the T → R transition is triggered by changes in the positions of key amino acid side chains surrounding the heme. In the T state, the porphyrin is slightly puckered, causing the heme iron to protrude somewhat on the proximal His (His F8) side. The binding of O2 causes the heme to assume a more planar conformation, shifting the position of the proximal His and the attached F helix (Fig. 5-11). These changes lead to adjustments in the ion pairs at the α1β2 interface.

Hemoglobin Binds Oxygen Cooperatively

Hemoglobin must bind oxygen efficiently in the lungs, where the pO2 is about 13.3 kPa, and release oxygen in the tissues, where the pO2 is about 4 kPa. Myoglobin, or
The T → R transition. (PDB ID 1HGA and 1BBB) In these depictions of deoxyhemoglobin, as in Figure 5–9, the β subunits are blue and the α subunits are gray. Positively charged side chains and chain termini involved in ion pairs are shown in blue, their negatively charged partners in red. The Lys C5 of each α subunit and Asp F4L of each β subunit are visible but not labeled (compare Fig. 5–9a). Note that the molecule is oriented slightly differently than in Figure 5–9. The transition from the T state to the R state shifts the subunit pairs substantially, affecting certain ion pairs. Most noticeably, the His HC3 residues at the carboxyl termini of the β subunits, which are involved in ion pairs in the T state, rotate in the R state toward the center of the molecule, where they are no longer in ion pairs. Another dramatic result of the T → R transition is a narrowing of the pocket between the β subunits.

Changes in conformation near heme on O₂ binding to deoxyhemoglobin. (Derived from PDB ID 1HGA and 1BBB) The shift in the position of helix F when heme binds O₂ is thought to be one of the adjustments that triggers the T → R transition.

any protein that binds oxygen with a hyperbolic binding curve, would be ill-suited to this function, for the reason illustrated in Figure 5–12. A protein that bound O₂ with high affinity would bind it efficiently in the lungs but would not release much of it in the tissues. If the protein bound oxygen with a sufficiently low affinity to release it in the tissues, it would not pick up much oxygen in the lungs.

Hemoglobin solves the problem by undergoing a transition from a low-affinity state (the T state) to a high-affinity state (the R state) as more O₂ molecules are bound. As a result, hemoglobin has a hybrid S-shaped, or sigmoid, binding curve for oxygen (Fig. 5–12). A single-subunit protein with a single ligand-binding site cannot produce a sigmoid binding curve—even if binding elicits a conformational change—because each molecule of ligand binds independently and cannot affect ligand binding to another molecule. In contrast, O₂ binding to individual subunits of hemoglobin can alter

A sigmoid (cooperative) binding curve. A sigmoid binding curve can be viewed as a hybrid curve reflecting a transition from a low-affinity to a high-affinity state. Because of its cooperative binding, as manifested by a sigmoid binding curve, hemoglobin is more sensitive to the small differences in O₂ concentration between the tissues and the lungs, allowing it to bind oxygen in the lungs (where pO₂ is high) and release it in the tissues (where pO₂ is low).
the affinity for \( O_2 \) in adjacent subunits. The first molecule of \( O_2 \) that interacts with deoxyhemoglobin binds weakly, because it binds to a subunit in the T state. Its binding, however, leads to conformational changes that are communicated to adjacent subunits, making it easier for additional molecules of \( O_2 \) to bind. In effect, the \( T \rightarrow R \) transition occurs more readily in the second subunit once \( O_2 \) is bound to the first subunit. The last (fourth) \( O_2 \) molecule binds to a heme in a subunit that is already in the R state, and hence it binds with much higher affinity than the first molecule.

An **allosteric protein** is one in which the binding of a ligand to one site affects the binding properties of another site on the same protein. The term “allosteric” derives from the Greek *allo*, “other,” and *stereos*, “solid” or “shape.” Allosteric proteins are those having “other shapes,” or conformations, induced by the binding of ligands referred to as modulators. The conformational changes induced by the modulator(s) interconvert more-active and less-active forms of the protein. The modulators for allosteric proteins may be either inhibitors or activators. When the normal ligand and modulator are identical, the interaction is termed **homotropic**. When the modulator is a molecule other than the normal ligand, the interaction is **heterotropic**. Some proteins have two or more modulators and therefore can have both homotropic and heterotropic interactions.

Cooperative binding of a ligand to a multimeric protein, such as we observe with the binding of \( O_2 \) to hemoglobin, is a form of allosteric binding. The binding of one ligand affects the affinities of any remaining unfilled binding sites, and \( O_2 \) can be considered as both a ligand and an activating homotropic modulator. There is only one binding site for \( O_2 \) on each subunit, so the allosteric effects giving rise to cooperativity are mediated by conformational changes transmitted from one subunit to another by subunit-subunit interactions. A sigmoid binding curve is diagnostic of cooperative binding. It permits a much more sensitive response to ligand concentration and is important to the function of many multisubunit proteins. The principle of allostery extends readily to regulatory enzymes, as we shall see in Chapter 6.

Cooperative conformational changes depend on variations in the structural stability of different parts of a protein, as described in Chapter 4. The binding sites of an allosteric protein typically consist of stable segments in proximity to relatively unstable segments, with the latter capable of frequent changes in conformation or disorganized motion (Fig. 5-13). When a ligand binds, the moving parts of the protein’s binding site may be stabilized in a particular conformation, affecting the conformation of adjacent polypeptide subunits. If the entire binding site were highly stable, then few structural changes could occur in this site or be propagated to other parts of the protein when a ligand binds.

As is the case with myoglobin, ligands other than oxygen can bind to hemoglobin. An important example is carbon monoxide, which binds to hemoglobin about 250 times better than does oxygen. Human exposure to CO can have tragic consequences (Box 5-1).

**Cooperative Ligand Binding Can Be Described Quantitatively**

Cooperative binding of oxygen by hemoglobin was first analyzed by Archibald Hill in 1910. From this work came a general approach to the study of cooperative ligand binding to multisubunit proteins.

For a protein with \( n \) binding sites, the equilibrium of Equation 5-1 becomes

\[
P + nL \rightleftharpoons PL_n
\]

and the expression for the association constant becomes

\[
K_a = \frac{[PL_n]}{[P][L]^n}
\]
Lake Powell, Arizona, August 2000. A family was vacationing in a rented houseboat. They turned on the electrical generator to power an air conditioner and a television. About 15 minutes later, two brothers, aged 8 and 11, jumped off the swim deck at the stern. Situated immediately below the deck was the exhaust port for the generator. Within two minutes, both boys were overcome by the carbon monoxide in the exhaust, which had become concentrated in the space under the deck. Both drowned. These deaths, along with a series of deaths in the 1990s that were linked to houseboats of similar design, eventually led to the recall and redesign of the generator exhaust assembly.

Carbon monoxide (CO), a colorless, odorless gas, is responsible for more than half of yearly deaths due to poisoning worldwide. CO has an approximately 250-fold greater affinity for hemoglobin than does oxygen. Consequently, relatively low levels of CO can have substantial and tragic effects. When CO combines with hemoglobin, the complex is referred to as carboxyhemoglobin, or COHb.

Some CO is produced by natural processes, but locally high levels generally result only from human activities. Engine and furnace exhausts are important sources, as CO is a byproduct of the incomplete combustion of fossil fuels. In the United States alone, nearly 4,000 people succumb to CO poisoning each year, both accidentally and intentionally. Many of the accidental deaths involve undetected CO buildup in enclosed spaces, such as when a household furnace malfunctions or leaks, venting CO into a home. However, CO poisoning can also occur in open spaces, as unsuspecting people at work or play inhale the exhaust from generators, outboard motors, tractor engines, recreational vehicles, or lawn mowers.

Carbon monoxide levels in the atmosphere are rarely dangerous, ranging from less than 0.05 parts per million (ppm) in remote and uninhabited areas to 3 to 4 ppm in some cities of the northern hemisphere. In the United States, the government-mandated (Occupational Safety and Health Administration, OSHA) limit for CO at worksites is 50 ppm for people working an eight-hour shift. The tight binding of CO to hemoglobin means that COHb can accumulate over time as people are exposed to a constant low-level source of CO.

In an average, healthy individual, 1% or less of the total hemoglobin is complexed as COHb. Since CO is a product of tobacco smoke, many smokers have COHb levels in the range of 3% to 8% of total hemoglobin, and the levels can rise to 15% for chain-smokers. COHb levels equilibrate at 50% in people who breathe air containing 570 ppm of CO for several hours. Reliable methods have been developed that relate CO content in the atmosphere to COHb levels in the blood (Fig. 1). In tests of houseboats with a generator exhaust like the one responsible for the Lake Powell deaths, CO levels reached 6,000 to 30,000 ppm under the swim deck, and atmospheric O2 levels under the deck declined from 21% to 12%. Even above the swim deck, CO levels of up to 7,200 ppm were detected, high enough to cause death within a few minutes.

How is a human affected by COHb? At levels of less than 10% of total hemoglobin, symptoms are rarely observed. At 15%, the individual experiences mild headaches. At 20% to 30%, the headache is severe and is generally accompanied by nausea, dizziness, confusion, disorientation, and some visual disturbances; these symptoms are generally reversed if the individual is treated with oxygen. At COHb levels of 30% to 50%, the neurological symptoms become more severe, and at levels near 50%, the individual loses consciousness and can sink into coma. Respiratory failure may follow. With prolonged exposure, some damage becomes permanent. Death normally occurs when COHb levels rise above 60%. Autopsy on the boys who died at Lake Powell revealed COHb levels of 59% and 62%.

Binding of CO to hemoglobin is affected by many factors, including exercise (Fig. 1) and changes in air pressure related to altitude. Because of their higher base levels of COHb, smokers exposed to a source of CO often develop symptoms faster than nonsmokers. Individuals with heart, lung, or blood diseases that reduce the availability of oxygen to tissues may also experience symptoms at lower levels of CO exposure. Fetuses are at particular risk for CO poisoning, because fetal hemoglobin has a somewhat higher affinity for CO than adult hemoglobin. Cases of CO exposure have been recorded in which the fetus died but the mother recovered.

(continued on next page)
It may seem surprising that the loss of half of one's hemoglobin to COHb can prove fatal—we know that people with any of several anemic conditions manage to function reasonably well with half the usual complement of active hemoglobin. However, the binding of CO to hemoglobin does more than remove protein from the pool available to bind oxygen. It also affects the affinity of the remaining hemoglobin subunits for oxygen. As CO binds to one or two subunits of a hemoglobin tetramer, the affinity for O2 is increased substantially in the remaining subunits (Fig. 2). Thus, a hemoglobin tetramer with two bound CO molecules can efficiently bind O2 in the lungs—but it releases very little of it in the tissues. Oxygen deprivation in the tissues rapidly becomes severe. To add to the problem, the effects of CO are not limited to interference with hemoglobin function. CO binds to other heme proteins and a variety of metalloproteins. The effects of these interactions are not yet well understood, but they may be responsible for some of the longer-term effects of acute but nonfatal CO poisoning.

When CO poisoning is suspected, rapid evacuation of the person away from the CO source is essential, but this does not always result in rapid recovery. When an individual is moved from the CO-polluted site to a normal, outdoor atmosphere, O2 begins to replace the CO in hemoglobin—but the COHb levels drop only slowly. The half-time is 2 to 6.5 hours, depending on individual and environmental factors. If 100% oxygen is administered with a mask, the rate of exchange can be increased about fourfold; the half-time for O2-CO exchange can be reduced to tens of minutes if 100% oxygen at a pressure of 3 atm (303 kPa) is supplied. Thus, rapid treatment by a properly equipped medical team is critical.

Carbon monoxide detectors in all homes are highly recommended. This is a simple and inexpensive measure to avoid possible tragedy. After completing the research for this box, we immediately purchased several new CO detectors for our homes.

The expression for \( \theta \) (see Eqn 5–8) is

\[
\theta = \frac{[L]^n}{[L]^n + K_d} \tag{5-14}
\]

Rearranging, then taking the log of both sides, yields

\[
\log \left( \frac{\theta}{1 - \theta} \right) = n \log [L] - \log K_d \tag{5-15}
\]

where \( K_d = [L]_{50}^4 \).

Equation 5–16 is the Hill equation, and a plot of \( \log [\theta/(1 - \theta)] \) versus \( \log [L] \) is called a Hill plot. Based on the equation, the Hill plot should have a slope of \( n \). However, the experimentally determined slope actually reflects not the number of binding sites but the degree of interaction between them. The slope of a Hill plot is therefore denoted by \( n_H \), the Hill coefficient, which is a measure of the degree of cooperativity. If \( n_H \) equals 1, ligand binding is not cooperative, a situation that can arise even in a multisubunit protein if the subunits do not communicate. An \( n_H \) of greater than 1 indicates positive cooperativity in ligand binding. This is the situation observed in hemoglobin, in which the binding of one molecule of ligand facilitates the binding of others. The theoretical upper limit for \( n_H \) is reached when \( n_H = n \). In this case the binding would be completely cooperative: all binding sites on the protein would bind ligand simultaneously, and no protein molecules partially saturated with ligand would be present under any conditions. This limit is never reached in practice, and the measured value of \( n_H \) is always less than the actual number of ligand-binding sites in the protein.

An \( n_H \) of less than 1 indicates negative cooperativity, in which the binding of one molecule of ligand impedes the binding of others. Well-documented cases of negative cooperativity are rare.

To adapt the Hill equation to the binding of oxygen to hemoglobin we must again substitute \( pO_2 \) for [L] and \( P_{50} \) for \( K_d \):

\[
\log \left( \frac{\theta}{1 - \theta} \right) = n \log pO_2 - n \log P_{50} \tag{5-17}
\]
subunits of a cooperatively binding protein are functionally identical, that each subunit can exist in (at least) two conformations, and that all subunits undergo the transition from one conformation to the other simultaneously. In this model, no protein has individual subunits in different conformations. The two conformations are in equilibrium. The ligand can bind to either conformation, but binds each with different affinity. Successive binding of ligand molecules to the low-affinity conformation (which is more stable in the absence of ligand) makes a transition to the high-affinity conformation more likely.

In the second model, the sequential model (Fig. 5–15b), proposed in 1966 by Daniel Koshland and colleagues, ligand binding can induce a change of conformation in an individual subunit. A conformational change in one subunit makes a similar change in an adjacent subunit, as well as the binding of a second ligand molecule, more likely. There are more potential intermediate states in this model than in the concerted model. The two models are not mutually exclusive; the concerted model may be viewed as the “all-or-none” limiting case of the sequential model. In Chapter 6 we use these models to investigate allosteric enzymes.

Hemoglobin Also Transports H\(^+\) and CO\(_2\)

In addition to carrying nearly all the oxygen required by cells from the lungs to the tissues, hemoglobin carries two end products of cellular respiration—H\(^+\) and CO\(_2\)—from the tissues to the lungs and the kidneys, where they are excreted. The CO\(_2\), produced by oxidation of organic fuels in mitochondria, is hydrated to form bicarbonate:

\[
\text{CO}_2 + \text{H}_2\text{O} \rightleftharpoons \text{H}^+ + \text{HCO}_3^-
\]

This reaction is catalyzed by carbonic anhydrase, an enzyme particularly abundant in erythrocytes. Carbon dioxide is not very soluble in aqueous solution, and bubbles of CO\(_2\) would form in the tissues and blood if it were not converted to bicarbonate. As you can see from the

---

**FIGURE 5–14** Hill plots for oxygen binding to myoglobin and hemoglobin. When \(n_t = 1\), there is no evident cooperativity. The maximum degree of cooperativity observed for hemoglobin corresponds approximately to \(n_t = 3\). Note that while this indicates a high level of cooperativity, \(n_t\) is less than \(n\), the number of O\(_2\)-binding sites in hemoglobin. This is normal for a protein that exhibits allosteric binding behavior.

**Two Models Suggest Mechanisms for Cooperative Binding**

Biochemists now know a great deal about the T and R states of hemoglobin, but much remains to be learned about how the T \(\rightarrow\) R transition occurs. Two models for the cooperative binding of ligands to proteins with multiple binding sites have greatly influenced thinking about this problem.

The first model was proposed by Jacques Monod, Jeffries Wyman, and Jean-Pierre Changeux in 1965, and is called the MWC model or the concerted model (Fig. 5–15a). The concerted model assumes that the

---

**FIGURE 5–15** Two general models for the interconversion of inactive and active forms of a protein during cooperative ligand binding. Although the models may be applied to any protein—including any enzyme (Chapter 6)—that exhibits cooperative binding, we show here four subunits because the model was originally proposed for hemoglobin. (a) In the concerted, or all-or-none, model (MWC model), all subunits are postulated to be in the same conformation, either all \(\bigcirc\) (low affinity or inactive) or all \(\square\) (high affinity or active). Depending on the equilibrium, \(K_t\), between \(\bigcirc\) and \(\square\) forms, the binding of one or more ligand molecules (L) will pull the equilibrium toward the \(\square\) form. Subunits with bound L are shaded. (b) In the sequential model, each individual subunit can be in either the \(\bigcirc\) or \(\square\) form. A very large number of conformations is thus possible.
reaction catalyzed by carbonic anhydrase, the hydration of CO₂ results in an increase in the H⁺ concentration (a decrease in pH) in the tissues. The binding of oxygen by hemoglobin is profoundly influenced by pH and CO₂ concentration, so the interconversion of CO₂ and bicarbonate is of great importance to the regulation of oxygen binding and release in the blood.

Hemoglobin transports about 40% of the total H⁺ and 15% to 20% of the CO₂ formed in the tissues to the lungs and kidneys. (The remainder of the H⁺ is absorbed by the plasma’s bicarbonate buffer; the remainder of the CO₂ is transported as dissolved HCO₃⁻ and CO₂.) The binding of H⁺ and CO₂ is inversely related to the binding of oxygen. At the relatively low pH and high CO₂ concentration of peripheral tissues, the affinity of hemoglobin for oxygen decreases as H⁺ and CO₂ are bound, and O₂ is released to the tissues. Conversely, in the capillaries of the lung, as CO₂ is excreted and the blood pH consequently rises, the affinity of hemoglobin for oxygen increases and the protein binds more O₂ for transport to the peripheral tissues. This effect of pH and CO₂ concentration on the binding and release of oxygen by hemoglobin is called the Bohr effect, after Christian Bohr, the Danish physiologist (and father of physicist Niels Bohr) who discovered it in 1904.

The binding equilibrium for hemoglobin and one molecule of oxygen can be designated by the reaction

\[ \text{Hb} + \text{O}_2 \rightleftharpoons \text{HbO}_2 \]

but this is not a complete statement. To account for the effect of H⁺ concentration on this binding equilibrium, we rewrite the reaction as

\[ \text{HbH}^+ + \text{O}_2 \rightleftharpoons \text{HbO}_2 + \text{H}^+ \]

where HbH⁺ denotes a protonated form of hemoglobin. This equation tells us that the O₂-saturation curve of hemoglobin is influenced by the H⁺ concentration (Fig. 5-16). Both O₂ and H⁺ are bound by hemoglobin, but with inverse affinity. When the oxygen concentration is high, as in the lungs, hemoglobin binds O₂ and releases protons. When the oxygen concentration is low, as in the peripheral tissues, H⁺ is bound and O₂ is released.

Oxygen and H⁺ are not bound at the same sites in hemoglobin. Oxygen binds to the iron atoms of the hemes, whereas H⁺ binds to any of several amino acid residues in the protein. A major contribution to the Bohr effect is made by His₁₆ (His HČ₃) of the β subunits. When protonated, this residue forms one of the ion pairs—to Asp¹⁴ (Asp FG1)—that helps stabilize deoxyhemoglobin in the T state (Fig. 5-9). The ion pair stabilizes the protonated form of His HČ₃, giving this residue an abnormally high pKₐ in the T state. The pKₐ falls to its normal value of 6.0 in the R state because the ion pair cannot form, and this residue is largely unprotonated in oxyhemoglobin at pH 7.6, the blood pH in the lungs. As the concentration of H⁺ rises, protonation of His HČ₃ promotes release of oxygen by favoring a transition to the T state. Protonation of the amino-terminal residues of the α subunits, certain other His residues, and perhaps other groups has a similar effect.

Thus we see that the four polypeptide chains of hemoglobin communicate with each other not only about O₂ binding to their heme groups but also about H⁺ binding to specific amino acid residues. And there is still more to the story. Hemoglobin also binds CO₂, again in a manner inversely related to the binding of oxygen. Carbon dioxide binds as a carbamate group to the α-amino group at the amino-terminal end of each globin chain, forming carbaminohemoglobin:

\[ \text{C} + \text{H}_2\text{N-C-C-} \rightarrow \text{C} \text{N-C-C-} \]

\[
\begin{align*}
\text{Amino-terminal residue} & \quad \text{Carbamino-terminal residue} \\
\text{O} & \quad \text{O} \\
\text{H} & \quad \text{H} \\
\text{O} & \quad \text{O} \\
\text{R} & \quad \text{R} \\
\text{O} & \quad \text{O} \\
\text{N} & \quad \text{N} \\
\text{C} & \quad \text{C} \\
\text{C} & \quad \text{C} \\
\text{H} & \quad \text{H} \\
\text{H} & \quad \text{H} \\
\end{align*}
\]

This reaction produces H⁺, contributing to the Bohr effect. The bound carbamates also form additional salt bridges (not shown in Fig. 5-9) that help to stabilize the T state and promote the release of oxygen.

When the concentration of carbon dioxide is high, as in peripheral tissues, some CO₂ binds to hemoglobin and the affinity for O₂ decreases, causing its release. Conversely, when hemoglobin reaches the lungs, the high oxygen concentration promotes binding of O₂ and release of CO₂. It is the capacity to communicate ligand-binding information from one polypeptide subunit to the others that makes the hemoglobin molecule so beautifully adapted to integrating the transport of O₂, CO₂, and H⁺ by erythrocytes.

**FIGURE 5-16** Effect of pH on oxygen binding to hemoglobin. The pH of blood is 7.6 in the lungs and 7.2 in the tissues. Experimental measurements on hemoglobin binding are often performed at pH 7.4.
Oxygen Binding to Hemoglobin Is Regulated by 2,3-Bisphosphoglycerate

The interaction of 2,3-bisphosphoglycerate (BPG) with hemoglobin molecules further refines the function of hemoglobin, and provides an example of heterotropic allosteric modulation.

2,3-Bisphosphoglycerate

BPG is present in relatively high concentrations in erythrocytes. When hemoglobin is isolated, it contains substantial amounts of bound BPG, which can be difficult to remove completely. In fact, the O₂-binding curves for hemoglobin that we have examined to this point were obtained in the presence of bound BPG. 2,3-Bisphosphoglycerate is known to greatly reduce the affinity of hemoglobin for oxygen—there is an inverse relationship between the binding of O₂ and the binding of BPG. We can therefore describe another binding process for hemoglobin:

$$\text{HbBPG} + \text{O}_2 \rightleftharpoons \text{HbO}_2 + \text{BPG}$$

BPG binds at a site distant from the oxygen-binding site and regulates the O₂-binding affinity of hemoglobin in relation to the pO₂ in the lungs. BPG is important in the physiological adaptation to the lower pO₂ at high altitudes. For a healthy human at sea level, the binding of O₂ to hemoglobin is regulated such that the amount of O₂ delivered to the tissues is nearly 40% of the maximum that could be carried by the blood (Fig. 5–17). Imagine that this person is suddenly transported from sea level to an altitude of 4,500 meters, where the pO₂ is considerably lower. The delivery of O₂ to the tissues is now reduced. However, after just a few hours at the higher altitude, the BPG concentration in the blood has begun to rise, leading to a decrease in the affinity of hemoglobin for oxygen. This adjustment in the BPG level has only a small effect on the binding of O₂ in the lungs but a considerable effect on the release of O₂ in the tissues. As a result, the delivery of oxygen to the tissues is restored to nearly 40% of the O₂ that can be transported by the blood. The situation is reversed when the person returns to sea level. The BPG concentration in erythrocytes also increases in people suffering from hypoxia, lowered oxygenation of peripheral tissues due to inadequate functioning of the lungs or circulatory system.

The site of BPG binding to hemoglobin is the cavity between the β subunits in the T state (Fig. 5–18). This cavity is lined with positively charged amino acid residues that interact with the negatively charged groups of BPG. Unlike O₂, only one molecule of BPG is bound to each hemoglobin tetramer. BPG lowers hemoglobin's affinity for oxygen by stabilizing the T state. The transition to the R state narrows the binding pocket for BPG, precluding BPG binding. In the absence of BPG, hemoglobin is converted to the R state more easily.

Regulation of oxygen binding to hemoglobin by BPG has an important role in fetal development. Because a fetus must extract oxygen from its mother's blood, fetal hemoglobin must have greater affinity than the maternal hemoglobin for O₂. The fetus synthesizes γ subunits rather than β subunits, forming α₂γ₂ hemoglobin. This tetramer has a much lower affinity for BPG than normal adult hemoglobin, and a correspondingly higher affinity for O₂. Oxygen-Binding Proteins—Hemoglobin Is Susceptible to Allosteric Regulation
**Sickle-Cell Anemia Is a Molecular Disease of Hemoglobin**

The hereditary human disease sickle-cell anemia demonstrates strikingly the importance of amino acid sequence in determining the secondary, tertiary, and quaternary structures of globular proteins, and thus their biological functions. Almost 500 genetic variants of hemoglobin are known to occur in the human population; all but a few are quite rare. Most variations consist of differences in a single amino acid residue. The effects on hemoglobin structure and function are often minor but can sometimes be extraordinary. Each hemoglobin variation is the product of an altered gene. The variant genes are called alleles. Because humans generally have two copies of each gene, an individual may have two copies of one allele (thus being homozygous for that gene) or one copy of each of two different alleles (thus heterozygous).

Sickle-cell anemia occurs in individuals who inherit the allele for sickle-cell hemoglobin from both parents. The erythrocytes of these individuals are fewer and also abnormal. In addition to an unusually large number of immature cells, the blood contains many long, thin, sickle-shaped erythrocytes (Fig. 5-19). When hemoglobin from sickle cells (called hemoglobin S) is deoxygenated, it becomes insoluble and forms polymers that aggregate into tubular fibers (Fig. 5-20). Normal hemoglobin (hemoglobin A) remains soluble on deoxygenation. The insoluble fibers of deoxygenated hemoglobin S cause the deformed, sickle shape of the erythrocytes, and the proportion of sickled cells increases greatly as blood is deoxygenated.

The altered properties of hemoglobin S result from a single amino acid substitution, a Val instead of a Glu residue at position 6 in the two β chains. The R group of valine has no electric charge, whereas glutamate has a negative charge at pH 7.4. Hemoglobin S therefore has two fewer negative charges than hemoglobin A (one fewer on each β chain). Replacement of the Glu residue by Val creates a "sticky" hydrophobic contact point at position 6 of the β chain, which is on the outer surface of the molecule. These sticky spots cause deoxyhemoglobin S molecules to associate abnormally with each other, forming the long, fibrous aggregates characteristic of this disorder. Oxygen-Binding Proteins—Defects in Hb Lead to Serious Genetic Disease

Sickle-cell anemia, as we have noted, occurs in individuals homozygous for the sickle-cell allele of the gene encoding the β subunit of hemoglobin. Individuals who receive the sickle-cell allele from only one parent and are thus heterozygous experience a milder condition called sickle-cell trait; only about 1% of their erythrocytes become sickled on deoxygenation. These individuals may live completely normal lives if they avoid vigorous exercise and other stresses on the circulatory system.

Sickle-cell anemia is life-threatening and painful. People with this disease suffer repeated crises brought on by physical exertion. They become weak, dizzy, and short of breath, and they also experience heart murmurs and an increased pulse rate. The hemoglobin content of their blood is only about half the normal value of 15 to 16 g/100 mL.
Hemoglobin S

Interaction between molecules

Strand formation

Alignment and crystallization (fiber formation)

FIGURE 5-20 Normal and sickle-cell hemoglobin. (a) Subtle differences between the conformations of hemoglobin A and hemoglobin S result from a single amino acid change in the β chains. (b) As a result of this change, deoxyhemoglobin S has a hydrophobic patch on its surface, which causes the molecules to aggregate into strands that align into insoluble fibers.

because sickled cells are very fragile and rupture easily; this results in anemia (“lack of blood”). An even more serious consequence is that capillaries become blocked by the long, abnormally shaped cells, causing severe pain and interfering with normal organ function—a major factor in the early death of many people with the disease.

Without medical treatment, people with sickle-cell anemia usually die in childhood. Curiously, the frequency of the sickle-cell allele in populations is unusually high in certain parts of Africa. Investigation into this matter led to the finding that in heterozygous individuals, the allele confers a small but significant resistance to lethal forms of malaria. Natural selection has resulted in an allele population that balances the deleterious effects of the homozygous condition against the resistance to malaria afforded by the heterozygous condition.

SUMMARY 5.1 Reversible Binding of a Protein to a Ligand: Oxygen-Binding Proteins

Protein function often entails interactions with other molecules. A protein binds a molecule, known as a ligand, at its binding site. Proteins may undergo conformational changes when a ligand binds, a process called induced fit. In a multisubunit protein, the binding of a ligand to one subunit may affect ligand binding to other subunits. Ligand binding can be regulated.

Myoglobin contains a heme prosthetic group, which binds oxygen. Heme consists of a single atom of Fe²⁺ coordinated within a porphyrin. Oxygen binds to myoglobin reversibly; this simple reversible binding can be described by an association constant $K_a$ or a dissociation constant $K_d$. For a monomeric protein such as myoglobin, the fraction of binding sites occupied by a ligand is a hyperbolic function of ligand concentration.

Normal adult hemoglobin has four heme-containing subunits, two α and two β, similar in structure to each other and to myoglobin. Hemoglobin exists in two interchangeable structural states, T and R. The T state is most stable when oxygen is not bound. Oxygen binding promotes transition to the R state.

Oxygen binding to hemoglobin is both allosteric and cooperative. As $O_2$ binds to one binding site, the hemoglobin undergoes conformational changes that affect the other binding sites—an example of allosteric behavior. Conformational changes between the T and R states, mediated by subunit-subunit interactions, result in cooperative binding; this is described by a sigmoid binding curve and can be analyzed by a Hill plot.

Two major models have been proposed to explain the cooperative binding of ligands to multisubunit proteins: the concerted model and the sequential model.

Hemoglobin also binds $H^+$ and $CO_2$, resulting in the formation of ion pairs that stabilize the T state and lessen the protein’s affinity for $O_2$ (the Bohr effect). Oxygen binding to hemoglobin is also modulated by 2,3-bisphosphoglycerate, which binds to and stabilizes the T state.
Sickle-cell anemia is a genetic disease caused by a single amino acid substitution (Glu to Val) in each β chain of hemoglobin. The change produces a hydrophobic patch on the surface of the hemoglobin that causes the molecules to aggregate into bundles of fibers. This homozygous condition results in serious medical complications.

5.2 Complementary Interactions between Proteins and Ligands: The Immune System and Immunoglobulins

We have seen how the conformations of oxygen-binding proteins affect and are affected by the binding of small ligands (O₂ or CO) to the heme group. However, most protein-ligand interactions do not involve a prosthetic group. Instead, the binding site for a ligand is more often like the hemoglobin binding site for O₂—a cleft in the protein lined with amino acid residues, arranged to make the binding interaction highly specific. Effective discrimination between ligands is the norm at binding sites, even when the ligands have only minor structural differences.

All vertebrates have an immune system capable of distinguishing molecular "self" from "nonself" and then destroying what is identified as nonself. In this way, the immune system eliminates viruses, bacteria, and other pathogens and molecules that may pose a threat to the organism. On a physiological level, the immune response is an intricate and coordinated set of interactions among many classes of proteins, molecules, and cell types. At the level of individual proteins, the immune response demonstrates how an acutely sensitive and specific biochemical system is built upon the reversible binding of ligands to proteins.

The Immune Response Features a Specialized Array of Cells and Proteins

Immunity is brought about by a variety of leukocytes (white blood cells), including macrophages and lymphocytes, all of which develop from undifferentiated stem cells in the bone marrow. Leukocytes can leave the bloodstream and patrol the tissues, each cell producing one or more proteins capable of recognizing and binding to molecules that might signal an infection.

The immune response consists of two complementary systems, the humoral and cellular immune systems. The humoral immune system (Latin humor, "fluid") is directed at bacterial infections and extracellular viruses (those found in the body fluids), but can also respond to individual foreign proteins. The cellular immune system destroys host cells infected by viruses and also destroys some parasites and foreign tissues.

At the heart of the humoral immune response are soluble proteins called antibodies or immunoglobulins, often abbreviated Ig. Immunoglobulins bind bacteria, viruses, or large molecules identified as foreign and target them for destruction. Making up 20% of blood protein, the immunoglobulins are produced by B lymphocytes, or B cells, so named because they complete their development in the bone marrow.

The agents at the heart of the cellular immune response are a class of T lymphocytes, or T cells (so called because the latter stages of their development occur in the thymus), known as cytotoxic T cells (T₅ cells, also called killer T cells). Recognition of infected cells or parasites involves proteins called T-cell receptors on the surface of T₅ cells. Receptors are proteins, usually found on the outer surface of cells and extending through the plasma membrane; they recognize and bind extracellular ligands, triggering changes inside the cell.

In addition to cytotoxic T cells, there are helper T cells (T₄ cells), whose function it is to produce soluble signaling proteins called cytokines, which include the interleukins. T₄ cells interact with macrophages. The T₄ cells participate only indirectly in the destruction of infected cells and pathogens, stimulating the selective proliferation of those T₅ and B cells that can bind to a particular antigen. This process, called clonal selection, increases the number of immune system cells that can respond to a particular pathogen. The importance of T₄ cells is dramatically illustrated by the epidemic produced by HIV (human immunodeficiency virus), the virus that causes AIDS (acquired immune deficiency syndrome). The primary targets of HIV infection are T₄ cells. Elimination of these cells progressively incapacitates the entire immune system. Table 5-2 summarizes the functions of some leukocytes of the immune system.

Each recognition protein of the immune system, either a T-cell receptor or an antibody produced by a B cell, specifically binds some particular chemical structure,

| Table 5-2: Some Types of Leukocytes Associated with the Immune System |
|--------------------------|-------------------------------------------------------------------|
| **Cell type**             | **Function**                                                      |
| Macrophages (B cells)     | Ingest large particles and cells by phagocytosis                 |
| B lymphocytes (B cells)   | Produce and secrete antibodies                                    |
| T lymphocytes (T cells)   | Interact with infected host cells through receptors on T-cell surface |
| Cytotoxic (killer) T cells (T₅) |                                                        |
| Helper T cells (T₄)       | Interact with macrophages and secrete cytokines (interleukins) that stimulate T₅, T₄, and B cells to proliferate. |
5.2 Complementary Interactions between Proteins and Ligands: The Immune System and Immunoglobulins

Humans are capable of producing more than $10^8$ different antibodies with distinct binding specificities. Given this extraordinary diversity, any chemical structure on the surface of a virus or invading cell will most likely be recognized and bound by one or more antibodies. Antibody diversity is derived from random reassembly of a set of immunoglobulin gene segments through genetic recombination mechanisms that are discussed in Chapter 25 (see Fig. 25-26).

A specialized lexicon is used to describe the unique interactions between antibodies or T-cell receptors and the molecules they bind. Any molecule or pathogen capable of eliciting an immune response is called an antigen. An antigen may be a virus, a bacterial cell wall, or an individual protein or other macromolecule. A complex antigen may be bound by several different antibodies. An individual antibody or T-cell receptor binds only a particular molecular structure within the antigen, called its antigenic determinant or epitope.

It would be unproductive for the immune system to respond to small molecules that are common intermediates and products of cellular metabolism. Molecules of $M_r < 5000$ are generally not antigenic. However, when small molecules are covalently attached to large proteins in the laboratory, they can be used to elicit an immune response. These small molecules are called haptens. The antibodies produced in response to protein-linked haptens will then bind to the same small molecules in their free form. Such antibodies are sometimes used in the development of analytical tests described later in this chapter or as catalytic antibodies (see Box 6-3). We now turn to a more detailed description of antibodies and their binding properties.

**Antibodies Have Two Identical Antigen-Binding Sites**

**Immunoglobulin G (IgG)** is the major class of antibody molecule and one of the most abundant proteins in the blood serum. IgG has four polypeptide chains: two large ones, called heavy chains, and two light chains, linked by noncovalent and disulfide bonds into a complex of $M_r 150,000$. The heavy chains of an IgG molecule interact at one end, then branch to interact separately with the light chains, forming a Y-shaped molecule (Fig. 5-21). At the “hinges” separating the base of an IgG molecule from its branches, the immunoglobulin can be cleaved with proteases. Cleavage with the protease papain liberates the basal fragment, called Fe because it usually crystallizes readily, and the two branches, called Fab, the antigen-binding fragments. Each branch has a single antigen-binding site.

![Antibody structure](image)

**FIGURE 5-21 Immunoglobulin G.** (a) Pairs of heavy and light chains combine to form a Y-shaped molecule. Two antigen-binding sites are formed by the combination of variable domains from one light (V_L) and one heavy (V_H) chain. Cleavage with papain separates the Fab and Fc portions of the protein in the hinge region. The Fc portion of the molecule also contains bound carbohydrate (shown in (b)). (b) A ribbon model of the first complete IgG molecule to be crystallized and structurally analyzed (PDB ID 1IGT). Although the molecule has two identical heavy chains (two shades of blue) and two identical light chains (two shades of red), it crystallized in the asymmetric conformation shown here. Conformational flexibility may be important to the function of immunoglobulins.
The fundamental structure of immunoglobulins was first established by Gerald Edelman and Rodney Porter. Each chain is made up of identifiable domains; some are constant in sequence and structure from one IgG to the next, others are variable. The constant domains have a characteristic structure known as the immunoglobulin fold, a well-conserved structural motif in the all-β class of proteins (Chapter 4). There are three of these constant domains in each heavy chain and one in each light chain. The heavy and light chains also have one variable domain each, in which most of the variability in amino acid sequence is found. The variable domains associate to create the antigen-binding site (Fig. 5–21, Fig. 5–22).

In many vertebrates, IgG is but one of five classes of immunoglobulins. Each class has a characteristic type of heavy chain, denoted α, δ, ε, γ, and μ for IgA, IgD, IgE, IgG, and IgM, respectively. Two types of light chain, κ and λ, occur in all classes of immunoglobulins. The overall structures of IgD and IgE are similar to that of IgG. IgM occurs either in a monomeric, membrane-bound form or in a secreted form that is a cross-linked pentamer of this basic structure (Fig. 5–23). IgA, found principally in secretions such as saliva, tears, and milk, can be a monomer, dimer, or trimer. IgM is the first antibody to be made by B lymphocytes and the major antibody in the early stages of a primary immune response. Some B cells soon begin to produce IgD (with the same antigen-binding site as the IgM produced by the same cell), but the particular function of IgD is less clear.

The IgG described above is the major antibody in secondary immune responses, which are initiated by a class of B cells called memory B cells. As part of the organism’s ongoing immunity to antigens already encountered and dealt with, IgG is the most abundant immunoglobulin in the blood. When IgG binds to an invading bacterium or virus, it activates certain leukocytes such as macrophages to engulf and destroy the invader, and also activates some other parts of the immune response. Receptors on the macrophage surface recognize and bind the Fc region of IgG. When these Fc receptors bind an antibody-pathogen complex, the macrophage engulfs the complex by phagocytosis (Fig. 5–24).

IgE plays an important role in the allergic response, interacting with basophils (phagocytic leukocytes) in the blood and with histamine-secreting cells called mast cells, which are widely distributed in tissues. This immunoglobulin binds, through its Fc region, to special Fc receptors on the basophils or mast cells. In this form, IgE serves as a receptor for antigen. If antigen is bound, the cells are induced to secrete histamine and other biologically active amines that cause dilation and increased permeability of blood vessels. These effects on the blood vessels are thought to facilitate the movement of immune system cells and proteins to sites of inflammation. They also produce the symptoms normally associated with allergies. Pollen or other allergens are recognized as foreign, triggering an immune response normally reserved for pathogens.
Figure 5-25: Induced fit in the binding of an antigen to IgG. The molecule here, shown in surface contour, is the Fab fragment of an IgG. The antigen is a small peptide derived from HIV. Two residues in the heavy chain (blue) and one in the light chain (pink) are colored to provide visual points of reference. (a) View of the Fab fragment in the absence of antigen, looking down on the antigen-binding site (PDB ID 1GFC). (b) The same view, but with the Fab fragment in the “bound” conformation (PDB ID 1GGI); the antigen is omitted to provide an unobstructed view of the altered binding site. Note how the binding cavity has enlarged and several groups have shifted position. (c) The same view as (b), but with the antigen in the binding site, pictured as a red stick structure.

Antibodies Bind Tightly and Specifically to Antigen

The binding specificity of an antibody is determined by the amino acid residues in the variable domains of its heavy and light chains. Many residues in these domains are variable, but not equally so. Some, particularly those lining the antigen-binding site, are hypervariable—especially likely to differ. Specificity is conferred by chemical complementarity between the antigen and its specific binding site, in terms of shape and the location of charged, nonpolar, and hydrogen-bonding groups. For example, a binding site with a negatively charged group may bind an antigen with a positive charge in the complementary position. In many instances, complementarity is achieved interactively as the structures of antigen and binding site influence each other as they come closer together. Conformational changes in the antibody and/or the antigen then allow the complementary groups to interact fully. This is an example of induced fit. The complex of a peptide derived from HIV (a model antigen) and an Fab molecule, shown in Figure 5-25, illustrates some of these properties. The changes in structure observed on antigen binding are particularly striking in this example.

A typical antibody-antigen interaction is quite strong, characterized by $K_d$ values as low as $10^{-10}$ M (recall that a lower $K_d$ corresponds to a stronger binding interaction; see Table 5-1). The $K_d$ reflects the energy derived from the various ionic, hydrogen-bonding, hydrophobic, and van der Waals interactions that stabilize the binding. The binding energy required to produce a $K_d$ of $10^{-10}$ M is about 65 kJ/mol.

The Antibody-Antigen Interaction Is the Basis for a Variety of Important Analytical Procedures

The extraordinary binding affinity and specificity of antibodies make them valuable analytical reagents. Two types of antibody preparations are in use: polyclonal and monoclonal. Polyclonal antibodies are those produced by many different B lymphocytes responding to one antigen, such as a protein injected into an animal. Cells in the population of B lymphocytes produce antibodies that bind specific, different epitopes within the antigen. Thus, polyclonal preparations contain a mixture of antibodies that recognize different parts of the protein. Monoclonal antibodies, in contrast, are synthesized by a population of identical B cells (a clone) grown in cell culture. These antibodies are homogeneous, all recognizing the same epitope. The techniques for producing monoclonal antibodies were developed by Georges Köhler and Cesar Milstein.

George Köhler, 1946–1995
Cesar Milstein, 1927–2002

The specificity of antibodies has practical uses. A selected antibody can be covalently attached to a resin and used in a chromatography column of the type shown in Figure 3-17c. When a mixture of proteins is added to the column, the antibody specifically binds its target protein and retains it on the column while other proteins are washed through. The target protein can then be eluted from the resin by a salt solution or some other agent. This is a powerful protein analytical tool.

In another versatile analytical technique, an antibody is attached to a radioactive label or some other reagent that makes it easy to detect. When the antibody
ELISA (b) SDS gel Immunoblot (c)

binds the target protein, the label reveals the presence of the protein in a solution or its location in a gel or even a living cell. Several variations of this procedure are illustrated in Figure 5–26.

An ELISA (enzyme-linked immunosorbent assay) can be used to rapidly screen for and quantify an antigen in a sample (Fig. 5–26b). Proteins in the sample are adsorbed to an inert surface, usually a 96-well polystyrene plate. The surface is washed with a solution of an inexpensive nonspecific protein (often casein from nonfat dry milk powder) to block proteins introduced in subsequent steps from adsorbing to unoccupied sites. The surface is then treated with a solution containing the primary antibody—an antibody against the protein of interest. Unbound antibody is washed away, and the surface is treated with a solution containing a secondary antibody—antibody against the primary antibody—linked to an enzyme that catalyzes a reaction that forms a colored product. After unbound secondary antibody is washed away, the substrate of the antibody-linked enzyme is added. Product formation (monitored as color intensity) is proportional to the concentration of the protein of interest in the sample.

In an immunoblot assay (Fig. 5–26c), proteins that have been separated by gel electrophoresis are transferred electrophoretically to a nitrocellulose membrane. The membrane is blocked (as described above for ELISA), then treated successively with primary antibody, secondary antibody linked to enzyme, and substrate. A colored precipitate forms only along the band containing the protein of interest. Immunoblotting allows the detection of a minor component in a sample and provides an approximation of its molecular weight.

We will encounter other aspects of antibodies in later chapters. They are extremely important in medicine and can tell us much about the structure of proteins and the action of genes.

### SUMMARY 5.2 Complementary Interactions between Proteins and Ligands: The Immune System and Immunoglobulins

- The immune response is mediated by interactions among an array of specialized leukocytes and their associated proteins. T lymphocytes produce T-cell receptors. B lymphocytes produce immunoglobulins. In a process called clonal selection, helper T cells induce the proliferation of B cells and cytotoxic T cells that produce immunoglobulins.
Humans have five classes of immunoglobulins, each with different biological functions. The most abundant class is IgG, a Y-shaped protein with two heavy and two light chains. The domains near the upper ends of the Y are hypervariable within the broad population of IgGs and form two antigen-binding sites.

- A given immunoglobulin generally binds to only a part, called the epitope, of a large antigen. Binding often involves a conformational change in the IgG, an induced fit to the antigen.

### 5.3 Protein Interactions Modulated by Chemical Energy: Actin, Myosin, and Molecular Motors

Organisms move. Cells move. Organelles and macromolecules within cells move. Most of these movements arise from the activity of a fascinating class of protein-based molecular motors. Fueled by chemical energy, usually derived from ATP, large aggregates of motor proteins undergo cyclic conformational changes that accumulate into a unified, directional force—the tiny force that pulls apart chromosomes in a dividing cell, and the immense force that levers a pouncing, quarter-ton jungle cat into the air.

The interactions among motor proteins, as you might predict, feature complementary arrangements of ionic, hydrogen-bonding, hydrophobic, and van der Waals interactions at protein binding sites. In motor proteins, however, these interactions achieve exceptionally high levels of spatial and temporal organization.

Motor proteins underlie the contraction of muscles, the migration of organelles along microtubules, the rotation of bacterial flagella, and the movement of some proteins along DNA. Proteins called kinesins and dyneins move along microtubules in cells, pulling along organelles or reorganizing chromosomes during cell division. An interaction of dynein with microtubules brings about the motion of eukaryotic flagella and cilia. Flagellar motion in bacteria involves a complex rotational motor at the base of the flagellum (see Fig. 19–39). Helicases, polymerases, and other proteins move along DNA as they carry out their functions in DNA metabolism (Chapter 25). Here, we focus on the well-studied example of the contractile proteins of vertebrate skeletal muscle as a paradigm for how proteins translate chemical energy into motion.

**The Major Proteins of Muscle Are Myosin and Actin**

The contractile force of muscle is generated by the interaction of two proteins, myosin and actin. These proteins are arranged in filaments that undergo transient interactions and slide past each other to bring about contraction. Together, actin and myosin make up more than 80% of the protein mass of muscle.

**Myosin** ($M_r 540,000$) has six subunits: two heavy chains (each of $M_r 220,000$) and four light chains (each of $M_r 20,000$). The heavy chains account for much of the overall structure. At their carboxyl termini, they are arranged as extended $\alpha$ helices, wrapped around each other in a fibrous, left-handed coiled coil similar to that of $\alpha$-keratin (Fig. 5–27a). At its amino terminus, each

![Myosin](image)

- **FIGURE 5–27** Myosin. (a) Myosin has two heavy chains (in two shades of pink), the carboxyl termini forming an extended coiled coil (tail) and the amino termini having globular domains (heads). Two light chains (blue) are associated with each myosin head. (b) Cleavage with trypsin and papain separates the myosin heads (S1 fragments) from the tails. (c) Ribbon representation of the myosin S1 fragment (from coordinates supplied by Ivan Rayment). The heavy chain is in gray, the two light chains in two shades of blue.
Heavy chain has a large globular domain containing a site where ATP is hydrolyzed. The light chains are associated with the globular domains. When myosin is treated briefly with the protease trypsin, much of the fibrous tail is cleaved off, dividing the protein into components called light and heavy meromyosin (Fig. 5–27b). The globular domain—called myosin subfragment 1, or S1, or simply the myosin head group—is liberated from heavy meromyosin by cleavage with papain. The S1 fragment is the motor domain that makes muscle contraction possible. S1 fragments can be crystallized, and their overall structure as determined by Ivan Rayment and Hazel Holden is shown in Figure 5–27c.

In muscle cells, molecules of myosin aggregate to form structures called thick filaments (Fig. 5–28a). These rodlike structures are the core of the contractile unit. Within a thick filament, several hundred myosin molecules are arranged with their fibrous “tails” associated to form a long bipolar structure. The globular domains project from either end of this structure, in regular stacked arrays.

The second major muscle protein, actin, is abundant in almost all eukaryotic cells. In muscle, molecules of monomeric actin, called G-actin (globular actin; , 42,000), associate to form a long polymer called F-actin (filamentous actin). The thin filament consists of F-actin (Fig. 5–28b), along with the proteins troponin and tropomyosin (discussed below). The filamentous parts of thin filaments assemble as successive monomeric actin molecules add to one end. On addition, each monomer binds ATP, then hydrolyzes it to ADP, so every actin molecule in the filament is complexed to ADP. This ATP hydrolysis by actin functions only in the assembly of the filaments; it does not contribute directly to the energy expended in muscle contraction. Each actin monomer in the thin filament can bind tightly and specifically to one myosin head group (Fig. 5–28c).

**Additional Proteins Organize the Thin and Thick Filaments into Ordered Structures**

Skeletal muscle consists of parallel bundles of muscle fibers, each fiber a single, very large, multinucleated cell, 20 to 100 μm in diameter, formed from many cells fused together; a single fiber often spans the length of the muscle. Each fiber contains about 1,000 myofibrils, 2 μm in diameter, each consisting of a vast number of regularly arrayed thick and thin filaments complexed to other proteins (Fig. 5–29). A system of flat membranous vesicles called the sarcoplasmic reticulum surrounds each myofibril. Examined under the electron microscope, muscle fibers reveal alternating regions of high and low electron density, called the A bands and I bands (Fig. 5–29b, c). The A and I bands arise from the arrangement of thick and thin filaments, which are aligned and partially overlapping. The I band is the region of the bundle that in cross section would contain only thin filaments. The darker A band stretches the length of the thick filament and includes the region where parallel thick and thin filaments overlap. Bisecting the I band is a thin structure called the Z disk, perpendicular to the thin filaments and serving as an anchor to which the thin filaments are attached. The A band too is bisected by a thin line, the M line or M disk, a region of high electron density in the middle of the thick filaments. The entire contractile unit, consisting of bundles of thick filaments interleaved at either end with bundles of thin filaments, is called the sarcomere. The
5.3 Protein Interactions Modulated by Chemical Energy: Actin, Myosin, and Molecular Motors

(a) Muscle fibers consist of single, elongated, multinucleated cells that arise from the fusion of many precursor cells. The fibers are made up of many myofibrils (only six are shown here for simplicity) surrounded by the membranous sarcoplasmic reticulum. The organization of thick and thin filaments in a myofibril gives it a striped appearance. When muscle contracts, the I bands narrow and the Z disks come closer together, as seen in electron micrographs of (b) relaxed and (c) contracted muscle.

![Diagram of muscle fibers and myofibrils](image)

arrangement of interleaved bundles allows the thick and thin filaments to slide past each other (by a mechanism discussed below), causing a progressive shortening of each sarcomere (Fig. 5-30).

The thin actin filaments are attached at one end to the Z disk in a regular pattern. The assembly includes the minor muscle proteins α-actinin, desmin, and vimentin. Thin filaments also contain a large protein called nebulin (~7,000 amino acid residues), thought to be structured as an α helix that is long enough to span the length of the filament. The M line similarly organizes the thick filaments. It contains the proteins paramyosin, C-protein, and M-protein. Another class of proteins called titins, the largest single polypeptide chains discovered thus far (the titin of human cardiac muscle has 26,926 amino acid residues), link the thick filaments to the Z disk, providing additional organization to the overall structure. Among their structural functions, the proteins nebulin and titin are believed to act as “molecular rulers,” regulating the length of the thin and thick filaments, respectively. Titin extends from the Z disk to the M line, regulating the length of the sarcomere itself and preventing overextension of the muscle. The characteristic sarcomere length varies from one muscle tissue to the next in a vertebrate, largely due to the different titin variants in the tissues.

![Diagram of muscle contraction](image)

FIGURE 5-30 Muscle contraction. Thick filaments are bipolar structures created by the association of many myosin molecules. (a) Muscle contraction occurs by the sliding of the thick and thin filaments past each other so that the Z disks in neighboring I bands draw closer together. (b) The thick and thin filaments are interleaved such that each thick filament is surrounded by six thin filaments.
The interaction between actin and myosin, like that between all proteins and ligands, involves weak bonds. When ATP is not bound to myosin, a face on the myosin head group binds tightly to actin (Fig. 5–31). When ATP binds to myosin and is hydrolyzed to ADP and phosphate, a coordinated and cyclic series of conformational changes occurs in which myosin releases the F-actin subunit and binds another subunit farther along the thin filament.

The cycle has four major steps (Fig. 5–31). In step 1, ATP binds to myosin and a cleft in the myosin molecule opens, disrupting the actin-myosin interaction so that the bound actin is released. ATP is then hydrolyzed in step 2, causing a conformational change in the protein to a "high-energy" state that moves the myosin head and changes its orientation in relation to the actin thin filament. Myosin then binds weakly to an F-actin subunit closer to the Z disk than the one just released. As the phosphate product of ATP hydrolysis is released from myosin in step 3, another conformational change occurs in which the myosin cleft closes, strengthening the myosin-actin binding. This is followed quickly by step 4, a "power stroke" during which the conformation of the myosin head returns to the original resting state, its orientation relative to the bound actin changing so as to pull the tail of the myosin toward the Z disk. ADP is then released to complete the cycle. Each cycle generates about 3 to 4 pN (piconewtons) of force and moves the thick filament 5 to 10 nm relative to the thin filament.

Myosin Thick Filaments Slide along Actin Thin Filaments

Because there are many myosin heads in a thick filament, at any given moment some (probably 1% to 3%) are bound to thin filaments. This prevents thick filaments from slipping backward when an individual myosin head releases the actin subunit to which it was bound. The thick filament thus actively slides forward past the adjacent thin filaments. This process, coordinated among the many sarcomeres in a muscle fiber, brings about muscle contraction.

The interaction between actin and myosin must be regulated so that contraction occurs only in response to appropriate signals from the nervous system. The regulation is mediated by a complex of two proteins, tropomyosin and troponin (Fig. 5–32). Tropomyosin binds to the thin filament, blocking the attachment sites for the myosin head groups. Troponin is a Ca²⁺-binding protein. A nerve impulse causes release of Ca²⁺ from the sarcoplasmic reticulum. The released Ca²⁺ binds to troponin (another protein-ligand interaction) and causes a conformational change in the tropomyosin–tropomysosin complexes, exposing the myosin-binding sites on the thin filaments. Contraction follows.

Working skeletal muscle requires two types of molecular functions that are common in proteins—binding and catalysis. The actin-myosin interaction, a protein-ligand interaction like that of immunoglobulins with...
antigens, is reversible and leaves the participants unchanged. When ATP binds myosin, however, it is hydrolyzed to ADP and Pi. Myosin is not only an actin-binding protein, it is also an ATPase—an enzyme. The function of enzymes in catalyzing chemical transformations is the topic of the next chapter.

**SUMMARY 5.3 Protein Interactions Modulated by Chemical Energy: Actin, Myosin, and Molecular Motors**

- Protein-ligand interactions achieve a special degree of spatial and temporal organization in motor proteins. Muscle contraction results from choreographed interactions between myosin and actin, coupled to the hydrolysis of ATP by myosin.

- Myosin consists of two heavy and four light chains, forming a fibrous coiled coil (tail) domain and a globular (head) domain. Myosin molecules are organized into thick filaments, which slide past thin filaments composed largely of actin. ATP hydrolysis in myosin is coupled to a series of conformational changes in the myosin head, leading to dissociation of myosin from one F-actin subunit and its eventual reassociation with another, farther along the thin filament. The myosin thus slides along the actin filaments.

- Muscle contraction is stimulated by the release of Ca$^{2+}$ from the sarcoplasmic reticulum. The Ca$^{2+}$ binds to the protein troponin, leading to a conformational change in a troponin-tropomyosin complex that triggers the cycle of actin-myosin interactions.

**Oxygen-Binding Proteins**

The paper that introduced the sequential model.

The concerted model was first proposed in this landmark paper.

A nice description of the imposing technical challenge of mimicking the highly evolved oxygen-transport function of blood.

**Immune System Proteins**

An interesting essay tracing the origins of our immune system.

in the partial pressure of CO₂ in the lungs from 6 kPa (holding drop in the pH of blood plasma from 7.4 to 7.2. (b) A decrease in the partial pressure of CO₂ in the lungs from 6 kPa (holding one's breath) to 2 kPa (normal). (c) An increase in the BPG level from 5 mM (normal altitudes) to 8 mM (high altitudes). (d) An increase in CO from 1 ppm parts per million (ppm) in a normal indoor atmosphere to 30 ppm in a home that has a malfunctioning or leaking furnace.

4. Reversible Ligand Binding The protein calcineurin binds to the protein calmodulin with an association rate of 8.9 × 10⁸ M⁻¹ s⁻¹ and an overall dissociation constant, K₆, of 10 nM. Calculate the dissociation rate, k₆, including appropriate units.

5. Cooperativity in Hemoglobin Under appropriate conditions, hemoglobin dissociates into its four subunits. The isolated α subunit binds oxygen, but the O₂-saturation curve is hyperbolic rather than sigmoid. In addition, the binding of oxygen to the isolated α subunit is not affected by the presence of H⁺, CO₂, or BPG. What do these observations indicate about the source of the cooperativity in hemoglobin?

6. Comparison of Fetal and Maternal Hemoglobins Studies of oxygen transport in pregnant mammals show that the O₂-saturation curves of fetal and maternal blood are markedly different when measured under the same conditions. Fetal erythrocytes contain a structural variant of hemoglobin, HbF, consisting of two α and two γ subunits (α₂γ₂), whereas maternal erythrocytes contain HbA (α₂β₂).

(a) Which hemoglobin has a higher affinity for oxygen under physiological conditions, HbA or HbF? Explain.

(b) What is the physiological significance of the different O₂ affinities?

(c) When all the BPG is carefully removed from samples of HbA and HbF, the measured O₂-saturation curves (and consequently the O₂ affinities) are displaced to the left. However, HbA now has a greater affinity for oxygen than does HbF. When BPG is reintroduced, the O₂-saturation curves return to normal, as shown in the graph. What is the effect of BPG on the O₂ affinity of hemoglobin? How can the above information be used to explain the different O₂ affinities of fetal and maternal hemoglobin?

Problems

1. Relationship between Affinity and Dissociation Constant Protein A has a binding site for ligand X with a K₆ of 10⁻⁶ M. Protein B has a binding site for ligand X with a K₆ of 10⁻⁸ M. Which protein has a higher affinity for ligand X? Explain your reasoning. Convert the K₆ for each protein.

2. Negative Cooperativity Which of the following situations would produce a Hill plot with n_Hig < 1.0? Explain your reasoning in each case.

(a) The protein has multiple subunits, each with a single ligand-binding site. Binding of ligand to one site decreases the binding affinity of other sites for the ligand.

(b) The protein is a single polypeptide with two ligand-binding sites, each having a different affinity for the ligand.

(c) The protein is a single polypeptide with a single ligand-binding site. As purified, the protein preparation is heterogeneous, containing some protein molecules that are partially denatured and thus have a lower binding affinity for the ligand.

3. Affinity for Oxygen of Hemoglobin What is the effect of the following changes on the O₂ affinity of hemoglobin? (a) A drop in the pH of blood plasma from 7.4 to 7.2. (b) A decrease in the partial pressure of CO₂ in the lungs from 6 kPa (holding one's breath) to 2 kPa (normal). (c) An increase in the BPG level from 5 mM (normal altitudes) to 8 mM (high altitudes). (d) An increase in CO from 1 ppm parts per million (ppm) in a normal indoor atmosphere to 30 ppm in a home that has a malfunctioning or leaking furnace.

7. Hemoglobin Variants There are almost 500 naturally occurring variants of hemoglobin. Most are the result of a single amino acid substitution in a globin polypeptide chain. Some variants produce clinical illness, though not all variants have deleterious effects. A brief sample follows.
HbS (sickle-cell Hb): substitutes a Val for a Glu on the surface
Hb Cowtown: eliminates an ion pair involved in T-state stabilization
Hb Memphis: substitutes one uncharged polar residue for another of similar size on the surface
Hb Bibba: substitutes a Pro for a Leu involved in an α helix
Hb Milwaukee: substitutes a Glu for a Val
Hb Providence: substitutes an Asn for a Lys that normally projects into the central cavity of the tetramer
Hb Philly: substitutes a Phe for a Tyr, disrupting hydrogen bonding at the αβ1 interface

Explain your choices for each of the following:
(a) The Hb variant least likely to cause pathological symptoms.
(b) The variant(s) most likely to show pI values different from that of HbA on an isoelectric focusing gel.
(c) The variant(s) most likely to show a decrease in BPG binding and an increase in the overall affinity of the hemoglobin for oxygen.

8. Oxygen Binding and Hemoglobin Structure A team of biochemists uses genetic engineering to modify the interface region between hemoglobin subunits. The resulting hemoglobin variants exist in solution primarily as αβ dimers (few, if any, ααββ tetramers form). Are these variants likely to bind oxygen more weakly or more tightly? Explain your answer.

9. Reversible (but Tight) Binding to an Antibody An antibody binds to an antigen with a K_d of 5 × 10^{-9} M. At what concentration of antigen will θ be (a) 0.2, (b) 0.5, (c) 0.6, (d) 0.8?

10. Using Antibodies to Probe Structure-Function Relationships in Proteins A monoclonal antibody binds to G-actin but not to F-actin. What does this tell you about the epitope recognized by the antibody?

11. The Immune System and Vaccines A host organism needs time, often days, to mount an immune response against a new antigen, but memory cells permit a rapid response to pathogens previously encountered. A vaccine to protect against a particular viral infection often consists of weakened or killed virus or isolated proteins from a viral protein coat. When injected into a human patient, the vaccine generally does not cause an infection and illness, but it effectively “teaches” the immune system what the viral particles look like, stimulating the production of memory cells. On subsequent infection, these cells can bind to the virus and trigger a rapid immune response. Some pathogens, including HIV, have developed mechanisms to evade the immune system, making it difficult or impossible to develop effective vaccines against them. What strategy could a pathogen use to evade the immune system? Assume that a host’s antibodies and/or T-cell receptors are available to bind to any structure that might appear on the surface of a pathogen and that, once bound, the pathogen is destroyed.

12. How We Become a “Stiff” When a vertebrate dies, its muscles stiffen as they are deprived of ATP, a state called rigor mortis. Explain the molecular basis of the rigor state.

13. Sarcomeres from Another Point of View The symmetry of thick and thin filaments in a sarcomere is such that six thin filaments ordinarily surround each thick filament in a hexagonal array. Draw a cross section (transverse cut) of a myofibril at the following points: (a) at the M line; (b) through the I band; (c) through the dense region of the A band; (d) through the less dense region of the A band, adjacent to the M line (see Fig. 5–29b, c).

14. Lysozyme and Antibodies To fully appreciate how proteins function in a cell, it is helpful to have a three-dimensional view of how proteins interact with other cellular components. Fortunately, this is possible using Web-based protein databases and three-dimensional molecular viewing utilities. Some molecular viewers require that you download a program or plug-in; some can be problematic when used with certain operating systems or browsers; some require the use of command-line code; some have a more user-friendly interface. We suggest you go to www.umass.edu/microbio/rasmol and look at the information about RasMol, Protein Explorer, and Jmol First Glance. Choose the viewer most compatible with your operating system, browser, and level of expertise. Then download and install any software or plug-ins you may need.

In this exercise you will examine the interactions between the enzyme lysozyme (Chapter 4) and the Fab portion of the anti-lysozyme antibody. Use the PDB identifier 1FDL to explore the structure of the IgG1 Fab fragment–lysozyme complex (antibody-antigen complex). To answer the following questions, use the information on the Structure Summary page at the Protein Data Bank (www.rcsb.org), and view the structure using RasMol, Protein Explorer, or Jmol First Glance.
(a) Which chains in the three-dimensional model correspond to the antibody fragment and which correspond to the antigen, lysozyme?
(b) What type of secondary structure predominates in this Fab fragment?
(c) How many amino acid residues are in the heavy and light chains of the Fab fragment? In lysozyme? Estimate the percentage of the lysozyme that interacts with the antigen-binding site of the antibody fragment.
(d) Identify the specific amino acid residues in lysozyme and in the variable regions of the Fab heavy and light chains that are situated at the antigen-antibody interface. Are the residues contiguous in the primary sequence of the polypeptide chains?

15. Exploring Reversible Interactions of Proteins and Ligands with Living Graphs Use the living graphs for Equations 5–8, 5–11, 5–14, and 5–16 to work through the following exercises.
(a) Reversible binding of a ligand to a simple protein, without cooperativity. For Equation 5–8, set up a plot of θ versus [L] (vertical and horizontal axes, respectively). Examine the plots generated when K_d is set at 5, 10, 20, and 100 μM. Higher affinity of the protein for the ligand means more binding at lower ligand concentrations. Suppose that four different proteins exhibit these four different K_d values for ligand L. Which protein would have the highest affinity for L?
Examined the plot generated when $K_d = 10 \mu M$. How much does $\theta$ increase when $[L]$ increases from 0.2 to 0.4 $\mu M$? How much does $\theta$ increase when $[L]$ increases from 40 to 80 $\mu M$?

You can do the same exercise for Equation 5-11. Convert $[L]$ to pO$_2$ and $K_d$ to $P_{50}$. Examine the curves generated when $P_{50}$ is set at 0.5, 1, 2, and 10 kPa. For the curve generated when $P_{50} = 1$ kPa, how much does $\theta$ change when the pO$_2$ increases from 0.02 to 0.04 kPa? From 4 to 8 kPa?

(b) Cooperative binding of a ligand to a multisubunit protein. Using Equation 5-14, generate a binding curve for a protein and ligand with $K_d = 10 \mu M$ and $n = 3$. Note the altered definition of $K_d$ in Equation 5-16. On the same plot, add a curve for a protein with $K_d = 20 \mu M$ and $n = 3$. Now see how both curves change when you change to $n = 4$. Generate Hill plots (Eqn 5-16) for each of these cases. For $K_d = 10 \mu M$ and $n = 3$, what is $\theta$ when $[L] = 20 \mu M$?

(c) Explore these equations further by varying all the parameters used above.

**Data Analysis Problem**

16. Protein Function During the 1980s, the structures of actin and myosin were known only at the resolution shown in Figure 5-28a, b. Although researchers knew that the S1 portion of myosin binds to actin and hydrolyzes ATP, there was a substantial debate about where in the myosin molecule the contractile force was generated. At the time, two competing models were proposed for the mechanism of force generation in myosin.

In the “hinge” model, S1 bound to actin, but the pulling force was generated by contraction of the “hinge region” in the myosin tail. The hinge region is in the heavy meromyosin portion of the myosin molecule, near where trypsin cleaves off light meromyosin (see Fig. 5-27b). This is roughly the point labeled “Two supercoiled $\alpha$ helices” in Figure 5-27a. In the “S1” model, the pulling force was generated in the S1 “head” itself and the tail was just for structural support.

Many experiments had been performed but provided no conclusive evidence. In 1987, James Spudich and his colleagues at Stanford University published a study that, although not conclusive, went a long way toward resolving this controversy.

Recombinant DNA techniques were not sufficiently developed to address this issue in vivo, so Spudich and colleagues used an interesting in vitro motility assay. The alga *Nitella* has extremely long cells, often several centimeters in length and about 1 mm in diameter. These cells have actin fibers that run along their long axes, and the cells can be cut open along their length to expose the actin fibers. Spudich and his group had observed that plastic beads coated with myosin would “walk” along these fibers in the presence of ATP, just as myosin would do in contracting muscle.

For these experiments, they used a more well-defined method for attaching the myosin to the beads. The “beads” were clumps of killed bacterial (Staphylococcus aureus) cells. These cells have a protein on their surface that binds to the Fc region of antibody molecules (Fig. 5-21a). The antibodies, in turn, bind to several (unknown) places along the tail of the myosin molecule. When bead-antibody-myosin complexes were prepared with intact myosin molecules, they would move along *Nitella* actin fibers in the presence of ATP.

(a) Sketch a diagram showing what a bead-antibody-myosin complex might look like at the molecular level.

(b) Why was ATP required for the beads to move along the actin fibers?

(c) Spudich and coworkers used antibodies that bound to the myosin tail. Why would this experiment have failed if they had used an antibody that bound to the part of S1 that normally binds to actin? Why would this experiment have failed if they had used an antibody that bound to actin?

To help focus in on the part of myosin responsible for force production, Spudich and his colleagues used trypsin to produce two partial myosin molecules (see Fig. 5-27): (1) heavy meromyosin (HMM), made by briefly digesting myosin with trypsin; HMM consists of S1 and the part of the tail that includes the hinge; and (2) short heavy meromyosin (SHMM), made from a more extensive digestion of HMM with trypsin; SHMM consists of S1 and a shorter part of the tail that does not include the hinge. Brief digestion of myosin with trypsin produces HMM and light meromyosin (Fig. 5-27), by cleavage of a single specific peptide bond in the myosin molecule.

(d) Why might trypsin attack this peptide bond first rather than other peptide bonds in myosin?

Spudich and colleagues prepared bead-antibody-myosin complexes with varying amounts of myosin, HMM, and SHMM, and measured their speeds along *Nitella* actin fibers in the presence of ATP. The graph below sketches their results.

(e) Which model (“S1” or “hinge”) is consistent with these results? Explain your reasoning.

(f) Provide a plausible explanation for why the speed of the beads increased with increasing myosin density.

(g) Provide a plausible explanation for why the speed of the beads reached a plateau at high myosin density.

The more extensive trypsin digestion required to produce SHMM had a side effect: another specific cleavage of the myosin polypeptide backbone in addition to the cleavage in the tail. This second cleavage was in the S1 head.

(h) Based on this information, why is it surprising that SHMM was still capable of moving beads along actin fibers?

(i) As it turns out, the tertiary structure of the S1 head remains intact in SHMM. Provide a plausible explanation of how the protein remains intact and functional even though the polypeptide backbone has been cleaved and is no longer continuous.

**Reference**

There are two fundamental conditions for life. First, the organism must be able to self-replicate (a topic considered in Part III); second, it must be able to catalyze chemical reactions efficiently and selectively. The central importance of catalysis may seem surprising, but it is easy to demonstrate. As described in Chapter 1, living systems make use of energy from the environment. Many of us, for example, consume substantial amounts of sucrose—common table sugar—as a kind of fuel, usually in the form of sweetened foods and drinks. The conversion of sucrose to CO$_2$ and H$_2$O in the presence of oxygen is a highly exergonic process, releasing free energy that we can use to think, move, taste, and see. However, a bag of sugar can remain on the shelf for years without any obvious conversion to CO$_2$ and H$_2$O. Although this chemical process is thermodynamically favorable, it is very slow! Yet when sucrose is consumed by a human (or almost any other organism), it releases its chemical energy in seconds. The difference is catalysis. Without catalysis, chemical reactions such as sucrose oxidation could not occur on a useful time scale, and thus could not sustain life.

In this chapter, then, we turn our attention to the reaction catalysts of biological systems: the enzymes, the most remarkable and highly specialized proteins. Enzymes have extraordinary catalytic power, often far greater than that of synthetic or inorganic catalysts. They have a high degree of specificity for their substrates, they accelerate chemical reactions tremendously, and they function in aqueous solutions under very mild conditions of temperature and pH. Few nonbiological catalysts have all these properties.

Enzymes are central to every biochemical process. Acting in organized sequences, they catalyze the hundreds of stepwise reactions that degrade nutrient molecules, conserve and transform chemical energy, and make biological macromolecules from simple precursors. The study of enzymes has immense practical importance. In some diseases, especially inheritable genetic disorders, there may be a deficiency or even a total absence of one or more enzymes. Other disease conditions may be caused by excessive activity of an enzyme. Measurements of the activities of enzymes in blood plasma, erythrocytes, or tissue samples are important in diagnosing certain illnesses. Many drugs act through interactions with enzymes. Enzymes are also important practical tools in chemical engineering, food technology, and agriculture.

We begin with descriptions of the properties of enzymes and the principles underlying their catalytic power, then introduce enzyme kinetics, a discipline that provides much of the framework for any discussion of enzymes. Specific examples of enzyme mechanisms are then provided, illustrating principles introduced earlier in the chapter. We end with a discussion of how enzyme activity is regulated.

### 6.1 An Introduction to Enzymes

Much of the history of biochemistry is the history of enzyme research. Biological catalysis was first recognized and described in the late 1700s, in studies on the digestion of meat by secretions of the stomach. Research continued in the 1800s with examinations of the conversion of starch to sugar by saliva and various plant
Enzymes, like other proteins, have molecular weights ranging from about 12,000 to more than 1 million. Some enzymes require no chemical groups for activity other than their amino acid residues. Others require an additional chemical component called a cofactor—either one or more inorganic ions, such as Fe^{2+}, Mg^{2+}, Mn^{2+}, or Zn^{2+} (Table 6-1), or a complex organic or metalloorganic molecule called a coenzyme. Coenzymes act as transient carriers of specific functional groups (Table 6-2). Most are derived from vitamins, organic nutrients required in small amounts in the diet. We consider coenzymes in more detail as we encounter them in the metabolic pathways discussed in Part II. Some enzymes require both a coenzyme and one or more metal ions for activity. A coenzyme or metal ion that is very tightly or even covalently bound to the enzyme protein is called a prosthetic group. A complete, catalytically active enzyme together with its bound coenzyme and/or metal ions is called a holoenzyme. The protein part of such an enzyme is called the apoenzyme or apoprotein. Finally, some enzyme proteins are modified covalently by phosphorylation, glycosylation, and other processes. Many of these alterations are involved in the regulation of enzyme activity.

**Enzymes Are Classified by the Reactions They Catalyze**

Many enzymes have been named by adding the suffix "-ase" to the name of their substrate or to a word or phrase describing their activity. Thus urease catalyzes hydrolysis of urea, and DNA polymerase catalyzes the polymerization of nucleotides to form DNA. Other enzymes were named by their discoverers for a broad function, before the specific reaction catalyzed was

**Most Enzymes Are Proteins**

With the exception of a small group of catalytic RNA molecules (Chapter 26), all enzymes are proteins. Their catalytic activity depends on the integrity of their native protein conformation. If an enzyme is denatured or dissociated into its subunits, catalytic activity is usually lost. If an enzyme is broken down into its component amino acids, its catalytic activity is always destroyed. Thus the primary, secondary, tertiary, and quaternary structures of protein enzymes are essential to their catalytic activity.

known. For example, an enzyme known to act in the digestion of foods was named pepsin, from the Greek pepsis, "digestion," and lysozyme was named for its ability to lyse (break down) bacterial cell walls. Still others were named for their source: trypsin, named in part from the Greek tryein, "to wear down," was obtained by rubbing pancreatic tissue with glycerin. Sometimes the same enzyme has two or more names, or two different enzymes have the same name. Because of such ambiguities, and the ever-increasing number of newly discovered enzymes, biochemists, by international agreement, have adopted a system for naming and classifying enzymes. This system divides enzymes into six classes, each with subclasses, based on the type of reaction catalyzed (Table 6-3). Each enzyme is assigned a four-part classification number and a systematic name, which identifies the reaction it catalyzes. As an example, the formal systematic name of the enzyme catalyzing the reaction

\[
\text{ATP + D-glucose} \rightarrow \text{ADP + D-glucose 6-phosphate}
\]

is ATP-glucose phosphotransferase, which indicates that it catalyzes the transfer of a phosphoryl group from ATP to glucose. Its Enzyme Commission number (E.C. number) is 2.7.1.1. The first number (2) denotes the class name (transferase); the second number (7), the subclass (phosphotransferase); the third number (1), a phosphotransferase with a hydroxyl group as acceptor; and the fourth number (1), D-glucose as the phosphoryl group acceptor. For many enzymes, a common name is more frequently used—in this case hexokinase. A complete list and description of the thousands of known enzymes is maintained by the Nomenclature Committee of the International Union of Biochemistry and Molecular Biology (www.chem.qmul.ac.uk/iubmb/enzyme). This chapter is devoted primarily to principles and properties common to all enzymes.

**SUMMARY 6.1 An Introduction to Enzymes**

- Life depends on powerful and specific catalysts: the enzymes. Almost every biochemical reaction is catalyzed by an enzyme.
- With the exception of a few catalytic RNAs, all known enzymes are proteins. Many require nonprotein coenzymes or cofactors for their catalytic function.
- Enzymes are classified according to the type of reaction they catalyze. All enzymes have formal E.C. numbers and names, and most have trivial names.

Enzymes

6.1 Enzyme Catalysis

The enzymatic catalysis of reactions is essential to living systems. Under biologically relevant conditions, uncatalyzed reactions tend to be slow—most biological molecules are quite stable in the neutral-pH, mild-temperature, aqueous environment inside cells. Furthermore, many common chemical processes are unfavorable or unlikely in the cellular environment, such as the transient formation of unstable charged intermediates or the collision of two or more molecules in the precise orientation required for reaction. Reactions required to digest food, send nerve signals, or contract a muscle simply do not occur at a useful rate without catalysis.

An enzyme circumvents these problems by providing a specific environment within which a given reaction can occur more rapidly. The distinguishing feature of an enzyme-catalyzed reaction is that it takes place within the confines of a pocket on the enzyme called the active site (Fig. 6–1). The molecule that is bound in the active site and acted upon by the enzyme is called the substrate. The surface of the active site is lined with amino acid residues with substituent groups that bind the substrate and catalyze its chemical transformation. Often, the active site encloses a substrate, sequestering it completely from solution. The enzyme-substrate complex, whose existence was first proposed by Charles-Adolphe Wurtz in 1880, is central to the action of enzymes. It is also the starting point for mathematical treatments that define the kinetic behavior of enzyme-catalyzed reactions and for theoretical descriptions of enzyme mechanisms.

6.2 How Enzymes Work

The enzymatic catalysis of reactions is essential to living systems. Under biologically relevant conditions, uncatalyzed reactions tend to be slow—most biological molecules are quite stable in the neutral-pH, mild-temperature, aqueous environment inside cells. Furthermore, many common chemical processes are unfavorable or unlikely in the cellular environment, such as the transient formation of unstable charged intermediates or the collision of two or more molecules in the precise orientation required for reaction. Reactions required to digest food, send nerve signals, or contract a muscle simply do not occur at a useful rate without catalysis.

An enzyme circumvents these problems by providing a specific environment within which a given reaction can occur more rapidly. The distinguishing feature of an enzyme-catalyzed reaction is that it takes place within the confines of a pocket on the enzyme called the active site (Fig. 6–1). The molecule that is bound in the active site and acted upon by the enzyme is called the substrate. The surface of the active site is lined with amino acid residues with substituent groups that bind the substrate and catalyze its chemical transformation. Often, the active site encloses a substrate, sequestering it completely from solution. The enzyme-substrate complex, whose existence was first proposed by Charles-Adolphe Wurtz in 1880, is central to the action of enzymes. It is also the starting point for mathematical treatments that define the kinetic behavior of enzyme-catalyzed reactions and for theoretical descriptions of enzyme mechanisms.

Enzymes Affect Reaction Rates, Not Equilibria

A simple enzymatic reaction might be written

\[ E + S \rightleftharpoons ES \rightleftharpoons EP \rightleftharpoons E + P \]  

(6–1)

where E, S, and P represent the enzyme, substrate, and product; ES and EP are transient complexes of the enzyme with the substrate and with the product.

To understand catalysis, we must first appreciate the important distinction between reaction equilibria and reaction rates. The function of a catalyst is to increase the rate of a reaction. Catalysts do not affect reaction equilibria. Any reaction, such as \( S \rightleftharpoons P \), can be described by a reaction coordinate diagram (Fig. 6–2), a picture of the energy changes during the reaction. As discussed in Chapter 1, energy in biological systems is described in terms of free energy, \( G \). In the coordinate diagram, the free energy of the system is plotted against the progress of the reaction (the reaction coordinate). The starting point for either the forward or the reverse reaction is called the ground state, the contribution to the free energy of the system by an average molecule (S or P) under a given set of conditions.

**KEY CONVENTION:** To describe the free-energy changes for reactions, chemists define a standard set of conditions (temperature 298 K; partial pressure of each gas 1 atm, or 101.3 kPa; concentration of each solute 1 M) and express the free-energy change for a reacting system under these conditions as \( \Delta G^\circ \), the standard free-energy change. Because biochemical systems commonly involve \( H^+ \) concentrations far below 1 M, biochemists define a biochemical standard free-energy change, \( \Delta G^\circ_b \), the standard free-energy change at pH 7.0; we employ this definition throughout the book. A more complete definition of \( \Delta G^\circ_b \) is given in Chapter 13.

The equilibrium between S and P reflects the difference in the free energies of their ground states. In the example shown in Figure 6–2, the free energy of the ground state of P is lower than that of S, so \( \Delta G^\circ_b \) for the reaction is negative and the equilibrium favors P. The position and direction of equilibrium are not affected by any catalyst.

**FIGURE 6–2** Reaction coordinate diagram. The free energy of the system is plotted against the progress of the reaction S \( \rightarrow \) P. A diagram of this kind is a description of the energy changes during the reaction, and the horizontal axis (reaction coordinate) reflects the progressive chemical changes (e.g., bond breakage or formation) as S is converted to P. The activation energies, \( \Delta G^\ast \), for the S \( \rightarrow \) P and P \( \rightarrow \) S reactions are indicated. \( \Delta G^\circ \) is the overall standard free-energy change in the direction S \( \rightarrow \) P.
A favorable equilibrium does not mean that the $S \rightarrow P$ conversion will occur at a detectable rate. The rate of a reaction is dependent on an entirely different parameter. There is an energy barrier between $S$ and $P$: the energy required for alignment of reacting groups, formation of transient unstable charges, bond rearrangements, and other transformations required for the reaction to proceed in either direction. This is illustrated by the energy “hill” in Figures 6–2 and 6–3. To undergo reaction, the molecules must overcome this barrier and therefore must be raised to a higher energy level. At the top of the energy hill is a point at which decay to the $S$ or $P$ state is equally probable (it is downhill either way). This is called the transition state. The transition state is not a chemical species with any significant stability and should not be confused with a reaction intermediate (such as ES or EP). It is simply a fleeting molecular moment in which events such as bond breakage, bond formation, and charge development have proceeded to the precise point at which decay to either substrate or product is equally likely. The difference between the energy levels of the ground state and the transition state is the activation energy, $\Delta G^\ddagger$. The rate of a reaction reflects this activation energy: a higher activation energy corresponds to a slower reaction. Reaction rates can be increased by raising the temperature and/or pressure, thereby increasing the number of molecules with sufficient energy to overcome the energy barrier. Alternatively, the activation energy can be lowered by adding a catalyst (Fig. 6–3). Catalysts enhance reaction rates by lowering activation energies.

Enzymes are no exception to the rule that catalysts do not affect reaction equilibria. The bidirectional arrows in Equation 6–1 make this point: any enzyme that catalyzes the reaction $S \rightarrow P$ also catalyzes the reaction $P \rightarrow S$. The role of enzymes is to accelerate the interconversion of $S$ and $P$. The enzyme is not used up in the process, and the equilibrium point is unaffected. However, the reaction reaches equilibrium much faster when the appropriate enzyme is present, because the rate of the reaction is increased.

This general principle is illustrated in the conversion of sucrose and oxygen to carbon dioxide and water:

$$C_{12}H_{22}O_{11} + 12O_2 \rightarrow 12CO_2 + 11H_2O$$

This conversion, which takes place through a series of separate reactions, has a very large and negative $\Delta G^\ddagger$, and at equilibrium the amount of sucrose present is negligible. Yet sucrose is a stable compound, because the activation energy barrier that must be overcome before sucrose reacts with oxygen is quite high. Sucrose can be stored in a container with oxygen almost indefinitely without reacting. In cells, however, sucrose is readily broken down to $CO_2$ and $H_2O$ in a series of reactions catalyzed by enzymes. These enzymes not only accelerate the reactions, they organize and control them so that much of the energy released is recovered in other chemical forms and made available to the cell for other tasks. The reaction pathway by which sucrose (and other sugars) is broken down is the primary energy-yielding pathway for cells, and the enzymes of this pathway allow the reaction sequence to proceed on a biologically useful time scale.

Any reaction may have several steps, involving the formation and decay of transient chemical species called reaction intermediates. A reaction intermediate is any species on the reaction pathway that has a finite chemical lifetime (longer than a molecular vibration, $\sim 10^{-13}$ seconds). When the $S \Rightarrow P$ reaction is catalyzed by an enzyme, the ES and EP complexes can be considered intermediates, even though $S$ and $P$ are stable chemical species (Eqn 6–1); the ES and EP complexes occupy valleys in the reaction coordinate diagram (Fig. 6–3). Additional, less stable chemical intermediates often exist in the course of an enzyme-catalyzed reaction. The interconversion of two sequential reaction intermediates thus constitutes a reaction step. When several steps occur in a reaction, the overall rate is determined by the step (or steps) with the highest activation energy; this is called the rate-limiting step. In a simple case, the rate-limiting step is the highest-energy point in the diagram for interconversion of $S$ and $P$. In practice, the rate-limiting step can vary with reaction conditions, and for many enzymes several steps may have similar activation energies, which means they are all partially rate-limiting.

Activation energies are energy barriers to chemical reactions. These barriers are crucial to life itself. The rate at which a molecule undergoes a particular reaction

![Figure 6-3](image)
Enzymes decrease as the activation barrier for that reaction increases. Without such energy barriers, complex macromolecules would revert spontaneously to much simpler molecular forms, and the complex and highly ordered structures and metabolic processes of cells could not exist. Over the course of evolution, enzymes have developed to lower activation energies selectively for reactions that are needed for cell survival.

**Reaction Rates and Equilibria Have Precise Thermodynamic Definitions**

Reaction *equilibria* are inextricably linked to the standard free-energy change for the reaction, $\Delta G^{\circ}$, and reaction *rates* are linked to the activation energy, $\Delta G^\ddagger$. A basic introduction to these thermodynamic relationships is the next step in understanding how enzymes work.

An equilibrium such as $S \rightleftharpoons P$ is described by an *equilibrium constant*, $K_{eq}$, or simply $K$ (p. 24). Under the standard conditions used to compare biochemical processes, an equilibrium constant is denoted $K'_{eq}$ (or $K'$):

$$K'_{eq} = \frac{[P]}{[S]} \quad (6-2)$$

From thermodynamics, the relationship between $K'_{eq}$ and $\Delta G^{\circ}$ can be described by the expression

$$\Delta G^{\circ} = -RT \ln K'_{eq} \quad (6-3)$$

where $R$ is the gas constant, 8.315 J/mol · K, and $T$ is the absolute temperature, 298 K (25 °C). Equation 6–3 is developed and discussed in more detail in Chapter 13. The important point here is that the equilibrium constant is directly related to the overall standard free-energy change for the reaction (Table 6–4). A large negative value for $\Delta G^{\circ}$ reflects a favorable reaction equilibrium—but as already noted, this does not mean the reaction will proceed at a rapid rate.

Note: The relationship is calculated from $\Delta G^{\circ} = -RT \ln K'_{eq}$ (Eqn 6-3).

The rate of any reaction is determined by the concentration of the reactant (or reactants) and by a rate constant, usually denoted by $k$. For the unimolecular reaction $S \rightarrow P$, the rate (or velocity) of the reaction, $V$—representing the amount of $S$ that reacts per unit time—is expressed by a rate equation:

$$V = k[S] \quad (6-4)$$

In this reaction, the rate depends only on the concentration of $S$. This is called a first-order reaction. The factor $k$ is a proportionality constant that reflects the probability of reaction under a given set of conditions (pH, temperature, and so forth). Here, $k$ is a first-order rate constant and has units of reciprocal time, such as $s^{-1}$. If a first-order reaction has a rate constant $k$ of $0.03 \, s^{-1}$, this may be interpreted (qualitatively) to mean that 3% of the available $S$ will be converted to $P$ in 1 s. A reaction with a rate constant of $2,000 \, s^{-1}$ will be over in a small fraction of a second. If a reaction rate depends on the concentration of two different compounds, or if the reaction is between two molecules of the same compound, the reaction is second order and $k$ is a second-order rate constant, with units of $M^{-1}s^{-1}$. The rate equation then becomes

$$V = k[S_1][S_2] \quad (6-5)$$

From transition-state theory we can derive an expression that relates the magnitude of a rate constant to the activation energy:

$$k = \frac{kT}{h} e^{-\Delta G^\ddagger/RT} \quad (6-6)$$

where $k$ is the Boltzmann constant and $h$ is Planck’s constant. The important point here is that the relationship between the rate constant $k$ and the activation energy $\Delta G^\ddagger$ is inverse and exponential. In simplified terms, this is the basis for the statement that a lower activation energy means a faster reaction rate.

Now we turn from what enzymes do to how they do it.

**A Few Principles Explain the Catalytic Power and Specificity of Enzymes**

Enzymes are extraordinary catalysts. The rate enhancements they bring about are in the range of 5 to 17 orders of magnitude (Table 6–5). Enzymes are also very specific, readily discriminating between substrates with quite similar structures. How can these enormous and highly selective rate enhancements be explained? What is the source of the energy for the dramatic lowering of the activation energies for specific reactions?

The answer to these questions has two distinct but interwoven parts. The first lies in the rearrangement of covalent bonds during an enzyme-catalyzed reaction. Chemical reactions of many types take place between substrates and enzymes’ functional groups (specific amino acid side chains, metal ions, and coenzymes). Catalytic functional groups on an enzyme may form a transient
covalent bond with a substrate and activate it for reaction, or a group may be transiently transferred from the substrate to the enzyme. In many cases, these reactions occur only in the enzyme active site. Covalent interactions between enzymes and substrates lower the activation energy (and thereby accelerate the reaction) by providing an alternative, lower-energy reaction path. The specific types of rearrangements that occur are described in Section 6.4.

The second part of the explanation lies in the noncovalent interactions between enzyme and substrate. Much of the energy required to lower activation energies is derived from weak, noncovalent interactions between substrate and enzyme. What really sets enzymes apart from most other catalysts is the formation of a specific ES complex. The interaction between substrate and enzyme in this complex is mediated by the same forces that stabilize protein structure, including hydrogen bonds and hydrophobic and ionic interactions (Chapter 4). Formation of each weak interaction in the ES complex is accompanied by release of a small amount of free energy that stabilizes the interaction. The energy derived from enzyme-substrate interaction is called binding energy, $\Delta G_B$. Its significance extends beyond a simple stabilization of the enzyme-substrate interaction. Binding energy is a major source of free energy used by enzymes to lower the activation energies of reactions.

Two fundamental and interrelated principles provide a general explanation for how enzymes use noncovalent binding energy:

1. Much of the catalytic power of enzymes is ultimately derived from the free energy released in forming many weak bonds and interactions between an enzyme and its substrate. This binding energy contributes to specificity as well as to catalysis.

2. Weak interactions are optimized in the reaction transition state; enzyme active sites are complementary not to the substrates per se but to the transition states through which substrates pass as they are converted to products during an enzymatic reaction.

These themes are critical to an understanding of enzymes, and they now become our primary focus.

### Weak Interactions between Enzyme and Substrate Are Optimized in the Transition State

How does an enzyme use binding energy to lower the activation energy for a reaction? Formation of the ES complex is not the explanation in itself, although some of the earliest considerations of enzyme mechanisms began with this idea. Studies on enzyme specificity carried out by Emil Fischer led him to propose, in 1894, that enzymes were structurally complementary to their substrates, so that they fit together like a lock and key (Fig. 6-4). This elegant idea, that a specific (exclusive) interaction between two biological molecules is mediated by molecular surfaces with complementary shapes, has greatly influenced the development of biochemistry, and such interactions lie at the heart of many biochemical processes. However, the “lock and key” hypothesis can be misleading when applied to enzymatic catalysis. An enzyme completely complementary to its substrate would be a very poor enzyme, as we can demonstrate.

**FIGURE 6-4** Complementary shapes of a substrate and its binding site on an enzyme. The enzyme dihydrofolate reductase with its substrate $\text{NADP}^+$ (red), unbound (top) and bound (bottom); another bound substrate, tetrahydrofolate (yellow), is also visible (PDB ID 1RA2). In this model, the $\text{NADP}^+$ binds to a pocket that is complementary to it in shape and ionic properties, an illustration of Emil Fischer’s “lock and key” hypothesis of enzyme action. In reality, the complementarity between protein and ligand (in this case substrate) is rarely perfect, as we saw in Chapter 5.
Consider an imaginary reaction, the breaking of a magnetized metal stick. The uncatalyzed reaction is shown in Figure 6–5a. Let’s examine two imaginary enzymes—two “stickases”—that could catalyze this reaction, both of which employ magnetic forces as a paradigm for the binding energy used by real enzymes. We first design an enzyme perfectly complementary to the substrate (Fig. 6–5b). The active site of this stickase is a pocket lined with magnets. To react (break), the stick must reach the transition state of the reaction, but the stick fits so tightly in the active site that it cannot bend, because bending would eliminate some of the magnetic interactions between stick and enzyme. Such an enzyme impedes the reaction, stabilizing the substrate instead. In a reaction coordinate diagram (Fig. 6–5b), this kind of ES complex would correspond to an energy trough from which the substrate would have difficulty escaping. Such an enzyme would be useless.

The modern notion of enzymatic catalysis, first proposed by Michael Polanyi (1921) and Haldane (1930), was elaborated by Linus Pauling in 1946: in order to catalyze reactions, an enzyme must be complementary to the reaction transition state. This means that optimal interactions between substrate and enzyme occur only in the transition state. Figure 6–5c demonstrates how such an enzyme can work. The metal stick binds to the stickase, but only a subset of the possible magnetic interactions are used in forming the ES complex. The bound substrate must still undergo the increase in free energy needed to reach the transition state. Now, however, the increase in free energy required to draw the stick into a bent and partially broken conformation is offset, or “paid for,” by the magnetic interactions (binding energy) that form between the enzyme and substrate in the transition state. Many of these interactions involve parts of the stick that are distant from the point of breakage; thus interactions between the stickase and nonreacting parts of the stick provide some of the energy needed to catalyze stick breakage. This “energy payment” translates into a lower net activation energy and a faster reaction rate.

![Diagram](image-url)

**Figure 6–5** An imaginary enzyme (stickase) designed to catalyze breakage of a metal stick. (a) Before the stick is broken, it must first be bent (the transition state). In both stickase examples, magnetic interactions take the place of weak bonding interactions between enzyme and substrate. (b) A stickase with a magnet-lined pocket complementary in structure to the stick (the substrate) stabilizes the substrate. Bending is impeded by the magnetic attraction between stick and stickase. (c) An enzyme with a pocket complementary to the reaction transition state helps to destabilize the stick, contributing to catalysis of the reaction. The binding energy of the magnetic interactions compensates for the increase in free energy required to bend the stick. Reaction coordinate diagrams (right) show the energy consequences of complementarity to substrate versus complementarity to transition state (ES complexes are omitted). \( \Delta G_M \): the difference between the transition-state energies of the uncatalyzed and catalyzed reactions, is contributed by the magnetic interactions between the stick and stickase. When the enzyme is complementary to the substrate (b), the ES complex is more stable and has less free energy in the ground state than substrate alone. The result is an increase in the activation energy.
Real enzymes work on an analogous principle. Some weak interactions are formed in the ES complex, but the full complement of such interactions between substrate and enzyme is formed only when the substrate reaches the transition state. The free energy (binding energy) released by the formation of these interactions partially offsets the energy required to reach the top of the energy hill. The summation of the unfavorable (positive) activation energy ΔG° and the favorable (negative) binding energy ΔGₐ results in a lower net activation energy (Fig. 6-6). Even on the enzyme, the transition state is not a stable species but a brief point in time that the substrate spends atop an energy hill. The enzyme-catalyzed reaction is much faster than the uncatalyzed process, however, because the hill is much smaller. The important principle is that weak binding interactions between the enzyme and the substrate provide a substantial driving force for enzymatic catalysis. The groups on the substrate that are involved in these weak interactions can be at some distance from the bonds that are broken or changed. The weak interactions formed only in the transition state are those that make the primary contribution to catalysis.

The requirement for multiple weak interactions to drive catalysis is one reason why enzymes (and some coenzymes) are so large. An enzyme must provide functional groups for ionic, hydrogen-bond, and other interactions, and also must precisely position these groups so that binding energy is optimized in the transition state. Adequate binding is accomplished most readily by positioning a substrate in a cavity (the active site) where it is effectively removed from water. The size of proteins reflects the need for superstructure to keep interacting groups properly positioned and to keep the cavity from collapsing.

**Binding Energy Contributes to Reaction Specificity and Catalysis**

Can we demonstrate quantitatively that binding energy accounts for the huge rate accelerations brought about by enzymes? Yes. As a point of reference, Equation 6-6 allows us to calculate that ΔG° must be lowered by about 5.7 kJ/mol to accelerate a first-order reaction by a factor of ten, under conditions commonly found in cells. The energy available from formation of a single weak interaction is generally estimated to be 4 to 30 kJ/mol. The overall energy available from a number of such interactions is therefore sufficient to lower activation energies by the 60 to 100 kJ/mol required to explain the large rate enhancements observed for many enzymes.

The same binding energy that provides energy for catalysis also gives an enzyme its specificity, the ability to discriminate between a substrate and a competing molecule. Conceptually, specificity is easy to distinguish from catalysis, but this distinction is much more difficult to make experimentally, because catalysis and specificity arise from the same phenomenon. If an enzyme active site has functional groups arranged optimally to form a variety of weak interactions with a particular substrate in the transition state, the enzyme will not be able to interact to the same degree with any other molecule. For example, if the substrate has a hydroxyl group that forms a hydrogen bond with a specific Glu residue on the enzyme, any molecule lacking a hydroxyl group at that particular position will be a poorer substrate for the enzyme. In addition, any molecule with an extra functional group for which the enzyme has no pocket or binding site is likely to be excluded from the enzyme. In general, specificity is derived from the formation of many weak interactions between the enzyme and its specific substrate molecule.

The importance of binding energy to catalysis can be readily demonstrated. For example, the glycolytic enzyme triose phosphate isomerase catalyzes the interconversion of glyceraldehyde 3-phosphate and dihydroxyacetone phosphate:

\[
\begin{align*}
\text{Glyceraldehyde} & \quad \text{Dihydroxyacetone} \\
\text{3-phosphate} & \quad \text{phosphate} \\
HC=O & \quad H_2C-OH \\
HC-OH & \quad C=O \\
C_3H_5OPO_3^+ & \text{triose phosphate} \\
& \text{isomerase} \\
& \text{H}_{3}C-OPO_{3}^- \\
\end{align*}
\]

This reaction rearranges the carbonyl and hydroxyl groups on carbons 1 and 2. However, more than 80% of the enzymatic rate acceleration has been traced to enzyme-substrate interactions involving the phosphate group on carbon 3 of the substrate. This was determined by comparing the enzyme-catalyzed reactions with glyceraldehyde 3-phosphate and with glyceraldehyde (no phosphate group at position 3) as substrate.

The general principles outlined above can be illustrated by a variety of recognized catalytic mechanisms. These mechanisms are not mutually exclusive, and a given enzyme might incorporate several types in its overall mechanism of action.

Consider what needs to occur for a reaction to take place. Prominent physical and thermodynamic factors contributing to ΔG°, the barrier to reaction, might include:
The entropy (freedom of motion) of molecules in solution, which reduces the possibility that they will react together; (2) the solvation shell of hydrogen-bonded water that surrounds and helps to stabilize most biomolecules in aqueous solution; (3) the distortion of substrates that must occur in many reactions; and (4) the need for proper alignment of catalytic functional groups on the enzyme. Binding energy can be used to overcome all these barriers.

First, a large restriction in the relative motions of two substrates that are to react, or entropy reduction, is one obvious benefit of binding them to an enzyme. Binding energy holds the substrates in the proper orientation to react—a substantial contribution to catalysis, because productive collisions between molecules in solution can be exceedingly rare. Substrates can be precisely aligned on the enzyme, with many weak interactions between each substrate and strategically located groups on the enzyme clamping the substrate molecules into the proper positions. Studies have shown that constraining the motion of two reactants can produce rate enhancements of many orders of magnitude (Fig. 6–7).

Second, formation of weak bonds between substrate and enzyme results in desolvation of the substrate. Enzyme-substrate interactions replace most or all of the hydrogen bonds between the substrate and water. Third, binding energy involving weak interactions formed only in the reaction transition state helps to compensate thermodynamically for any distortion, primarily electron redistribution, that the substrate must undergo to react.

Finally, the enzyme itself usually undergoes a change in conformation when the substrate binds, induced by multiple weak interactions with the substrate. This is referred to as induced fit, a mechanism postulated by Daniel Koshland in 1958. The motions can affect a small part of the enzyme near the active site, or can involve changes in the positioning of entire domains. Typically, a network of coupled motions occurs throughout the enzyme that ultimately brings about the required changes in the active site. Induced fit serves to bring specific functional groups on the enzyme into the proper position to catalyze the reaction. The conformational change also permits formation of additional weak bonding interactions in the transition state. In either case, the new enzyme conformation has enhanced catalytic properties. As we have seen, induced fit is a common feature of the reversible binding of ligands to proteins (Chapter 5). Induced fit is also important in the interaction of almost every enzyme with its substrate.

**Specific Catalytic Groups Contribute to Catalysis**

In most enzymes, the binding energy used to form the ES complex is just one of several contributors to the overall catalytic mechanism. Once a substrate is bound to an enzyme, properly positioned catalytic functional groups aid in the cleavage and formation of bonds by a variety of mechanisms, including general acid-base catalysis, covalent catalysis, and metal ion catalysis. These are distinct from mechanisms based on binding energy, because they generally involve transient covalent interaction with a substrate or group transfer to or from a substrate.

**General Acid-Base Catalysis**

Many biochemical reactions involve the formation of unstable charged intermediates that tend to break down rapidly to their constituent reactant species, thus impeding the reaction (Fig. 6–8). Charged intermediates can often be stabilized by the transfer of protons to or from the substrate or intermediate to form a species that breaks down more readily to products. For nonenzymatic reactions, the proton transfers can involve either the constituents of water alone or other weak proton donors or acceptors. Catalysis of the type that uses only the $\text{H}^+$ ($\text{H}_2\text{O}^+$) or $\text{OH}^-$ ions present in water is referred to as specific acid-base catalysis. If protons are transferred between the intermediate and water faster than the intermediate breaks down to reactants, the intermediate is effectively stabilized every time it forms. No additional catalysis...
Without catalysis, unstable (charged) intermediate breaks down rapidly to form reactants.

When proton transfer to or from H₂O is faster than the rate of breakdown of intermediates, the presence of other proton donors or acceptors does not increase the rate of the reaction.

When proton transfer to or from H₂O is slower than the rate of breakdown of intermediates, only a fraction of the intermediates formed are stabilized. The presence of alternative proton donors (HA) or acceptors (B⁻) increases the rate of the reaction.

FIGURE 6-8 How a catalyst circumvents unfavorable charge development during cleavage of an amide. The hydrolysis of an amide bond, shown here, is the same reaction as that catalyzed by chymotrypsin and other proteases. Charge development is unfavorable and can be circumvented by donation of a proton by H₃O⁺ (specific acid catalysis) or HA (general acid catalysis), where HA represents any acid. Similarly, charge can be neutralized by proton abstraction by OH⁻ (specific base catalysis) or B⁻ (general base catalysis), where B⁻ represents any base.

mediated by other proton acceptors or donors will occur. In many cases, however, water is not enough. The term general acid-base catalysis refers to proton transfers mediated by other classes of molecules. For nonenzymatic reactions in aqueous solutions, this occurs only when the unstable reaction intermediate breaks down to reactants faster than protons can be transferred to or from water. Many weak organic acids can supplement water as proton donors in this situation, or weak organic bases can serve as proton acceptors.

In the active site of an enzyme, a number of amino acid side chains can similarly act as proton donors and acceptors (Fig. 6-9). These groups can be precisely positioned in an enzyme active site to allow proton transfers, providing rate enhancements of the order of 10⁴ to 10⁵. This type of catalysis occurs on the vast majority of enzymes. In fact, proton transfers are the most common biochemical reactions.

Covalent Catalysis In covalent catalysis, a transient covalent bond is formed between the enzyme and the substrate. Consider the hydrolysis of a bond between groups A and B:

\[ A - B + H_2O \rightarrow A + B \]

In the presence of a covalent catalyst (an enzyme with a nucleophilic group X⁻) the reaction becomes

\[ A - B + X⁻ \rightarrow A - X + B \rightarrow A + X⁻ + B \]

This alters the pathway of the reaction, and it results in catalysis only when the new pathway has a lower activation energy than the uncatalyzed pathway. Both of the new steps must be faster than the uncatalyzed reaction. A number of amino acid side chains, including all those in Figure 6-9, and the functional groups of some enzyme cofactors can serve as nucleophiles in the formation of covalent bonds with substrates. These covalent complexes always undergo further reaction to regenerate the free enzyme. The covalent bond formed between the enzyme and the substrate can activate a substrate for further reaction in a manner that is usually specific to the particular group or coenzyme.

Metal Ion Catalysis Metals, whether tightly bound to the enzyme or taken up from solution along with the substrate, can participate in catalysis in several ways.

Ionic interactions between an enzyme-bound metal and a substrate can help orient the substrate for reaction or stabilize charged reaction transition states. This use of weak bonding interactions between metal and substrate is similar to some of the uses of enzyme-substrate binding energy described earlier. Metals can also mediate oxidation-reduction reactions by reversible changes in the metal ion's oxidation state. Nearly a third of all known enzymes require one or more metal ions for catalytic activity.

Most enzymes combine several catalytic strategies to bring about a rate enhancement. A good example is the use of covalent catalysis, general acid-base catalysis, and transition-state stabilization in the reaction catalyzed by chymotrypsin, detailed in Section 6.4.

**SUMMARY 6.2 How Enzymes Work**

- Enzymes are highly effective catalysts, commonly enhancing reaction rates by a factor of $10^5$ to $10^{16}$.
- Enzyme-catalyzed reactions are characterized by the formation of a complex between substrate and enzyme (an ES complex). Substrate binding occurs in a pocket on the enzyme called the active site.
- The function of enzymes and other catalysts is to lower the activation energy, $\Delta G^\ddagger$, for a reaction and thereby enhance the reaction rate. The equilibrium of a reaction is unaffected by the enzyme.
- A significant part of the energy used for enzymatic rate enhancements is derived from weak interactions (hydrogen bonds and hydrophobic and ionic interactions) between substrate and enzyme. The enzyme active site is structured so that some of these weak interactions occur preferentially in the reaction transition state, thus stabilizing the transition state. The need for multiple interactions is one reason for the large size of enzymes. The binding energy, $\Delta G_B$, can be used to lower substrate entropy or to cause a conformational change in the enzyme (induced fit). Binding energy also accounts for the exquisite specificity of enzymes for their substrates.
- Additional catalytic mechanisms employed by enzymes include general acid-base catalysis, covalent catalysis, and metal ion catalysis. Catalysis often involves transient covalent interactions between the substrate and the enzyme, or group transfers to and from the enzyme, so as to provide a new, lower-energy reaction path.

### 6.3 Enzyme Kinetics as an Approach to Understanding Mechanism

Biochemists commonly use several approaches to study the mechanism of action of purified enzymes. The three-dimensional structure of the protein provides important information, which is enhanced by classical protein chemistry and modern methods of site-directed mutagenesis (changing the amino acid sequence of a protein by genetic engineering; see Fig. 9–11). These technologies permit enzymologists to examine the role of individual amino acids in enzyme structure and action. However, the oldest approach to understanding enzyme mechanisms, and the one that remains most important, is to determine the rate of a reaction and how it changes in response to changes in experimental parameters, a discipline known as enzyme kinetics. We provide here a basic introduction to the kinetics of enzyme-catalyzed reactions. More advanced treatments are available in the sources cited at the end of the chapter.

#### Substrate Concentration Affects the Rate of Enzyme-Catalyzed Reactions

A key factor affecting the rate of a reaction catalyzed by an enzyme is the concentration of substrate, $[S]$. However, studying the effects of substrate concentration is complicated by the fact that $[S]$ changes during the course of an in vitro reaction as substrate is converted to product. One simplifying approach in kinetics experiments is to measure the initial rate (or initial velocity), designated $V_0$ (Fig. 6–10). In a typical reaction, the enzyme may be present in nanomolar quantities, whereas $[S]$ may be five or six orders of magnitude higher. If only the beginning of the reaction is monitored (often the first 60 seconds or less), changes in $[S]$ can be limited to a few percent, and $[S]$ can be regarded as constant. $V_0$ can then be explored as a function of $[S]$, which is adjusted by the investigator. The effect on $V_0$ of varying $[S]$ when the enzyme concentration is held constant is

![Figure 6–10 Initial velocities of enzyme-catalyzed reactions. A theoretical enzyme catalyzes the reaction $S \rightarrow P$, and is present at a concentration sufficient to catalyze the reaction at a maximum velocity, $V_{max}$, of 1 $\mu$M/min. The Michaelis constant, $K_m$ (explained in the text), is 0.5 $\mu$M. Progress curves are shown for substrate concentrations below, at, and above the $K_m$. The rate of an enzyme-catalyzed reaction declines as substrate is converted to product. A tangent to each curve taken at time $= 0$ defines the initial velocity, $V_0$, of each reaction.](image-url)
Substrate concentration, [S] (mM)

FIGURE 6-11  Effect of substrate concentration on the initial velocity of an enzyme-catalyzed reaction. The maximum velocity, $V_{\text{max}}$, is extrapolated from the plot, because $V_0$ approaches but never quite reaches $V_{\text{max}}$. The substrate concentration at which $V_0$ is half maximal is $K_m$, the Michaelis constant. The concentration of enzyme in an experiment such as this is generally so low that $E_i \gg E_f$ even when $[S]$ is described as low or relatively low. The units shown are typical for enzyme-catalyzed reactions and are given only to help illustrate the meaning of $V_0$ and $[S]$. (Note that the curve describes part of a rectangular hyperbola, with one asymptote at $V_{\text{max}}$. If the curve were continued below $[S] = 0$, it would approach a vertical asymptote at $[S] = K_m$.)

FIGURE 6-11 shows the effect of substrate concentration on the initial velocity of an enzyme-catalyzed reaction. At relatively low concentrations of substrate, $V_0$ increases almost linearly with an increase in $[S]$. At higher substrate concentrations, $V_0$ increases by smaller and smaller amounts in response to increases in $[S]$. Finally, a point is reached beyond which increases in $V_0$ are vanishingly small as $[S]$ increases. This plateau-like $V_0$ region is close to the maximum velocity, $V_{\text{max}}$.

The ES complex is the key to understanding this kinetic behavior, just as it was a starting point for our discussion of catalysis. The kinetic pattern in Figure 6-11 led Victor Henri, following the lead of Wurtz, to propose in 1903 that the combination of an enzyme with its substrate molecule to form an ES complex is a necessary step in enzymatic catalysis. This idea was expanded into a general theory of enzyme action, particularly by Leonor Michaelis and Maud Menten in 1913. They postulated that the enzyme first combines reversibly with its substrate to form an enzyme-substrate complex in a relatively fast reversible step:

$$E + S \xrightleftharpoons[k_{-1}]{k_1} ES \quad (6-7)$$

The ES complex then breaks down in a slower second step to yield the free enzyme and the reaction product $P$:

$$ES \xrightleftharpoons[k_{-2}]{k_2} E + P \quad (6-8)$$

Because the slower second reaction (Eqn 6–8) must limit the rate of the overall reaction, the overall rate must be proportional to the concentration of the species that reacts in the second step, that is, ES.

At any given instant in an enzyme-catalyzed reaction, the enzyme exists in two forms, the free or uncombined form $E$ and the combined form $ES$. At low $[S]$, most of the enzyme is in the uncombined form $E$. Here, the rate is proportional to $[S]$ because the equilibrium of Equation 6–7 is pushed toward formation of more ES as $[S]$ increases. The maximum initial rate of the catalyzed reaction ($V_{\text{max}}$) is observed when virtually all the enzyme is present as the ES complex and $[E]$ is vanishingly small. Under these conditions, the enzyme is “saturated” with its substrate, so that further increases in $[S]$ have no effect on rate. This condition exists when $[S]$ is sufficiently high that essentially all the free enzyme has been converted to the ES form. After the ES complex breaks down to yield the product $P$, the enzyme is free to catalyze reaction of another molecule of substrate. The saturation effect is a distinguishing characteristic of enzymatic catalysts and is responsible for the plateau observed in Figure 6-11. The pattern seen in Figure 6–11 is sometimes referred to as saturation kinetics.

When the enzyme is first mixed with a large excess of substrate, there is an initial period, the pre-steady state, during which the concentration of ES builds up. This period is usually too short to be easily observed, lasting just microseconds, and is not evident in Figure 6–10. The reaction quickly achieves a steady state in which $[ES]$ (and the concentrations of any other intermediates) remains approximately constant over time. The concept of a steady state was introduced by G. E. Briggs and Haldane in 1925. The measured $V_0$ generally reflects the steady state, even though $V_0$ is limited to the early part of the reaction, and analysis of these initial rates is referred to as steady-state kinetics.

The Relationship between Substrate Concentration and Reaction Rate Can Be Expressed Quantitatively

The curve expressing the relationship between $[S]$ and $V_0$ (Fig. 6–11) has the same general shape for most enzymes (it approaches a rectangular hyperbola), which can be expressed algebraically by the Michaelis-Menten equation. Michaelis and Menten derived this equation starting from their basic hypothesis that the rate-limiting step in enzymatic reactions is the
breakdown of the ES complex to product and free enzyme. The equation is

\[ V_0 = \frac{V_{\text{max}}[S]}{K_m + [S]} \]  

(6-9)

The important terms are \([S], V_0, V_{\text{max}},\) and a constant called the Michaelis constant, \(K_m\). All these terms are readily measured experimentally.

Here we develop the basic logic and the algebraic steps in a modern derivation of the Michaelis-Menten equation, which includes the steady-state assumption introduced by Briggs and Haldane. The derivation starts with the two basic steps of the formation and breakdown of ES (Eqns 6-7 and 6-8). Early in the reaction, the concentration of the product, \([P]\), is negligible, and we make the simplifying assumption that the reverse reaction, \(P \rightarrow S\) (described by \(k_{-2}\)), can be ignored. This assumption is not critical but it simplifies our task. The overall reaction then reduces to

\[ E + S \xrightarrow{k_1} ES \xrightarrow{k_{-1}} E + P \]  

(6-10)

\(V_0\) is determined by the breakdown of ES to form product, which is determined by [ES]:

\[ V_0 = k_2[ES] \]  

(6-11)

Because [ES] in Equation 6-11 is not easily measured experimentally, we must begin by finding an alternative expression for this term. First, we introduce the term \([E]\), representing the total enzyme concentration (the sum of free and substrate-bound enzyme). Free or unbound enzyme can then be represented by \([E] - [ES]\). Also, because \([S]\) is ordinarily far greater than \([E]\), the amount of substrate bound by the enzyme at any given time is negligible compared with the total [S]. With these conditions in mind, the following steps lead us to an expression for \(V_0\) in terms of easily measurable parameters.

**Step 1** The rates of formation and breakdown of ES are determined by the steps governed by the rate constants \(k_1\) (formation) and \(k_{-1} + k_2\) (breakdown to reactants and products, respectively), according to the expressions

\[
\begin{align*}
\text{Rate of ES formation} & = k_1([E] - [ES])[S] \\
\text{Rate of ES breakdown} & = k_{-1}[ES] + k_2[ES]
\end{align*}
\]  

(6-12)-(6-13)

**Step 2** We now make an important assumption: that the initial rate of reaction reflects a steady state in which [ES] is constant—that is, the rate of formation of ES is equal to the rate of its breakdown. This is called the steady-state assumption. The expressions in Equations 6-12 and 6-13 can be equated for the steady state, giving

\[ k_1([E] - [ES])[S] = k_{-1}[ES] + k_2[ES] \]  

(6-14)

**Step 3** In a series of algebraic steps, we now solve Equation 6-14 for [ES]. First, the left side is multiplied out and the right side simplified to give

\[ k_1[E][S] - k_1[ES][S] = (k_{-1} + k_2)[ES] \]  

(6-15)

Adding the term \(k_1[ES][S]\) to both sides of the equation and simplifying gives

\[ k_1[E][S] = (k_1[S] + k_{-1} + k_2)[ES] \]  

(6-16)

We then solve this equation for [ES]:

\[ [ES] = \frac{k_1[E][S]}{k_1[S] + k_{-1} + k_2} \]  

(6-17)

This can now be simplified further, combining the rate constants into one expression:

\[ [ES] = \frac{[E][S]}{[S] + (k_{-1} + k_2)/k_1} \]  

(6-18)

The term \((k_{-1} + k_2)/k_1\) is defined as the Michaelis constant, \(K_m\). Substituting this into Equation 6-18 simplifies the expression to

\[ [ES] = \frac{[E][S]}{K_m + [S]} \]  

(6-19)

**Step 4** We can now express \(V_0\) in terms of [ES]. Substituting the right side of Equation 6-19 for [ES] in Equation 6-11 gives

\[ V_0 = \frac{k_2[E][S]}{K_m + [S]} \]  

(6-20)

This equation can be further simplified. Because the maximum velocity occurs when the enzyme is saturated (that is, with [ES] = [E]), \(V_{\text{max}}\) can be defined as \(k_2[E]\). Substituting this in Equation 6-20 gives Equation 6-9:

\[ V_0 = \frac{V_{\text{max}}[S]}{K_m + [S]} \]  

This is the **Michaelis-Menten equation**, the rate equation for a one-substrate enzyme-catalyzed reaction. It is a statement of the quantitative relationship between the initial velocity \(V_0\), the maximum velocity \(V_{\text{max}}\), and the initial substrate concentration [S], all related through the Michaelis constant \(K_m\). Note that \(K_m\) has units of concentration. Does the equation fit experimental observations? Yes; we can confirm this by considering the limiting situations where [S] is very high or very low, as shown in Figure 6-12.

An important numerical relationship emerges from the Michaelis-Menten equation in the special case when \(V_0\) is exactly one-half \(V_{\text{max}}\) (Fig. 6-12). Then

\[ \frac{V_{\text{max}}}{2} = \frac{V_{\text{max}}[S]}{K_m + [S]} \]  

(6-21)

On dividing by \(V_{\text{max}}\), we obtain

\[ \frac{1}{2} = \frac{[S]}{K_m + [S]} \]  

(6-22)

Solving for \(K_m\), we get \(K_m + [S] = 2[S]\), or

\[ K_m = [S], \text{ when } V_0 = \frac{1}{2}V_{\text{max}} \]  

(6-23)
This is a very useful, practical definition of \( K_m \); \( K_m \) is equivalent to the substrate concentration at which \( V_0 \) is one-half \( V_{\text{max}} \).

The Michaelis-Menten equation (Eqn 6–9) can be algebraically transformed into versions that are useful in the practical determination of \( K_m \) and \( V_{\text{max}} \) (Box 6–1) and, as we describe later, in the analysis of inhibitor action (see Box 6–2 on page 202).

**Kinetic Parameters Are Used to Compare Enzyme Activities**

It is important to distinguish between the Michaelis-Menten equation and the specific kinetic mechanism on which it was originally based. The equation describes the kinetic behavior of a great many enzymes, and all enzymes that exhibit a hyperbolic dependence of \( V_0 \) on \( [S] \) are said to follow Michaelis-Menten kinetics. The practical rule that \( K_m = [S] \) when \( V_0 = \frac{1}{2} V_{\text{max}} \) (Eqn 6–23) holds for all enzymes that follow Michaelis-Menten kinetics. (The most important exceptions to Michaelis-Menten kinetics are the regulatory enzymes, discussed in Section 6.5.) However, the Michaelis-Menten equation does not depend on the relatively simple two-step reaction mechanism proposed by Michaelis.

---

**Figure 6–12** Dependence of initial velocity on substrate concentration.

This graph shows the kinetic parameters that define the limits of the curve at high and low [S]. At low [S], \( K_m \gg [S] \) and the [S] term in the denominator of the Michaelis-Menten equation (Eqn 6–9) becomes insignificant. The equation simplifies to \( V_0 = V_{\text{max}} [S]/K_m \) and \( V_0 \) exhibits a linear dependence on [S], as observed here. At high [S], where \( [S] \gg K_m \), the \( K_m \) term in the denominator of the Michaelis-Menten equation becomes insignificant and the equation simplifies to \( V_0 = V_{\text{max}} \), this is consistent with the plateau observed at high [S]. The Michaelis-Menten equation is therefore consistent with the observed dependence of \( V_0 \) on [S], and the shape of the curve is defined by the terms \( V_{\text{max}}/K_m \) at low [S] and \( V_{\text{max}} \) at high [S].

---

**Box 6–1 Transforms of the Michaelis-Menten Equation: The Double-Reciprocal Plot**

The Michaelis-Menten equation

\[
V_0 = \frac{V_{\text{max}} [S]}{K_m + [S]}
\]

can be algebraically transformed into equations that are more useful in plotting experimental data. One common transformation is derived simply by taking the reciprocal of both sides of the Michaelis-Menten equation:

\[
\frac{1}{V_0} = \frac{K_m + [S]}{V_{\text{max}} [S]} \frac{1}{V_{\text{max}}}
\]

Separating the components of the numerator on the right side of the equation gives

\[
\frac{1}{V_0} = \frac{K_m}{V_{\text{max}} [S]} + \frac{[S]}{V_{\text{max}}}
\]

which simplifies to

\[
\frac{1}{V_0} = \frac{K_m}{V_{\text{max}} [S]} + \frac{1}{V_{\text{max}}}
\]

This form of the Michaelis-Menten equation is called the **Lineweaver-Burk equation**. For enzymes obeying the Michaelis-Menten relationship, a plot of \( 1/V_0 \) versus \( 1/[S] \) (the “double reciprocal” of the \( V_0 \) versus \( [S] \) plot we have been using to this point) yields a straight line (Fig. 1). This line has a slope of \( K_m/V_{\text{max}} \), an intercept of \( 1/V_{\text{max}} \) on the \( 1/V_0 \) axis, and an intercept of \( -1/K_m \) on the \( 1/[S] \) axis. The double-reciprocal presentation, also called a Lineweaver-Burk plot, has the great advantage of allowing a more accurate determination of \( V_{\text{max}} \), which can only be approximated from a simple plot of \( V_0 \) versus \( [S] \) (see Fig. 6–12).

Other transformations of the Michaelis-Menten equation have been derived, each with some particular advantage in analyzing enzyme kinetic data. (See Problem 14 at the end of this chapter.)

The double-reciprocal plot of enzyme reaction rates is very useful in distinguishing between certain types of enzymatic reaction mechanisms (see Fig. 6–14) and in analyzing enzyme inhibition (see Box 6–2).
Enzymes and Michaelis-Menten (Eqn 6-10). Many enzymes that follow Michaelis-Menten kinetics have quite different reaction mechanisms, and enzymes that catalyze reactions with six or eight identifiable steps often exhibit the same steady-state kinetic behavior. Even though Equation 6-23 holds true for many enzymes, both the magnitude and the real meaning of $V_{\text{max}}$ and $K_{m}$ can differ from one enzyme to the next. This is an important limitation of the steady-state approach to enzyme kinetics. The parameters $V_{\text{max}}$ and $K_{m}$ can be obtained experimentally for any given enzyme, but by themselves they provide little information about the number, rates, or chemical nature of discrete steps in the reaction. Steady-state kinetics nevertheless is the standard language by which biochemists compare and characterize the catalytic efficiencies of enzymes.

**Interpreting $V_{\text{max}}$ and $K_{m}$** Figure 6-12 shows a simple graphical method for obtaining an approximate value for $K_{m}$. A more convenient procedure, using a double-reciprocal plot, is presented in Box 6-1. The $K_{m}$ can vary greatly from enzyme to enzyme, and even for different substrates of the same enzyme (Table 6-6). The term is sometimes used (often inappropriately) as an indicator of the affinity of an enzyme for its substrate. The actual meaning of $K_{m}$ depends on specific aspects of the reaction mechanism such as the number and relative rates of the individual steps. For reactions with two steps,

$$K_{m} = \frac{k_2 + k_{-1}}{k_1} \quad (6-24)$$

When $k_2$ is rate-limiting, $k_2 << k_{-1}$ and $K_{m}$ reduces to $k_{-1}/k_1$, which is defined as the dissociation constant, $K_d$, of the ES complex. Where these conditions hold, $K_{m}$ does represent a measure of the affinity of the enzyme for its substrate in the ES complex. However, this scenario does not apply for most enzymes. Sometimes $k_2 >> k_{-1}$, and then $K_{m} = k_2/k_1$. In other cases, $k_2$ and $k_{-1}$ are comparable and $K_{m}$ remains a more complex function of all three rate constants (Eqn 6-24). The Michaelis-Menten equation and the characteristic saturation behavior of the enzyme still apply, but $K_{m}$ cannot be considered a simple measure of substrate affinity. Even more common are cases in which the reaction goes through several steps after formation of ES; $K_{m}$ can then become a very complex function of many rate constants.

The quantity $V_{\text{max}}$ also varies greatly from one enzyme to the next. If an enzyme reacts by the two-step Michaelis-Menten mechanism, $V_{\text{max}} = k_2[E]$, where $k_2$ is rate-limiting. However, the number of reaction steps and the identity of the rate-limiting step(s) can vary from enzyme to enzyme.

For example, consider the quite common situation where product release, $EP \rightarrow E + P$, is rate-limiting. Early in the reaction (when $[P]$ is low), the overall reaction can be described by the scheme

$$E + S \xrightarrow{k_1} ES \xrightarrow{k_{-1}} EP \xrightarrow{k_2} E + P \quad (6-25)$$

In this case, most of the enzyme is in the EP form at saturation, and $V_{\text{max}} = k_2[E]$. It is useful to define a more general rate constant, $k_{\text{cat}}$, to describe the limiting rate of any enzyme-catalyzed reaction at saturation. If the reaction has several steps and one is clearly rate-limiting, $k_{\text{cat}}$ is equivalent to the rate constant for that limiting step. For the simple reaction of Equation 6-10, $k_{\text{cat}} = k_2$. For the reaction of Equation 6-25, $k_{\text{cat}} = k_3$. When several steps are partially rate-limiting, $k_{\text{cat}}$ can become a complex function of several of the rate constants that define each individual reaction step. In the Michaelis-Menten equation, $k_{\text{cat}} = V_{\text{max}}/[E]$, and Equation 6-9 becomes

$$V_0 = \frac{k_{\text{cat}}[E][S]}{K_{m} + [S]} \quad (6-26)$$

The constant $k_{\text{cat}}$ is a first-order rate constant and hence has units of reciprocal time. It is also called the turnover number. It is equivalent to the number of substrate molecules converted to product in a given unit of time on a single enzyme molecule when the enzyme is saturated with substrate. The turnover numbers of several enzymes are given in Table 6-7.

Comparing Catalytic Mechanisms and Efficiencies

The kinetic parameters $k_{\text{cat}}$ and $K_m$ are useful for the study and comparison of different enzymes, whether their reaction mechanisms are simple or complex. Each enzyme has values of $k_{\text{cat}}$ and $K_m$ that reflect the cellular environment, the concentration of substrate normally encountered in vivo by the enzyme, and the chemistry of the reaction being catalyzed.

The parameters $k_{\text{cat}}$ and $K_m$ also allow us to evaluate the kinetic efficiency of enzymes, but either parameter alone is insufficient for this task. Two enzymes catalyzing different reactions may have the same $k_{\text{cat}}$ (turnover number), yet the rates of the uncatalyzed reactions may be different and thus the rate enhancements brought about by the enzymes may differ greatly. Experimentally, the $K_m$ for an enzyme tends to be similar to the cellular concentration of its substrate. An enzyme that acts on a substrate present at a very low concentration in the cell usually has a lower $K_m$ than an enzyme that acts on a substrate that is more abundant.

The best way to compare the catalytic efficiencies of different enzymes or the turnover of different substrates by the same enzyme is to compare the ratio $k_{\text{cat}}/K_m$ for the two reactions. This parameter, sometimes called the specificity constant, is the rate constant for the conversion of $E + S$ to $E + P$. When $[S] << K_m$, Equation 6-26 reduces to the form

$$V_0 = \frac{k_{\text{cat}}[E_i][S]}{K_m + [S]} \quad \text{(6-27)}$$

$V_0$ in this case depends on the concentration of two reactants, $[E_i]$ and $[S]$; therefore this is a second-order rate equation and the constant $k_{\text{cat}}/K_m$ is a second-order rate constant with units of $\text{M}^{-1}\text{s}^{-1}$. There is an upper limit to $k_{\text{cat}}/K_m$, imposed by the rate at which $E$ and $S$ can diffuse together in an aqueous solution. This diffusion-controlled limit is $10^8$ to $10^9 \text{M}^{-1}\text{s}^{-1}$, and many enzymes have a $k_{\text{cat}}/K_m$ near this range (Table 6-8). Such enzymes are said to have achieved catalytic perfection. Note that different values of $k_{\text{cat}}$ and $K_m$ can produce the maximum ratio.

### WORKED EXAMPLE 6-1 Determining $K_m$

An enzyme is discovered that catalyzes the chemical reaction

$$\text{SAD} \rightleftharpoons \text{HAPPY}$$

A team of motivated researchers sets out to study the enzyme, which they call happyase. They find that the $k_{\text{cat}}$ for happyase is $600 \text{ s}^{-1}$. They carry out several experiments.

When $[E_i] = 20 \text{ nm}$ and $[\text{SAD}] = 40 \text{ M}$, the reaction velocity, $V_0$, is $9.6 \mu\text{M} \text{ s}^{-1}$. Calculate $K_m$ for the substrate SAD.

**Solution:** We know $k_{\text{cat}}, [E_i], [S]$, and $V_0$. We want to solve for $K_m$. Equation 6-26, in which we substitute $k_{\text{cat}}[E_i]$ for $V_0$ in the Michaelis-Menten equation, is most useful here. Substituting our known values in Equation 6-26 allows us to solve for $K_m$.

$$V_0 = \frac{k_{\text{cat}}[E_i][S]}{K_m + [S]}$$

$$9.6 \mu\text{M} \text{ s}^{-1} = \frac{(600 \text{ s}^{-1})(0.020 \mu\text{M})(40 \mu\text{M})}{K_m + 40 \mu\text{M}}$$

$$9.6 \mu\text{M} \text{ s}^{-1} = \frac{480 \mu\text{M}^2 \text{ s}^{-1}}{K_m + 40 \mu\text{M}}$$

$$9.6 \mu\text{M} \text{ s}^{-1}(K_m + 40 \mu\text{M}) = 480 \mu\text{M}^2 \text{ s}^{-1}$$

$$K_m + 40 \mu\text{M} = 480 \mu\text{M}^2 \text{ s}^{-1}$$

$$K_m + 40 \mu\text{M} = 480 \mu\text{M}^2 \text{ s}^{-1}$$

$$K_m = 50 \mu\text{M} - 40 \mu\text{M}$$

$$K_m = 10 \mu\text{M}$$

Once you have worked with this equation, you will recognize shortcuts to solve problems like this. For example, one can calculate $V_{\text{max}}$ knowing that $k_{\text{cat}}[E_i] = V_{\text{max}} (600 \text{ s}^{-1} \times 0.020 \mu\text{M} = 12 \mu\text{M} \text{ s}^{-1}$ in this case). A

simple rearrangement of Equation 6–26 by dividing both sides by $V_{\text{max}}$ gives

$$\frac{V_0}{V_{\text{max}}} = \frac{[S]}{K_\text{m} + [S]}$$

Thus, the ratio $V_0/V_{\text{max}} = 9.6 \mu\text{M s}^{-1}/12 \mu\text{M s}^{-1} = [S]/(K_\text{m} + [S])$. This simplifies the process of solving for $K_\text{m}$, giving 0.25[S] or 10 $\mu\text{M}$.

**WORKED EXAMPLE 6–2 Determining [S]**

In a separate happyase experiment using $[E_0] = 10 \text{ nM}$, the reaction velocity, $V_0$, is measured as 3 $\mu\text{M s}^{-1}$. What is the [S] used in this experiment?

**Solution:** Using the same logic as in Worked Example 6–1, we see that the $V_{\text{max}}$ for this enzyme concentration is 6 $\mu\text{M s}^{-1}$. Note that the $V_0$ is exactly half of the $V_{\text{max}}$. Recall that $K_\text{m}$ is by definition equal to the [S] where $V_0 = V_{\text{max}}/2$. Thus, the [S] in this problem must be the same as the $K_\text{m}$, or 10 $\mu\text{M}$. If $V_0$ were anything other than $V_{\text{max}}/2$, it would be simplest to use the expression $V_0/V_{\text{max}} = [S]/(K_\text{m} + [S])$ to solve for [S].

Many Enzymes Catalyze Reactions with Two or More Substrates

We have seen how [S] affects the rate of a simple enzymatic reaction ($S \rightarrow P$) with only one substrate molecule. In most enzymatic reactions, however, two (and sometimes more) different substrate molecules bind to the enzyme and participate in the reaction. For example, in the reaction catalyzed by hexokinase, ATP and glucose are the substrate molecules, and ADP and glucose 6-phosphate are the products:

$$\text{ATP} + \text{glucose} \rightarrow \text{ADP} + \text{glucose 6-phosphate}$$

The rates of such bisubstrate reactions can also be analyzed by the Michaelis-Menten approach. Hexokinase has a characteristic $K_\text{m}$ for each of its substrates (Table 6–6).

Enzymatic reactions with two substrates usually involve transfer of an atom or a functional group from one substrate to the other. These reactions proceed by one of several different pathways. In some cases, both substrates are bound to the enzyme concurrently at some point in the course of the reaction, forming a noncovalent ternary complex (Fig. 6–13a); the substrates bind in a random sequence or in a specific order. In other cases, the first substrate is converted to product and dissociates before the second substrate binds, so no ternary complex is formed. An example of this is the Ping-Pong, or double-displacement, mechanism (Fig. 6–13b). Steady-state kinetics can often help distinguish among these possibilities (Fig. 6–14).

---

**FIGURE 6–13 Common mechanisms for enzyme-catalyzed bisubstrate reactions.** (a) The enzyme and both substrates come together to form a ternary complex. In ordered binding, substrate 1 must bind before substrate 2 can bind productively. In random binding, the substrates can bind in either order. (b) An enzyme-substrate complex forms, a product leaves the complex, the altered enzyme forms a second complex with another substrate molecule, and the second product leaves, regenerating the enzyme. Substrate 1 may transfer a functional group to the enzyme (to form the covalently modified $E'$), which is subsequently transferred to substrate 2. This is called a Ping-Pong or double-displacement mechanism.

**FIGURE 6–14 Steady-state kinetic analysis of bisubstrate reactions.** In these double-reciprocal plots (see Box 6–1), the concentration of substrate 1 is varied while the concentration of substrate 2 is held constant. This is repeated for several values of [S2], generating several separate lines. (a) Intersecting lines indicate that a ternary complex is formed in the reaction; (b) parallel lines indicate a Ping-Pong (double-displacement) pathway.
Pre-steady State Kinetics Can Provide Evidence for Specific Reaction Steps

We have introduced kinetics as the primary method for studying the steps in an enzymatic reaction, and we have also outlined the limitations of the most common kinetic parameters in providing such information. The two most important experimental parameters obtained from steady-state kinetics are $k_{\text{cat}}$ and $k_{\text{cat}}/K_m$. Variation in $k_{\text{cat}}$ and $k_{\text{cat}}/K_m$ with changes in pH or temperature can provide additional information about steps in a reaction pathway. In the case of bisubstrate reactions, steady-state kinetics can help determine whether a ternary complex is formed during the reaction (Fig. 6-14). A more complete picture generally requires more sophisticated kinetic methods that go beyond the scope of an introductory text. Here, we briefly introduce one of the most important kinetic approaches for studying reaction mechanisms, pre-steady state kinetics.

A complete description of an enzyme-catalyzed reaction requires direct measurement of the rates of individual reaction steps—for example, the association of enzyme and substrate to form the ES complex. It is during the pre-steady state (see p. 195) that the rates of many reaction steps can be measured independently and events during reaction of a single substrate molecule can be observed. Because the pre-steady state phase is generally very short, the experiments often require specialized techniques for very rapid mixing and sampling. One objective is to gain a complete and quantitative picture of the energy changes during the reaction. As we have already noted, reaction rates and equilibria are related to the free-energy changes during a reaction. Another objective is to measure the rate of individual reaction steps. In a number of cases investigators have been able to record the rates of every individual step in a multistep enzymatic reaction. Some examples of the application of pre-steady state kinetics are included in the descriptions of specific enzymes in Section 6.4.

Enzymes Are Subject to Reversible or Irreversible Inhibition

Enzyme inhibitors are molecules that interfere with catalysis, slowing or halting enzymatic reactions. Enzymes catalyze virtually all cellular processes, so it should not be surprising that enzyme inhibitors are among the most important pharmaceutical agents known. For example, aspirin (acetylsalicylate) inhibits the enzyme that catalyzes the first step in the synthesis of prostaglandins, compounds involved in many processes, including some that produce pain. The study of enzyme inhibitors also has provided valuable information about enzyme mechanisms and has helped define some metabolic pathways. There are two broad classes of enzyme inhibitors: reversible and irreversible.

Reversible Inhibition One common type of reversible inhibition is called competitive (Fig. 6-15a).

![FIGURE 6-15 Three types of reversible inhibition. (a) Competitive inhibitors bind to the enzyme's active site; $K_i$ is the equilibrium constant for inhibitor binding to E. (b) Uncompetitive inhibitors bind at a separate site, but bind only to the ES complex; $K_i'$ is the equilibrium constant for inhibitor binding to ES. (c) Mixed inhibitors bind at a separate site, but may bind to either E or ES.](image-url)
presence of a competitive inhibitor, the Michaelis-Menten equation (Eqn 6–9) becomes

\[ V_0 = \frac{V_{\text{max}}[S]}{\alpha K_m + [S]} \]  

Equation 6–28 describes the important features of competitive inhibition. The experimentally determined variable \( \alpha K_m \), the \( K_m \) observed in the presence of the inhibitor, is often called the “apparent” \( K_m \).

A medical therapy based on competition at the active site is used to treat patients who have ingested methanol, a solvent found in gas-line antifreeze. The liver enzyme alcohol dehydrogenase converts methanol to formaldehyde, which is damaging to many tissues. Blindness is a common result of methanol ingestion, because the eyes are particularly sensitive to formaldehyde. Ethanol competes effectively with methanol as an alternative substrate for alcohol dehydrogenase. The effect of ethanol is much like that of a competitive inhibitor, with the distinction that ethanol is also

\[
\alpha = 1 + \frac{[I]}{K_I}
\]

The double-reciprocal plot (see Box 6–1) offers an easy way of determining whether an enzyme inhibitor is competitive, uncompetitive, or mixed. Two sets of rate experiments are carried out, with the enzyme concentration held constant in each set. In the first set, \([S]\) is also held constant, permitting measurement of the effect of increasing inhibitor concentration \([I]\) on the initial rate \( V_0 \) (not shown). In the second set, \([I]\) is held constant but \([S]\) is varied. The results are plotted as \(1/V_0\) versus \(1/[S]\).

Figure 1 shows a set of double-reciprocal plots, one obtained in the absence of inhibitor and two at different concentrations of a competitive inhibitor. Increasing \([I]\) results in a family of lines with a common intercept on the \(1/V_0\) axis but with different slopes. Because the intercept on the \(1/V_0\) axis equals \(1/V_{\text{max}}\), we know that \( V_{\text{max}} \) is unchanged by the presence of a competitive inhibitor. That is, regardless of the concentration of a competitive inhibitor, a sufficiently high substrate concentration will always displace the inhibitor from the enzyme’s active site. Above the graph is the rearrangement of Equation 6–28 on which the plot is based. The value of \( \alpha \) can be calculated from the change in slope at any given \([I]\). Knowing \([I]\) and \( \alpha \), we can calculate \( K_I \) from the expression

\[
\alpha = 1 + \frac{[I]}{K_I}
\]

For uncompetitive and mixed inhibition, similar plots of rate data give the families of lines shown in Figures 2 and 3. Changes in axis intercepts signal changes in \( V_{\text{max}} \) and \( K_m \).
a substrate for alcohol dehydrogenase and its concentration will decrease over time as the enzyme converts it to acetaldehyde. The therapy for methanol poisoning is slow intravenous infusion of ethanol, at a rate that maintains a controlled concentration in the bloodstream for several hours. This slows the formation of formaldehyde, lessening the danger while the kidneys filter out the methanol to be excreted harmlessly in the urine.

Two other types of reversible inhibition, uncompetitive and mixed, though often defined in terms of one-substrate enzymes, are in practice observed only with enzymes having two or more substrates. An uncompetitive inhibitor (Fig. 6–15b) binds at a site distinct from the substrate active site and, unlike a competitive inhibitor, binds only to the ES complex. In the presence of an uncompetitive inhibitor, the Michaelis-Menten equation is altered to

$$V_0 = \frac{V_{\text{max}} [S]}{K_m + \alpha'[S]}$$  \hspace{1cm} (6–29)

Where

$$\alpha' = 1 + \frac{[I]}{K_I} \quad \text{and} \quad K_I = \frac{\text{[ES][I]}}{\text{[ESI]}}$$

As described by Equation 6–29, at high concentrations of substrate, $V_0$ approaches $V_{\text{max}}/\alpha'$. Thus, an uncompetitive inhibitor lowers the measured $V_{\text{max}}$. Apparent $K_m$ also decreases, because the [S] required to reach one-half $V_{\text{max}}$ decreases by the factor $\alpha'$.

A mixed inhibitor (Fig. 6–15c) also binds at a site distinct from the substrate active site, but it binds to either E or ES. The rate equation describing mixed inhibition is

$$V_0 = \frac{V_{\text{max}} [S]}{\alpha K_m + \alpha'[S]}$$  \hspace{1cm} (6–30)

where $\alpha$ and $\alpha'$ are defined as above. A mixed inhibitor usually affects both $K_m$ and $V_{\text{max}}$. The special case of $\alpha = \alpha'$, rarely encountered in experiments, classically has been defined as noncompetitive inhibition. Examine Equation 6–30 to see why a noncompetitive inhibitor would affect the $V_{\text{max}}$ but not the $K_m$.

Equation 6–30 is a general expression for the effects of reversible inhibitors, simplifying to the expressions for competitive and uncompetitive inhibition when $\alpha'$ = 1.0 or $\alpha$ = 1.0, respectively. From this expression we can summarize the effects of inhibitors on individual kinetic parameters. For all reversible inhibitors, apparent $V_{\text{max}} = V_{\text{max}}/\alpha'$, because the right side of Equation 6–30 always simplifies to $V_{\text{max}}/\alpha'$ at sufficiently high substrate concentrations. For competitive inhibitors, $\alpha' = 1.0$ and can thus be ignored. Taking this expression for apparent $V_{\text{max}}$, we can also derive a general expression for apparent $K_m$ to show how this parameter changes in the presence of reversible inhibitors. Apparent $K_m$, as always, equals the [S] at which $V_0$ is one-half apparent $V_{\text{max}}$ or,

more generally, when $V_0 = V_{\text{max}}/2\alpha'$. This condition is met when $[S] = \alpha K_m/\alpha'$. Thus, apparent $K_m = \alpha K_m/\alpha'$. This expression is simpler when either $\alpha$ or $\alpha'$ is 1.0 (for uncompetitive or competitive inhibitors), as summarized in Table 6–9.

In practice, uncompetitive and mixed inhibition are observed only for enzymes with two or more substrates—say, S₁ and S₂—and are very important in the experimental analysis of such enzymes. If an inhibitor binds to the site normally occupied by S₁, it may act as a competitive inhibitor in experiments in which [S₁] is varied. If an inhibitor binds to the site normally occupied by S₂, it may act as a mixed or uncompetitive inhibitor of S₁. The actual inhibition patterns observed depend on whether the S₁- and S₂-binding events are ordered or random, and thus the order in which substrates bind and products leave the active site can be determined. Use of one of the reaction products as an inhibitor is often particularly informative. If only one of two reaction products is present, no reverse reaction can take place. However, a product generally binds to some part of the active site, thus serving as an inhibitor. Enzymologists can use elaborate kinetic studies involving different combinations and amounts of products and inhibitors to develop a detailed picture of the mechanism of a bisubstrate reaction.

**WORKED EXAMPLE 6–3  Effect of Inhibitor on $K_m$**

The researchers working on happyase (see Worked Examples 6–1 and 6–2, pp. 199, 200) discover that the compound STRESS is a potent competitive inhibitor of happyase. Addition of 1 nM STRESS increases the measured $K_m$ for SAD by a factor of 2. What are the values for $\alpha$ and $\alpha'$ under these conditions?

**Solution:** Recall that the apparent $K_m$, the $K_m$ measured in the presence of a competitive inhibitor, is defined as $\alpha K_m$. Because $K_m$ for SAD increases by a factor of 2 in the presence of 1 nM STRESS, the value of $\alpha$ must be 2. The value of $\alpha'$ for a competitive inhibitor is 1 by definition.

Irreversible Inhibition The irreversible inhibitors bind covalently with or destroy a functional group on an enzyme that is essential for the enzyme's activity, or form a particularly stable noncovalent association. Formation
of a covalent link between an irreversible inhibitor and an enzyme is common. Irreversible inhibitors are another useful tool for studying reaction mechanisms. Amino acids with key catalytic functions in the active site can sometimes be identified by determining which residue is covalently linked to an inhibitor after the enzyme is inactivated. An example is shown in Figure 6-16.

A special class of irreversible inhibitors is the suicide inactivators. These compounds are relatively unreactive until they bind to the active site of a specific enzyme. A suicide inactivator undergoes the first few chemical steps of the normal enzymatic reaction, but instead of being transformed into the normal product, the inactivator is converted to a very reactive compound that combines irreversibly with the enzyme. These compounds are also called mechanism-based inactivators, because they hijack the normal enzyme reaction mechanism to inactivate the enzyme. Suicide inactivators play a significant role in rational drug design, a modern approach to obtaining new pharmaceutical agents in which chemists synthesize novel substrates based on knowledge of substrates and reaction mechanisms. A well-designed suicide inactivator is specific for a single enzyme and is unreactive until it is within that enzyme's active site, so drugs based on this approach can offer the important advantage of few side effects (see Box 22–3). Some examples of irreversible inhibitors of medical importance are described at the end of Section 6.4.

**Enzyme Activity Depends on pH**

Enzymes have an optimum pH (or pH range) at which their activity is maximal (Fig. 6-17); at higher or lower pH, activity decreases. This is not surprising. Amino acid side chains in the active site may act as weak acids and bases with critical functions that depend on their maintaining a certain state of ionization, and elsewhere in the protein ionized side chains may play an essential role in the interactions that maintain protein structure. Removing a proton from a His residue, for example, might eliminate an ionic interaction essential for stabilizing the active conformation of the enzyme. A less common cause of pH sensitivity is titration of a group on the substrate.

The pH range over which an enzyme undergoes changes in activity can provide a clue to the type of amino acid residue involved (see Table 3-1). A change in activity near pH 7.0, for example, often reflects titration of a His residue. The effects of pH must be interpreted with some caution, however. In the closely packed environment of a protein, the $pK_a$ of amino acid side chains can be significantly altered. For example, a nearby positive charge can lower the $pK_a$ of a Lys residue, and a nearby negative charge can increase it. Such effects sometimes result in a $pK_a$ that is shifted by several pH units from its value in the free amino acid. In the enzyme acetoacetate decarboxylase, for example, one Lys residue has a $pK_a$ of 6.6 (compared with 10.5 in free lysine) due to electrostatic effects of nearby positive charges.

**SUMMARY 6.3 Enzyme Kinetics as an Approach to Understanding Mechanism**

- Most enzymes have certain kinetic properties in common. When substrate is added to an enzyme, the reaction rapidly achieves a steady state in
which the rate at which the ES complex forms balances the rate at which it breaks down. As [S] increases, the steady-state activity of a fixed concentration of enzyme increases in a hyperbolic fashion to approach a characteristic maximum rate, \( V_{\text{max}} \), at which essentially all the enzyme has formed a complex with substrate.

- The substrate concentration that results in a reaction rate equal to one-half \( V_{\text{max}} \) is the Michaelis constant \( K_m \), which is characteristic for each enzyme acting on a given substrate. The Michaelis-Menten equation

\[
V_o = \frac{V_{\text{max}} [S]}{K_m + [S]}
\]

relates initial velocity to [S] and \( V_{\text{max}} \) through the constant \( K_m \). Michaelis-Menten kinetics is also called steady-state kinetics.

- \( K_m \) and \( V_{\text{max}} \) have different meanings for different enzymes. The limiting rate of an enzyme-catalyzed reaction at saturation is described by the constant \( k_{\text{cat}} \), the turnover number. The ratio \( k_{\text{cat}}/K_m \) provides a good measure of catalytic efficiency. The Michaelis-Menten equation is also applicable to bisubstrate reactions, which occur by ternary-complex or Ping-Pong (double-displacement) pathways.

- Reversible inhibition of an enzyme may be competitive, uncompetitive, or mixed. Competitive inhibitors compete with substrate by binding reversibly to the active site, but they are not transformed by the enzyme. Uncompetitive inhibitors bind only to the ES complex, at a site distinct from the active site. Mixed inhibitors bind to either E or ES, again at a site distinct from the active site. In irreversible inhibition an inhibitor binds permanently to an active site by forming a covalent bond or a very stable noncovalent interaction.

- Every enzyme has an optimum pH (or pH range) at which it has maximal activity.

### 6.4 Examples of Enzymatic Reactions

Thus far we have focused on the general principles of catalysis and on introducing some of the kinetic parameters used to describe enzyme action. We now turn to several examples of specific enzyme reaction mechanisms.

An understanding of the complete mechanism of action of a purified enzyme requires identification of all substrates, cofactors, products, and regulators. Moreover, it requires a knowledge of (1) the temporal sequence in which enzyme-bound reaction intermediates form, (2) the structure of each intermediate and each transition state, (3) the rates of interconversion between intermediates, (4) the structural relationship of the enzyme to each intermediate, and (5) the energy contributed by all reacting and interacting groups to intermediate complexes and transition states. As yet, there is probably no enzyme for which we have an understanding that meets all these requirements.

We present here the mechanisms for four enzymes: chymotrypsin, hexokinase, enolase, and lysozyme. These examples are not intended to cover all possible classes of enzyme chemistry. They are chosen in part because they are among the best understood enzymes, and in part because they clearly illustrate some general principles outlined in this chapter. The discussion concentrates on selected principles, along with some key experiments that have helped to bring these principles into focus. We use the chymotrypsin example to review some of the conventions used to depict enzyme mechanisms. Much mechanistic detail and experimental evidence is necessarily omitted; no one book could completely document the rich experimental history of these enzymes. Also absent from these discussions is the special contribution of coenzymes to the catalytic activity of many enzymes. The function of coenzymes is chemically varied, and we describe each as it is encountered in Part II.

#### The Chymotrypsin Mechanism Involves Acylation and Deacylation of a Ser Residue

Bovine pancreatic chymotrypsin (Mr 25,191) is a protease, an enzyme that catalyzes the hydrolytic cleavage of peptide bonds. This protease is specific for peptide bonds adjacent to aromatic amino acid residues (Trp, Phe, Tyr). The three-dimensional structure of chymotrypsin is shown in Figure 6–18, with functional groups in the active site emphasized. The reaction catalyzed by this enzyme illustrates the principle of transition-state stabilization and also provides a classic example of general acid-base catalysis and covalent catalysis.

Chymotrypsin enhances the rate of peptide bond hydrolysis by a factor of at least \( 10^9 \). It does not catalyze a direct attack of water on the peptide bond; instead, a transient covalent acyl-enzyme intermediate is formed. The reaction thus has two distinct phases. In the acylation phase, the peptide bond is cleaved and an ester linkage is formed between the peptide carbonyl carbon and the enzyme. In the deacylation phase, the ester linkage is hydrolyzed and the nonacylated enzyme regenerated.

The first evidence for a covalent acyl-enzyme intermediate came from a classic application of pre-steady state kinetics. In addition to its action on polypeptides, chymotrypsin also catalyzes the hydrolysis of small esters and amides. These reactions are much slower than hydrolysis of peptides because less binding energy is available with smaller substrates, and they are therefore easier to study. Investigations by B. S. Hartley and B. A. Kilby in 1954 found that chymotrypsin hydrolysis of the
ester p-nitrophenylacetate, as measured by release of p-nitrophenol, proceeds with a rapid burst before leveling off to a slower rate (Fig. 6–19). By extrapolating back to zero time, they concluded that the burst phase corresponded to just under one molecule of p-nitrophenol released for every enzyme molecule present. Hartley and Kilby suggested that this reflected a rapid acylation of all the enzyme molecules (with release of p-nitrophenol), with the rate for subsequent turnover of the enzyme limited by a slow deacylation step. Similar results have since been obtained with many other enzymes. The observation of a burst phase provides yet another example of the use of kinetics to break down a reaction into its constituent steps.

**FIGURE 6–18 Structure of chymotrypsin.** (PDB ID 7GCH) (a) A representation of primary structure, showing disulfide bonds and the amino acid residues crucial to catalysis. The protein consists of three polypeptide chains linked by disulfide bonds. (The numbering of residues in chymotrypsin, with “missing” residues 14, 15, 147, and 148, is explained in Fig. 6–38.) The active-site amino acid residues are grouped together in the three-dimensional structure. (b) A depiction of the enzyme emphasizing its surface. The pocket in which the aromatic amino acid side chain of the substrate is bound is shown in green. Key active-site residues, including Ser195, His57, and Asp102, are red. The roles of these residues in catalysis are illustrated in Figure 6–21. (c) The polypeptide backbone as a ribbon structure. Disulfide bonds are yellow; the three chains are colored as in part (a). (d) A close-up of the active site with a substrate (mostly green) bound. Two of the active-site residues, Ser195 and His57 (both red), are partly visible. The hydroxyl of Ser195 attacks the carbonyl group of the substrate (the oxygen is purple); the developing negative charge on the oxygen is stabilized by the oxyanion hole (amide nitrogens, including one from Ser195, in orange), as explained in Figure 6–21. In the substrate, the aromatic amino acid side chain and the amide nitrogen of the peptide bond to be cleaved (protruding toward the viewer and projecting the path of the rest of the substrate polypeptide chain) are in blue.

**FIGURE 6–19 Pre–steady state kinetic evidence for an acyl-enzyme intermediate.** The hydrolysis of p-nitrophenylacetate by chymotrypsin is measured by release of p-nitrophenol (a colored product). Initially, the reaction releases a rapid burst of p-nitrophenol nearly stoichiometric with the amount of enzyme present. This reflects the fast acylation phase of the reaction. The subsequent rate is slower, because enzyme turnover is limited by the rate of the slower deacylation phase.
Additional features of the chymotrypsin mechanism have been discovered by analyzing the dependence of the reaction on pH. The rate of chymotrypsin-catalyzed cleavage generally exhibits a bell-shaped pH-rate profile (Fig. 6–20). The rates plotted in Figure 6–20a are obtained at low (subsaturating) substrate concentrations and therefore represent $k_{cat}/K_m$ (see Eqn 6–27, p. 199). The plot can be dissected further by first obtaining the maximum rates at each pH, and then plotting $k_{cat}$ alone versus pH (Fig. 6–20b); after obtaining the $K_m$ at each pH, researchers can then plot $1/K_m$ (Fig. 6–20c). Kinetic and structural analyses have revealed that the change in $k_{cat}$ reflects the ionization state of His$^{57}$. The decline in $k_{cat}$ at low pH results from protonation of His$^{57}$ (so that it cannot extract a proton from Ser$^{195}$ in step (1) of the reaction; see Fig. 6–21). This rate reduction illustrates the importance of general acid and general base catalysis in the mechanism for chymotrypsin. The changes in the $1/K_m$ term reflect the ionization of the $\alpha$-amino group of Ile$^{16}$ (at the amino-terminal end of one of chymotrypsin’s three polypeptide chains). This group forms a salt bridge to Asp$^{193}$, stabilizing the active conformation of the enzyme. When this group loses its proton at high pH, the salt bridge is eliminated and a conformational change closes the hydrophobic pocket where the aromatic amino acid side chain of the substrate inserts (Fig. 6–18). Substrates can no longer bind properly, which is measured kinetically as an increase in $K_m$.

The nucleophile in the acylation phase is the oxygen of Ser$^{195}$. (Proteases with a Ser residue that plays this role in reaction mechanisms are called serine proteases.) The $pK_a$ of a Ser hydroxyl group is generally too high for the unprotonated form to be present in significant concentrations at physiological pH. However, in chymotrypsin, Ser$^{195}$ is linked to His$^{57}$ and Asp$^{102}$ in a hydrogen-bonding network referred to as the catalytic triad. When a peptide substrate binds to chymotrypsin, a subtle change in conformation compresses the hydrogen bond between His$^{57}$ and Asp$^{102}$, resulting in a stronger interaction, called a low-barrier hydrogen bond. This enhanced interaction increases the $pK_a$ of His$^{57}$ from ~7 (for free histidine) to >12, allowing the His residue to act as an enhanced general base that can remove the proton from the Ser$^{195}$ hydroxyl. Deprotonation prevents development of a very unstable positive charge on the Ser$^{195}$ hydroxyl and makes the Ser side chain a stronger nucleophile. At later reaction stages, His$^{57}$ also acts as a proton donor, protonating the amino group in the displaced portion of the substrate (the leaving group).

As the Ser$^{195}$ oxygen attacks the carbonyl group of the substrate, a very short-lived tetrahedral intermediate is formed in which the carbonyl oxygen acquires a negative charge (Fig. 6–21, step (2)). This charge, forming within a pocket on the enzyme called the oxyanion hole, is stabilized by hydrogen bonds contributed by the amide groups of two peptide bonds in the chymotrypsin backbone. One of these hydrogen bonds (contributed by Gly$^{195}$) is present only in this intermediate and in the transition states for its formation and breakdown; it reduces the energy required to reach these states. This is an example of the use of binding energy in catalysis.

The role of transition state complementarity in enzyme catalysis is further explored in Box 6–3.
How to Read Reaction Mechanisms—A Refresher

Chemical reaction mechanisms, which trace the formation and breakage of covalent bonds, are communicated with dots and curved arrows, a convention known informally as "electron pushing." A covalent bond consists of a shared pair of electrons. Nonbonded electrons important to the reaction mechanism are designated by dots (—OH). Curved arrows (—) represent the movement of electron pairs. For movement of a single electron (as in a free radical reaction), a single-headed (fishhook-type) arrow is used (—). Most reaction steps involve an unshared electron pair (as in the chymotrypsin mechanism).

Some atoms are more electronegative than others; that is, they more strongly attract electrons. The relative electronegativities of atoms encountered in this text are F > O > N > C = S > P = H. For example, the two electron pairs making up a C=O (carbonyl) bond are not shared equally; the carbon is relatively electron-deficient as the oxygen draws away the electrons. Many reactions involve an electron-rich atom (a nucleophile) reacting with an electron-deficient atom (an electrophile). Some common nucleophiles and electrophiles in biochemistry are shown at right.

In general, a reaction mechanism is initiated at an unshared electron pair of a nucleophile. In mechanism diagrams, the base of the electron-pushing arrow originates near the electron-pair dots, and the head of the arrow points directly at the electrophilic center being attacked. Where the unshared electron pair confers a formal negative charge on the nucleophile, the negative charge symbol itself can represent the unshared electron pair and serves as the base of the arrow. In the chymotrypsin mechanism, the nucleophilic electron pair in the ES complex between steps 1 and 2 is provided by the oxygen of the Ser195 hydroxyl group. This electron pair (2 of the 8 valence electrons of the hydroxyl oxygen) provides the base of the curved arrow. The electrophilic center under attack is the carbonyl carbon of the peptide bond to be cleaved. The C, O, and N atoms have a maximum of 8 valence electrons, and H has a maximum of 2. These atoms are occasionally found in unstable states with less than their maximum allotment of electrons, but C, O, and N cannot have more than 8. Thus, when the electron pair from chymotrypsin's Ser195 attacks the substrate's carbonyl carbon, an electron pair is displaced from the carbon valence shell (you cannot have 5 bonds to carbon!). These electrons move toward the more electronegative carbonyl oxygen. The oxygen has 8 valence electrons both before and after this chemical process, but the number shared with the carbon is reduced from 4 to 2, and the carbonyl oxygen acquires a negative charge. In the next step, the electron pair conferring the negative charge on the oxygen moves back to re-form a bond with carbon and reestablish the carbonyl linkage. Again, an electron pair must be displaced from the carbon, and this time it is the electron pair shared with the amino group of the peptide linkage. This breaks the peptide bond. The remaining steps follow a similar pattern.
Interaction of Ser^{195} and His^{57} generates a strongly nucleophilic alkoxide ion on Ser^{195}; the ion attacks the peptide carbonyl group, forming a tetrahedral acyl-enzyme. This is accompanied by formation of a short-lived negative charge on the carbonyl oxygen of the substrate, which is stabilized by hydrogen bonding in the oxyanion hole.

**MECHANISM FIGURE 6–21** Hydrolytic cleavage of a peptide bond by chymotrypsin. The reaction has two phases. In the acylation phase (steps 1 to 3), formation of a covalent acyl-enzyme intermediate is coupled to cleavage of the peptide bond. In the deacylation phase (steps 4 to 6), deacylation regenerates the free enzyme; this is essentially the reverse of the acylation phase, with water mirroring, in reverse, the role of the amine component of the substrate.

*Chymotrypsin Mechanism*

- **Short-lived intermediate** (acylation)
- **Acyl-enzyme intermediate**
- **Short-lived intermediate** (deacylation)
- **Acyl-enzyme intermediate**

*The tetrahedral intermediate in the chymotrypsin reaction pathway, and the second tetrahedral intermediate that forms later, are sometimes referred to as transition states, which can lead to confusion. An intermediate is any chemical species with a finite lifetime, “finite” being defined as longer than the time required for a molecular vibration (~10^{-13} seconds). A transition state is simply the maximum-energy species formed on the reaction coordinate and does not have a finite lifetime. The tetrahedral intermediates formed in the chymotrypsin reaction closely resemble, both energetically and structurally, the transition states leading to their formation and breakdown. However, the intermediate represents a committed stage of completed bond formation, whereas the transition state is part of the process of reaction. In the case of chymotrypsin, given the close relationship between the intermediate and the actual transition state the distinction between them is routinely glossed over. Furthermore, the interaction of the negatively charged oxygen with the amide nitrogens in the oxyanion hole, often referred to as transition-state stabilization, also serves to stabilize the intermediate in this case. Not all intermediates are so short-lived that they resemble transition states. The chymotrypsin acyl-enzyme intermediate is much more stable and more readily detected and studied, and it is never confused with a transition state.*
The transition state of a reaction is difficult to study because it is so short-lived. To understand enzymatic catalysis, however, we must understand what occurs during this fleeting moment in the course of a reaction. Complementarity between an enzyme and the transition state is virtually a requirement for catalysis, because the energy hill upon which the transition state sits is what the enzyme must lower if catalysis is to occur. How can we obtain evidence for enzyme–transition state complementarity? Fortunately, we have a variety of approaches, old and new, to address this problem, each providing compelling evidence in support of this general principle of enzyme action.

Structure-Activity Correlations

If enzymes are complementary to reaction transition states, then some functional groups in both the substrate and the enzyme must interact preferentially in the transition state rather than in the ES complex. Changing these groups should have little effect on formation of the ES complex and hence should not affect kinetic parameters (the dissociation constant, $K_d$, or sometimes $K_m$ if $K_d = K_m$) that reflect the $E + S \rightleftharpoons ES$ equilibrium. Changing these same groups should have a large effect on the overall rate ($k_{cat}$ or $k_{cat}/K_m$) of the reaction, however, because the bound substrate lacks potential binding interactions needed to lower the activation energy.

An excellent example of this effect is seen in the kinetics associated with a series of related substrates for the enzyme chymotrypsin (Fig. 1). Chymotrypsin normally catalyzes the hydrolysis of peptide bonds next to aromatic amino acids. The substrates shown in Figure 1 are convenient smaller models for the natural substrates (long polypeptides and proteins). The additional chemical groups added in each substrate (A to B to C) are shaded. As the table shows, the interaction between the enzyme and these added functional groups has a minimal effect on $K_m$ (taken here as a reflection of $K_d$) but a large, positive effect on $k_{cat}$ and $k_{cat}/K_m$. This is what we would expect if the interaction contributed largely to stabilization of the transition state. The results also demonstrate that the rate of a reaction can be affected greatly by enzyme-substrate interactions that are physically remote from the covalent bonds that are altered in the enzyme-catalyzed reaction. Chymotrypsin is described in more detail in the text.

A complementary experimental approach is to modify the enzyme, eliminating certain enzyme-substrate interactions by replacing specific amino acid residues through site-directed mutagenesis (see Fig. 9-11). Results from such experiments again demonstrate the importance of binding energy in stabilizing the transition state.

Transition-State Analogs

Even though transition states cannot be observed directly, chemists can often predict the approximate structure of a transition state based on accumulated knowledge about reaction mechanisms. The transition state is by definition transient and so unstable that direct measurement of the binding interaction between this species and the enzyme is impossible. In some cases, however, stable molecules can be designed that resemble transition states. These are called transition-
state analogs. In principle, they should bind to an enzyme more tightly than does the substrate in the ES complex, because they should fit the active site better (that is, form a greater number of weak interactions) than the substrate itself. The idea of transition-state analogs was suggested by Pauling in the 1940s, and it has been explored using a number of enzymes. These experiments have the limitation that a transition-state analog cannot perfectly mimic a transition state. Some analogs, however, bind an enzyme $10^2$ to $10^6$ times more tightly than does the normal substrate, providing good evidence that enzyme active sites are indeed complementary to transition states. The same principle is used in the pharmaceutical industry to design new drugs. The powerful anti-HIV drugs called protease inhibitors were designed in part as tight-binding transition-state analogs directed at the active site of HIV protease.

Catalytic Antibodies

If a transition-state analog can be designed for the reaction $S \rightarrow P$ then an antibody that binds tightly to this analog might be expected to catalyze $S \rightarrow P$. Antibodies (immunoglobulins; see Fig. 5-21) are key components of the immune response. When a transition-state analog is used as a protein-bound epitope to stimulate the production of antibodies, the antibodies that bind it are potential catalysts of the corresponding reaction. This use of "catalytic antibodies," first suggested by William P. Jencks in 1969, has become practical with the development of laboratory techniques to produce quantities of identical antibodies that bind one specific antigen (monoclonal antibodies, p. 173).

Pioneering work in the laboratories of Richard Lerner and Peter Schultz has resulted in the isolation of a number of monoclonal antibodies that catalyze the hydrolysis of esters or carbonates (Fig. 2). In these reactions, the attack by water ($\text{OH}^-$) on the carbonyl carbon produces a tetrahedral transition state in which a partial negative charge has developed on the carbonyl oxygen. Phosphonate ester compounds mimic the structure and charge distribution of this transition state in ester hydrolysis, making them good transition-state analogs; phosphate ester compounds are used for carbonate hydrolysis reactions. Antibodies that bind the phosphonate or phosphate compound tightly have been found to accelerate the corresponding ester or carbonate hydrolysis reaction by factors of $10^3$ to $10^4$. Structural analyses of a few of these catalytic antibodies have shown that some catalytic amino acid side chains are arranged such that they could interact with the substrate in the transition state.

Catalytic antibodies generally do not approach the catalytic efficiency of enzymes, but medical and industrial uses for them are nevertheless emerging. For example, catalytic antibodies designed to degrade cocaine are being investigated as a potential aid in the treatment of cocaine addiction.

Hexokinase Undergoes Induced Fit on Substrate Binding

Yeast hexokinase ($M_r$ 107,862) is a bisubstrate enzyme that catalyzes the reversible reaction

$$\text{Glucose 6-phosphate} \rightleftharpoons \text{ATP} + \text{ADP} + \text{Mg}^{2+}$$

ATP and ADP always bind to enzymes as a complex with the metal ion Mg$^{2+}$.

The hydroxyl at C-6 of glucose (to which the $\gamma$-phosphoryl of ATP is transferred in the hexokinase reaction) is similar in chemical reactivity to water, and water freely enters the enzyme active site. Yet hexokinase favors the reaction with glucose by a factor of $10^6$. The enzyme can discriminate between glucose and water because of a conformational change in the enzyme when the correct substrates binds (Fig. 6-22). Hexokinase thus provides a good example of induced fit. When glucose is not present, the enzyme is in an inactive conformation with the active-site amino acid side chains out of position for reaction. When glucose (but not water) and Mg $\cdot$ ATP bind, the binding energy derived from this interaction induces a conformational change in hexokinase to the catalytically active form.

This model has been reinforced by kinetic studies. The five-carbon sugar xylose, stereochemically similar to glucose but one carbon shorter, binds to hexokinase but in a position where it cannot be phosphorylated. Nevertheless, addition of xylose to the reaction mixture increases the rate of ATP hydrolysis. Evidently, the binding of xylose is sufficient to induce a change in hexokinase to its active conformation, and the enzyme is thereby “tricked” into phosphorylating water. The hexokinase reaction also illustrates that enzyme specificity is not always a simple matter of binding one compound but not another. In the case of hexokinase, specificity is observed not in the formation of the ES complex but in the relative rates of subsequent catalytic steps. Water is not excluded from the active site, but reaction rates increase greatly in the presence of the functional phosphoryl group acceptor (glucose).

Induced fit is only one aspect of the catalytic mechanism of hexokinase—like chymotrypsin, hexokinase uses several catalytic strategies. For example, the active-site amino acid residues (those brought into position by the conformational change that follows substrate binding) participate in general acid-base catalysis and transition-state stabilization.
6.4 Examples of Enzymatic Reactions

**MECHANISM Figure 6-23** Two-step reaction catalyzed by enolase.
(a) The mechanism by which enolase converts 2-phosphoglycerate (2-PGA) to phosphoenolpyruvate. The carboxyl group of 2-PGA is coordinated by two magnesium ions at the active site. (b) The substrate, 2-PGA.

**The Enolase Reaction Mechanism Requires Metal Ions**

Another glycolytic enzyme, enolase, catalyzes the reversible dehydration of 2-phosphoglycerate to phosphoenolpyruvate:

\[
\text{H}_2\text{C}-\text{O}-\text{P}^-\text{O}^- \xrightarrow{\text{Enolase}} \text{H}_2\text{C}-\text{O}-\text{P}^-\text{O}^- + \text{H}_2\text{O}
\]

Yeast enolase (M₉ 93,316) is a dimer with 436 amino acid residues per subunit. The enolase reaction illustrates one type of metal ion catalysis and provides an additional example of general acid-base catalysis and transition-state stabilization. The reaction occurs in two steps (Fig. 6-23a). First, Lys⁴⁴⁵ acts as a general base catalyst, abstracting a proton from C-2 of 2-phosphoglycerate; then Glu²¹¹ acts as a general acid catalyst, donating a proton to the —OH leaving group. The proton at C-2 of 2-phosphoglycerate is not very acidic and thus is not readily removed.

However, in the enzyme active site, 2-phosphoglycerate undergoes strong ionic interactions with two bound Mg²⁺ ions (Fig. 6-23b), making the C-2 proton more acidic (lowering the pKₐ) and easier to abstract. Hydrogen bonding to other active-site amino acid residues also contributes to the overall mechanism. The various interactions effectively stabilize both the enolate intermediate and the transition state preceding its formation.

**Lysozyme Uses Two Successive Nucleophilic Displacement Reactions**

Lysozyme is a natural antibacterial agent found in tears and egg whites. The hen egg white lysozyme (M₉ 14,296) is a monomer with 129 amino acid residues. This was the first enzyme to have its three-dimensional structure determined, by David Phillips and colleagues in 1965. The structure revealed four stabilizing disulfide bonds and a cleft containing the active site (Fig. 6-24a). More than five decades of investigations have provided a detailed picture of the structure and activity of the enzyme, and an interesting story of how biochemical science progresses.
The substrate of lysozyme is peptidoglycan, a carbohydrate found in many bacterial cell walls (see Fig. 20–31). Lysozyme cleaves the \((\beta 1\rightarrow 4)\) glycosidic C–O bond (see p. 243) between the two types of sugar residue in the molecule, \(N\)-acetylmuramic acid (Mur2Ac) and \(N\)-acetylglucosamine (GlcNAc), often referred to as NAM and NAG, respectively, in the research literature on enzymology (Fig. 6–24b). Six residues of the alternating Mur2Ac and GlcNAc in peptidoglycan bind in the active site, in binding sites labeled A through F. Model building has shown that the lactyl side chain of Mur2Ac cannot be accommodated in sites C and E, restricting Mur2Ac binding to sites B, D, and F. Only one of the bound glycosidic bonds is cleaved, that between a Mur2Ac residue in site D and a GlcNAc residue in site E. The key catalytic amino acid residues in the active site are Glu\textsuperscript{35} and Asp\textsuperscript{52} (Fig. 6–25a).

The reaction is a nucleophilic substitution, with \(-\text{OH}\) from water replacing the GlcNAc at C-1 of Mur2Ac.

With the active site residues identified and a detailed structure of the enzyme available, the path to understanding the reaction mechanism seemed open in the 1960s. However, definitive evidence for a particular mechanism eluded investigators for nearly four decades.

There are two chemically reasonable mechanisms that could generate the observed product of lysozyme-mediated cleavage of the glycosidic bond. Phillips and colleagues proposed a dissociative (S\textsubscript{N}1-type) mechanism (Fig. 6–25a, left), in which the GlcNAc initially dissociates in step (1) to leave behind a glycosyl cation (a carbocation) intermediate. In this mechanism, the departing GlcNAc is protonated by general acid catalysis by Glu\textsuperscript{35}, located in a hydrophobic pocket that gives its carboxyl group an unusually high \(pK_a\). The carbocation is stabilized by resonance involving the adjacent ring oxygen, as well as by electrostatic interaction with the negative charge on the nearby Asp\textsuperscript{52}. In step (2), water attacks at C-1 of Mur2Ac to yield the product. The alternative mechanism (Fig. 6–25a, right) involves two consecutive direct-displacement (S\textsubscript{N}2-type) steps. In step (1), Asp\textsuperscript{52} attacks C-1 of Mur2Ac to displace the GlcNAc. As in the first mechanism, Glu\textsuperscript{35} acts as a general acid to protonate the departing GlcNAc. In step (2), water attacks at C-1 of Mur2Ac to displace the Asp\textsuperscript{52} and generate product.

The Phillips mechanism (S\textsubscript{N}1), was widely accepted for more than three decades. However, some controversy persisted and tests continued. The scientific method sometimes advances an issue slowly, and a truly insightful experiment can be difficult to design. Some early
A rearrangement produces a glycosyl carbocation. General acid catalysis by Glu₃⁵ protonates the displaced GlcNAc oxygen and facilitates its departure.

Asp⁵² acts as a covalent catalyst, directly displacing the GlcNAc via an Sn₂ mechanism. Glu₃⁵ protonates the GlcNAc to facilitate its departure.

General base catalysis by Glu₃⁵ facilitates the attack of water on the glycosyl carbocation to form product.

Glu₃⁵ acts as a general base catalyst to facilitate the Sn₂ attack of water, displacing Asp⁵² and generating product.

**MECHANISM FIGURE 6-25 Lysozyme reaction.** In this reaction (described in the text), the water introduced into the product at C-1 of Mur2Ac is in the same configuration as the original glycosidic bond. The reaction is thus a molecular substitution with retention of configuration. (a) Two proposed pathways potentially explain the overall reaction and its properties. The Sn₁ pathway (left) is the original Phillips mechanism. The Sn₂ pathway (right) is the mechanism most consistent with current data. (b) A surface rendering of the lysozyme active site with the covalent enzyme-substrate intermediate shown as a ball-and-stick structure. Side chains of active-site residues are shown as ball-and-stick structures protruding from ribbons (PDB ID 1H6M).
arguments against the Phillips mechanism were suggestive but not completely persuasive. For example, the half-life of the proposed glycosyl cation was estimated to be $10^{-12}$ seconds, just longer than a molecular vibration and not long enough for the needed diffusion of other molecules. More important, lysozyme is a member of a family of enzymes called "retaining glycosidases," all of which catalyze reactions in which the product has the same anomic configuration as the substrate (anomic configurations of carbohydrates are examined in Chapter 7), and all of which are known to have reactive covalent intermediates like that envisioned in the alternative (S_n2) pathway. Hence, the Phillips mechanism ran counter to experimental findings for closely related enzymes.

A compelling experiment tipped the scales decidedly in favor of the S_n2 pathway, as reported by Stephen Withers and colleagues in 2001. Making use of a mutant enzyme (with residue 35 changed from Glu to Gln) and artificial substrates, which combined to slow the rate of key steps in the reaction, these workers were able to stabilize the elusive covalent intermediate. This in turn allowed them to observe the intermediate directly, using both mass spectrometry and x-ray crystallography (Fig. 6-25b).

Is the lysozyme mechanism now proven? No. A key feature of the scientific method, as Albert Einstein once summarized it, is "No amount of experimentation can ever prove me right; a single experiment can prove me wrong." In the case of the lysozyme mechanism, one might argue (and some have) that the artificial substrates, with fluorine substitutions at C-1 and C-2, that were used to stabilize the covalent intermediate might have altered the reaction pathway. The highly electronegative fluorine could destabilize an already electron-deficient oxocarbenium ion in the glycosyl cation intermediate that might occur in an S_n1 pathway. However, the S_n2 pathway is now the mechanism most in concert with available data.

An Understanding of Enzyme Mechanism Drives Important Advances in Medicine

The drugs used to treat maladies ranging from headache to HIV infection are almost always inhibitors of an enzyme. Two examples are explored here: the antibiotic penicillin (and its derivatives) and the protease inhibitors used to treat HIV infections, all of which are irreversible inhibitors.

Penicillin was discovered in 1928 by Alexander Fleming, but it took another 15 years before this relatively unstable compound was understood well enough to use it as a pharmaceutical agent to treat bacterial infections. Penicillin interferes with the synthesis of peptidoglycan (described in Chapter 20, Fig. 20-32), the major component of the rigid cell wall that protects bacteria from osmotic lysis. Peptidoglycan consists of polysaccharides and peptides cross-linked in several steps that include a transpeptidase reaction (Fig. 6-26). It is

![Figure 6-26: The transpeptidase reaction. This reaction, which links two peptidoglycan precursors into a larger polymer, is facilitated by an active-site Ser and a covalent catalysis mechanism similar to that of chymotrypsin. Note that peptidoglycan is one of the few places in nature where α-amino acid residues are found. The active-site Ser attacks the carbonyl of the peptide bond between the two α-Ala residues, creating a covalent ester linkage between the substrate and the enzyme with release of the terminal α-Ala residue. An amino group from the second peptidoglycan precursor then attacks the ester linkage, displacing the enzyme and cross-linking the two precursors.](https://example.com/figure626.png)
6.4 Examples of Enzymatic Reactions

FIGURE 6–27 Transpeptidase inhibition by β-lactam antibiotics. (a) β-Lactam antibiotics feature a five-membered thiazolidine ring fused to a four-membered β-lactam ring. The latter ring is strained and includes an amide moiety that plays a critical role in the inactivation of peptidoglycan synthesis. The R group varies in different penicillins. Penicillin G was the first to be isolated and remains one of the most effective, but it is degraded by stomach acid and must be administered by injection. Penicillin V is nearly as effective and is acid stable, so it can be administered orally. Amoxicillin has a broad range of effectiveness, is readily administered orally, and is thus the most widely prescribed β-lactam antibiotic. (b) Attack on the amide moiety of the β-lactam ring by a transpeptidase active-site Ser results in a covalent acyl-enzyme product. This is hydrolyzed so slowly that adduct formation is practically irreversible, and the transpeptidase is inactivated.

by injection. Penicillin V is nearly as effective and is acid stable, so it can be administered orally. Amoxicillin has a broad range of effectiveness, is readily administered orally, and is thus the most widely prescribed β-lactam antibiotic. (b) Attack on the amide moiety of the β-lactam ring by a transpeptidase active-site Ser results in a covalent acyl-enzyme product. This is hydrolyzed so slowly that adduct formation is practically irreversible, and the transpeptidase is inactivated.

this reaction that is inhibited by penicillin and related compounds (Fig. 6–27a), all of which mimic one conformation of the D-Ala–D-Ala segment of the peptidoglycan precursor. The peptide bond in the precursor is replaced by a highly reactive β-lactam ring. When penicillin binds to the transpeptidase, an active-site Ser attacks the carbonyl of the β-lactam ring and generates a covalent adduct between penicillin and the enzyme. However, the leaving group remains attached because it is linked by the remnant of the β-lactam ring (Fig. 6–27b). The covalent complex irreversibly inactivates the enzyme. This, in turn, blocks synthesis of the bacterial cell wall, and most bacteria die as the fragile inner membrane bursts under osmotic pressure.

Human use of penicillin and its derivatives has led to the evolution of strains of pathogenic bacteria that express β-lactamases (Fig. 6–28a), enzymes that cleave β-lactam antibiotics, rendering them inactive. The bacteria thereby become resistant to the antibiotics. The genes for these enzymes have spread rapidly through bacterial populations under the selective pressure imposed by the use (and often overuse) of β-lactam antibiotics. Human medicine responded with the development of compounds such as clavulanic acid, a...
suicide inactivator, which irreversibly inactivates the \( \beta \)-lactamases (Fig. 6–28b). Clavulanic acid mimics the structure of a \( \beta \)-lactam antibiotic, and forms a covalent adduct with a Ser in the \( \beta \)-lactamase active site. This leads to a rearrangement that creates a much more reactive derivative, which is subsequently attacked by another nucleophile in the active site to irreversibly acylate the enzyme and inactivate it. Amoxicillin and clavulanic acid are combined in a widely used pharmaceutical formulation with the trade name Augmentin. The cycle of chemical warfare between humans and bacteria continues unabated. Strains of disease-causing bacteria that are resistant to both amoxicillin and clavulanic acid (reflecting mutations in \( \beta \)-lactamase that render it unreactive to clavulanic acid) have been discovered. The development of new antibiotics promises to be a growth industry for the foreseeable future.

Antiviral agents provide another example of modern drug development. The human immunodeficiency virus (HIV) is the causative agent of acquired immune deficiency syndrome, or AIDS. In 2005, an estimated 37 to 45 million people worldwide were living with HIV infections, with 3.9 to 6.6 million new infections that year and more than 2.4 million fatalities. AIDS first surfaced as a world epidemic in the 1980s; HIV was discovered soon after and identified as a retrovirus. Retroviruses possess an RNA genome and an enzyme, reverse transcriptase, capable of using RNA to direct the synthesis of a complementary DNA. Efforts to understand HIV and develop therapies for HIV infection benefited from decades of basic research on other retroviruses. A retrovirus such as HIV has a relatively simple life cycle (see Fig. 26–33). Its RNA genome is converted to duplex DNA in several steps catalyzed by a reverse transcriptase (described in Chapter 26). The duplex DNA is then inserted into a chromosome in the nucleus of the host cell by the enzyme integrase (described in Chapter 25). The integrated copy of the viral genome can remain dormant indefinitely. Alternatively, it can be transcribed back into RNA, which can then be translated into proteins to construct new virus particles. Most of the viral genes are translated into large polyproteins, which are cut by the HIV protease into the individual proteins needed to make the virus (see Fig. 26–34). There are only three key enzymes in this cycle—the reverse transcriptase, the integrase, and the protease—which thus are the potential drug targets.
There are four major subclasses of proteases. Serine proteases, such as chymotrypsin and trypsin, and cysteine proteases (in which Cys serves a catalytic role similar to that of Ser in the active site) feature covalent enzyme-substrate complexes; aspartyl proteases and metalloproteases do not. The HIV protease is an aspartyl protease. Two active-site Asp residues facilitate a direct attack of water on the peptide bond to be cleaved (Fig. 6-29). The initial product of the attack of water on the carbonyl group of the peptide bond to be cleaved is an unstable tetrahedral intermediate, much as we have seen for the chymotrypsin reaction. This intermediate is close in structure and energy to the reaction transition state. The drugs that have been developed as HIV protease inhibitors form noncovalent complexes with the enzyme, but they bind to it so tightly that they can be considered irreversible inhibitors. The tight binding is derived in part from their design as transition-state analogs (see Box 6-3). The success of these drugs makes a point worth emphasizing. The catalytic principles we have studied in this chapter are not simply abstruse ideas to be memorized—their application saves lives.

The HIV protease cleaves peptide bonds between Phe and Pro residues most efficiently. The active site thus has a pocket to bind aromatic groups next to the bond to be cleaved. The structures of several HIV protease inhibitors are shown in Figure 6-30. Although the structures appear varied, they all share a core structure—a main chain with a hydroxyl group positioned next to a branch containing a benzyl group. This arrangement targets the benzyl group to the aromatic binding pocket. The adjacent hydroxyl group mimics the negatively charged oxygen in the tetrahedral intermediate in the normal reaction, providing a transition-state analog. The remainder of each inhibitor structure was designed to fit into and bind to various crevices along the surface of the enzyme, enhancing overall binding. Availability of these effective drugs has vastly increased the lifespan and quality of life of millions of people with HIV and AIDS.

**FIGURE 6–29** Mechanism of action of HIV protease. Two active-site Asp residues (from different subunits) act as general acid-base catalysts, facilitating the attack of water on the peptide bond. The unstable tetrahedral intermediate in the reaction pathway is highlighted in pink.
SUMMARY 6.4 Examples of Enzymatic Reactions

- Chymotrypsin is a serine protease with a well-understood mechanism, featuring general acid-base catalysis, covalent catalysis, and transition-state stabilization.
- Hexokinase provides an excellent example of induced fit as a means of using substrate binding energy.
- The enolase reaction proceeds via metal ion catalysis.
- Lysozyme makes use of covalent catalysis and general acid catalysis as it promotes two successive nucleophilic displacement reactions.
- Understanding enzyme mechanism allows the development of drugs to inhibit enzyme action.

6.5 Regulatory Enzymes

In cellular metabolism, groups of enzymes work together in sequential pathways to carry out a given metabolic process, such as the multireaction breakdown of glucose to lactate or the multireaction synthesis of an amino acid from simpler precursors. In such enzyme systems, the reaction product of one enzyme becomes the substrate of the next.

Most of the enzymes in each metabolic pathway follow the kinetic patterns we have already described. Each pathway, however, includes one or more enzymes that have a greater effect on the rate of the overall sequence. These regulatory enzymes exhibit increased or decreased catalytic activity in response to certain signals. Adjustments in the rate of reactions catalyzed by regulatory enzymes, and therefore in the rate of entire metabolic sequences, allow the cell to meet changing needs for energy and for biomolecules required in growth and repair.

In most multienzyme systems, the first enzyme of the sequence is a regulatory enzyme. This is an excellent place to regulate a pathway, because catalysis of even the first few reactions of a sequence that leads to an unneeded product diverts energy and metabolites from more important processes. Other enzymes in the sequence may play subtler roles in modulating the flux through a pathway, as described in Chapter 15.

The activities of regulatory enzymes are modulated in a variety of ways. Allosteric enzymes function through reversible, noncovalent binding of regulatory compounds called allosteric modulators or allosteric effectors, which are generally small metabolites or cofactors. Other enzymes are regulated by reversible covalent modification. Both classes of regulatory enzymes tend to be multisubunit proteins, and in some cases the regulatory site(s) and the active site are on separate subunits. Metabolic systems have at least two other mechanisms of enzyme regulation. Some enzymes are stimulated or inhibited when they are bound by separate regulatory proteins. Others are activated when peptide segments are removed by proteolytic cleavage; unlike effector-mediated regulation, regulation by proteolytic cleavage is irreversible. Important examples of both mechanisms are found in physiological processes such as digestion, blood clotting, hormone action, and vision.

Cell growth and survival depend on efficient use of resources, and this efficiency is made possible by regulatory enzymes. No single rule governs the occurrence of different types of regulation in different systems. To a degree, allosteric (noncovalent) regulation may permit fine-tuning of metabolic pathways that are required continuously but at different levels of activity as cellular conditions change. Regulation by covalent modification may be all or none—usually the case with proteolytic cleavage—or it may allow for subtle changes in activity. Several types of regulation may occur in a single regulatory enzyme. The remainder of this chapter is devoted to a discussion of these methods of enzyme regulation.

Allosteric Enzymes Undergo Conformational Changes in Response to Modulator Binding

As we saw in Chapter 5, allosteric proteins are those having "other shapes" or conformations induced by the binding of modulators. The same concept applies to certain regulatory enzymes, as conformational changes induced by one or more modulators interconvert more-active and less-active forms of the enzyme. The modulators for allosteric enzymes may be inhibitory or stimulatory. Often the modulator is the substrate itself; regulatory enzymes for which substrate and modulator are identical are called homotropic. The effect is similar to that of O₂ binding to hemoglobin (Chapter 5): binding of the ligand—or substrate, in the case of enzymes—causes conformational changes that affect the subsequent activity of other sites on the protein. When the modulator is a molecule other than the substrate, the enzyme is said to be heterotropic. Note that allosteric modulators should not be confused with competitive and mixed inhibitors. Although the latter bind at a second site on the enzyme, they do not necessarily mediate conformational changes between active and inactive forms, and the kinetic effects are distinct.

The properties of allosteric enzymes are significantly different from those of simple nonregulatory enzymes. Some of the differences are structural. In addition to active sites, allosteric enzymes generally have one or more regulatory, or allosteric, sites for binding the modulator (Fig. 6-31). Just as an enzyme's active site is specific for its substrate, each regulatory site is specific for its modulator. Enzymes with several modulators generally have different specific binding sites for each. In homotropic enzymes, the active site and regulatory site are the same.

Allosteric enzymes are generally larger and more complex than nonallosteric enzymes. Most have two or more subunits. Aspartate transcarbamoylase, which catalyzes an early reaction in the biosynthesis of pyrimidines, is a...
In many multienzyme systems, the regulatory enzymes are specifically inhibited by the end product of the pathway whenever the concentration of the end product exceeds the cell's requirements. When the regulatory enzyme reaction is slowed, subsequent enzymes may operate at different rates as their substrate pools are depleted. The rate of production of the pathway's end product is thereby brought into balance with the cell's needs. This type of regulation is called feedback inhibition. Buildup of the end product ultimately slows the entire pathway.

One of the first known examples of allosteric feedback inhibition was the bacterial enzyme system that catalyzes the conversion of \( L \)-threonine to \( L \)-isoleucine in five steps (Fig. 6-33). In this system, the first enzyme, threonine dehydratase, is inhibited by isoleucine, the product of the last reaction of the series. This is an example of heterotropic allosteric inhibition. Isoleucine is quite specific as an inhibitor. No other intermediate in this sequence inhibits threonine dehydratase, nor is any other enzyme in the sequence inhibited by isoleucine. Isoleucine binds not to the active site but to another specific site on the enzyme molecule, the regulatory site.
This binding is noncovalent and readily reversible; if the isoleucine concentration decreases, the rate of threonine dehydration increases. Thus threonine dehydratase activity responds rapidly and reversibly to fluctuations in the cellular concentration of isoleucine. As we shall see in Part II of this book, the patterns of regulation in many other metabolic pathways are much more complex.

The Kinetic Properties of Allosteric Enzymes Diverge from Michaelis-Menten Behavior

Allosteric enzymes show relationships between $V_0$ and $[S]$ that differ from Michaelis-Menten kinetics. They do exhibit saturation with the substrate when $[S]$ is sufficiently high, but for some allosteric enzymes, plots of $V_0$ versus $[S]$ (Fig. 6-34) produce a sigmoid saturation curve, rather than the hyperbolic curve typical of non-regulatory enzymes. On the sigmoid saturation curve we can find a value of $[S]$ at which $V_0$ is half-maximal, but we cannot refer to it with the designation $K_m$, because the enzyme does not follow the hyperbolic Michaelis-Menten relationship. Instead, the symbol $[S]_0.5$ or $K_0.5$ is often used to represent the substrate concentration giving half-maximal velocity of the reaction catalyzed by an allosteric enzyme (Fig. 6-34).

Sigmoid kinetic behavior generally reflects cooperative interactions between protein subunits. In other words, changes in the structure of one subunit are translated into structural changes in adjacent subunits, an effect mediated by noncovalent interactions at the interface between subunits. The principles are particularly well illustrated by a nonenzyme: O$_2$ binding to hemoglobin. Sigmoid kinetic behavior is explained by the concerted and sequential models for subunit interactions (see Fig. 5-15).

Homotropic allosteric enzymes generally are multisubunit proteins and, as noted earlier, the same binding site on each subunit functions as both the active site and the regulatory site. Most commonly, the substrate acts as a positive modulator (an activator), because the subunits act cooperatively: the binding of one molecule of substrate to one binding site alters the enzyme’s conformation and enhances the binding of subsequent substrate molecules. This accounts for the sigmoid rather than hyperbolic change in $V_0$ with increasing $[S]$. One characteristic of sigmoid kinetics is that small changes in the concentration of a modulator can be associated with large changes in activity. As is evident in Figure 6-34a, a relatively small increase in $[S]$ in the steep part of the curve causes a comparatively large increase in $V_0$.

For heterotropic allosteric enzymes, those whose modulators are metabolites other than the normal substrate, it is difficult to generalize about the shape of the substrate-saturation curve. An activator may cause the curve to become more nearly hyperbolic, with a decrease in $K_{0.5}$ but no change in $V_{max}$, resulting in an increased reaction velocity at a fixed substrate concentration ($V_0$ is higher for any value of $[S]$; Fig. 6-34b, upper curve). Other heterotropic allosteric enzymes respond to an activator by an increase in $V_{max}$ with little change in $K_{0.5}$ (Fig. 6-34c). A negative modulator (an inhibitor) may produce a more sigmoid substrate-saturation curve, with an increase in $K_{0.5}$ (Fig. 6-34b, lower curve). Heterotropic allosteric enzymes therefore show different kinds of responses in their substrate-activity curves, because some have inhibitory modulators, some have activating modulators, and some have both.

![Figure 6-34 Substrate-activity curves for representative allosteric enzymes.](image-url)
Some Enzymes Are Regulated by Reversible Covalent Modification

In another important class of regulatory enzymes, activity is modulated by covalent modification of one or more of the amino acid residues in the enzyme molecule. Over 500 different types of covalent modification have been found in proteins. Common modifying groups include phosphoryl, acetyl, adenylyl, uridylyl, methyl, amide, carboxyl, myristoyl, palmitoyl, prenyl, hydroxyl, sulfate, and adenosine diphosphate ribosyl groups (Fig. 6–35). There are even entire proteins that are used as specialized modifying groups, including ubiquitin and sumo. These varied groups are generally linked to and removed from a regulated enzyme by separate enzymes. When an amino acid residue in an enzyme is modified, a novel amino acid with altered properties has effectively been introduced into the enzyme. Introduction of a charge can alter the local properties of the enzyme and induce a change in conformation. Introduction of a hydrophobic group can trigger association with a membrane. The changes are often substantial and can be critical to the function of the altered enzyme.

The variety of enzyme modifications is too great to cover in detail, but some examples can be offered. An example of an enzyme regulated by methylation is the methyl-accepting chemotaxis protein of bacteria. This protein is part of a system that permits a bacterium to swim toward an attractant (such as a sugar) in solution and away from repellent chemicals. The methylating agent is S-adenosylmethionine (adoMet) (see Fig. 18–18). Acetylation is a common modification, with approximately 80% of the soluble proteins in eukaryotes, including many enzymes, acetylated at their amino termini. Ubiquitin is added to proteins as a tag that predetermines them for proteolytic degradation (see Fig. 27–47). Ubiquitination can also have a regulatory function. Sumo is found attached to many eukaryotic nuclear proteins with roles in the regulation of transcription, chromatin structure, and DNA repair.

ADP-ribosylation is an especially interesting reaction, observed in a number of proteins; the ADP-ribose is derived from nicotinamide adenine dinucleotide (NAD) (see Fig. 8–38). This type of modification occurs for the bacterial enzyme dinitrogenase reductase, resulting in regulation of the important process of biological nitrogen fixation. Diphtheria toxin and cholera toxin are enzymes that catalyze the ADP-ribosylation (and inactivation) of key cellular enzymes or proteins.

Phosphorylation is probably the most important type of regulatory modification. It is estimated that one-third of all proteins in a eukaryotic cell are phosphorylated, and one or (often) many phosphorylation events are part of virtually every regulatory process. Some proteins have only one phosphorylated residue, others have several, and a few have dozens of sites for phosphorylation. This mode of covalent modification is central to a large number of regulatory pathways, and we therefore

![FIGURE 6-35 Some enzyme modification reactions.](image-url)
Phosphoryl Groups Affect the Structure and Catalytic Activity of Enzymes

The attachment of phosphoryl groups to specific amino acid residues of a protein is catalyzed by protein kinases; removal of phosphoryl groups is catalyzed by protein phosphatases. The addition of a phosphoryl group to a Ser, Thr, or Tyr residue introduces a bulky, charged group into a region that was only moderately polar. The oxygen atoms of a phosphoryl group can hydrogen-bond with one or several groups in a protein, commonly the amide groups of the peptide backbone at the start of an α helix or the charged guanidinium group of an Arg residue. The two negative charges on a phosphorylated side chain can also repel neighboring negatively charged (Asp or Glu) residues. When the modified side chain is located in a region of an enzyme critical to its three-dimensional structure, phosphorylation can have dramatic effects on enzyme conformation and thus on substrate binding and catalysis.

An important example of enzyme regulation by phosphorylation is seen in glycogen phosphorylase (MW 94,500) of muscle and liver (Chapter 15), which catalyzes the reaction

\[(\text{Glucose})_n + P_i \rightarrow (\text{glucose})_{n-1} + \text{glucose 1-phosphate} \]

Glycogen

The glucose 1-phosphate so formed can be used for ATP synthesis in muscle or converted to free glucose in the liver. Glycogen phosphorylase occurs in two forms: the more active phosphorylase a and the less active phosphorylase b (Fig. 6–36). Phosphorylase a has two subunits, each with a specific Ser residue that is phosphorylated at its hydroxyl group. These serine phosphate residues are required for maximal activity of the enzyme. The phosphoryl groups can be hydrolytically removed by a separate enzyme called phosphorylase phosphatase:

\[
\text{Phosphorylase a} + 2H_2O \rightarrow \text{phosphorylase b} + 2P_i
\]

(more active) (less active)

In this reaction, phosphorylase a is converted to phosphorylase b by the cleavage of two serine phosphate covalent bonds, one on each subunit of glycogen phosphorylase.

Phosphorylase b can in turn be reactivated—covalently transformed back into active phosphorylase a—by another enzyme, phosphorylase kinase, which catalyzes the transfer of phosphoryl groups from ATP to the hydroxyl groups of the two specific Ser residues in phosphorylase b:

\[
2\text{ATP} + \text{phosphorylase b} \rightarrow 2\text{ADP} + \text{phosphorylase a}
\]

(less active) (more active)

The breakdown of glycogen in skeletal muscles and the liver is regulated by variations in the ratio of the two forms of glycogen phosphorylase. The a and b forms differ in their secondary, tertiary, and quaternary structures; the active site undergoes changes in structure and, consequently, changes in catalytic activity as the two forms are interconverted.

The regulation of glycogen phosphorylase by phosphorylation illustrates the effects on both structure and catalytic activity of adding a phosphoryl group. In the unphosphorylated state, each subunit of this enzyme is folded so as to bring the 20 residues at its amino terminus, including a number of basic residues, into a region containing several acidic amino acids; this produces an

![FIGURE 6–36 Regulation of muscle glycogen phosphorylase activity by multiple mechanisms. The activity of glycogen phosphorylase in muscle is subjected to a multilevel system of regulation, involving covalent modification (phosphorylation), allosteric regulation, and a regulatory cascade sensitive to hormonal status that acts on the enzymes involved in phosphorylation and dephosphorylation. In the more active form of the enzyme, phosphorylase a, specific Ser residues, one on each subunit, are phosphorylated. Phosphorylase a is converted to the less active phosphorylase b by enzymatic loss of these phosphoryl groups, promoted by phosphoprotein phosphatase 1 (PP1). Phosphorylase b can be reconverted (reactivated) to phosphorylase a by the action of phosphorylase kinase. The activity of both forms of the enzyme is allosterically regulated by an activator (AMP) and by inhibitors (glucose 6-phosphate and ATP) that bind to separate sites on the enzyme. The activities of phosphorylase kinase and PP1 are also regulated via a short pathway that responds to the hormones glucagon and epinephrine. When blood sugar levels are low, the pancreas and adrenal glands secrete glucagon and epinephrine. Epinephrine binds to its receptor in muscle and some other tissues, and activates the enzyme adenyl cyclase. Glucagon plays a similar role, binding to receptors in the liver. This leads to the synthesis of high levels of the modified nucleotide cyclic AMP (cAMP; see p. 298), activating the enzyme cAMP-dependent protein kinase (also called protein kinase A or PKA). PKA phosphorylates several target proteins, among them phosphorylase kinase and phosphoprotein phosphatase inhibitor 1 (PP1-1). The phosphorylated phosphorylase kinase is activated and in turn phosphorylates and activates glycogen phosphorylase. At the same time, the phosphorylated PP1-1 interacts with and inhibits PP1. PP1-1 also keeps itself active (phosphorylated) by inhibiting phosphoprotein phosphatase 2B (PP2B), the enzyme that dephosphorylates (inactivates) it. In this way, the equilibrium between the a and b forms of glycogen phosphorylase is shifted decisively toward the more active glycogen phosphorylase a. Note that the two forms of phosphorylase kinase are both activated to a degree by Ca²⁺ ion (not shown). This pathway is discussed in more detail in Chapters 14, 15, and 23.]
electrostatic interaction that stabilizes the conformation. Phosphorylation of Ser^{14} interferes with this interaction, forcing the amino-terminal domain out of the acidic environment and into a conformation that allows interaction between the \( \Phi \)-Ser and several Arg side chains. In this conformation, the enzyme is much more active.

Phosphorylation of an enzyme can affect catalysis in another way: by altering substrate-binding affinity. For example, when isocitrate dehydrogenase (an enzyme of the citric acid cycle; Chapter 16) is phosphorylated, electrostatic repulsion by the phosphoryl group inhibits the binding of citrate (a tricarboxylic acid) at the active site.

Multiple Phosphorylations Allow Exquisite Regulatory Control

The Ser, Thr, or Tyr residues that are phosphorylated in regulated proteins occur within common structural motifs, called consensus sequences, that are recognized by specific protein kinases (Table 6–10). Some kinases are basophilic, preferring to phosphorylate a residue having basic neighbors; others have different substrate preferences, such as for a residue near a Pro residue. Amino acid sequence is not the only important factor in determining whether a given residue will be phosphorylated, however. Protein folding brings together residues that are distant in the primary sequence; the resulting three-dimensional structure can determine whether a protein kinase has access to a given residue and can recognize it as a substrate. Another factor influencing the substrate specificity of certain protein kinases is the proximity of other phosphorylated residues.

Regulation by phosphorylation is often complicated. Some proteins have consensus sequences recognized by several different protein kinases, each of which can phosphorylate the protein and alter its enzymatic activity. In some cases, phosphorylation is hierarchical: a certain residue can be phosphorylated only if a neighboring residue has already been phosphorylated. For example, glycogen synthase, the enzyme that catalyzes the condensation of glucose monomers to form glycogen (Chapter 15), is inactivated by phosphorylation of specific Ser residues and is also modulated by at least four other protein kinases that phosphorylate four other

**FIGURE 6–37** Multiple regulatory phosphorylations. The enzyme glycogen synthase has at least nine separate sites in five designated regions susceptible to phosphorylation by one of the cellular protein kinases. Thus, regulation of this enzyme is a matter not of binary (on/off) switching but of finely tuned modulation of activity over a wide range in response to a variety of signals.

sites in the enzyme (Fig. 6–37). The enzyme is not a substrate for glycogen synthase kinase 3, for example, until one site has been phosphorylated by casein kinase II. Some phosphorylations inhibit glycogen synthase more than others, and some combinations of phosphorylations are cumulative. These multiple regulatory phosphorylations provide the potential for extremely subtle modulation of enzyme activity.

To serve as an effective regulatory mechanism, phosphorylation must be reversible. In general, phosphoryl groups are added and removed by different enzymes, and the processes can therefore be separately regulated. Cells contain a family of phosphoprotein phosphatases that hydrolyze specific [P]-Ser, [P]-Thr, and [P]-Tyr esters, releasing P. The phosphoprotein phosphatases we know of thus far act only on a subset of phosphoproteins, but they show less substrate specificity than protein kinases.

Some Enzymes and Other Proteins Are Regulated by Proteolytic Cleavage of an Enzyme Precursor

For some enzymes, an inactive precursor called a zymogen is cleaved to form the active enzyme. Many proteolytic enzymes (proteases) of the stomach and pancreas are regulated in this way. Chymotrypsin and trypsin are initially synthesized as chymotrypsinogen and trypsinogen (Fig. 6–38). Specific cleavage causes conformational changes that expose the enzyme active site.
Because this type of activation is irreversible, other mechanisms are needed to inactivate these enzymes. Proteases are inactivated by inhibitor proteins that bind very tightly to the enzyme active site. For example, pancreatic trypsin inhibitor (M, 6,000) binds to and inhibits trypsin. α1-Antiproteinase (M, 53,000) primarily inhibits neutrophil elastase (neutrophils are a type of leukocyte, or white blood cell; elastase is a protease acting on elastin, a component of some connective tissues). An insufficiency of α1-antiproteinase, which can be caused by exposure to cigarette smoke, has been associated with lung damage, including emphysema.

Proteases are not the only proteins activated by proteolysis. In other cases, however, the precursors are called not zymogens but, more generally, proproteins or proenzymes, as appropriate. For example, the connective tissue protein collagen is initially synthesized as the soluble precursor procollagen. Blood clotting is mediated by a complicated cascade of proteolytic activations: fibrin, the protein of blood clots, is produced by proteolysis of fibrinogen, its inactive proprotein; the protease responsible for this activation is thrombin (similar in many respects to chymotrypsin), which itself is produced by proteolysis of a proprotein (in this case a zymogen), prothrombin.

Some Regulatory Enzymes Use Several Regulatory Mechanisms

Glycogen phosphorylase catalyzes the first reaction in a pathway that feeds stored glucose into energy-yielding carbohydrate metabolism (Chapters 14 and 15). This is an important metabolic pathway, and its regulation is correspondingly complex. Although the primary regulation of glycogen phosphorylase is through covalent modification, as outlined in Figure 6–36, glycogen phosphorylase is also modulated allosterically by AMP, which is an activator of phosphorylase b, and by glucose 6-phosphate and ATP, both inhibitors. In addition, the enzymes that add and remove the phosphoryl groups are themselves regulated by—and so the entire system is sensitive to—the levels of hormones that regulate blood sugar (Fig. 6–36; see also Chapters 15 and 23).

Other complex regulatory enzymes are found at key metabolic crossroads. Bacterial glutamine synthetase, which catalyzes a reaction that introduces reduced nitrogen into cellular metabolism (Chapter 22), is among the most complex regulatory enzymes known. It is regulated allosterically (with at least eight different modulators); by reversible covalent modification; and by the association of other regulatory proteins, a mechanism examined in detail when we consider the regulation of specific metabolic pathways.

What is the advantage of such complexity in the regulation of enzymatic activity? We began this chapter by stressing the central importance of catalysis to the very existence of life. The control of catalysis is also critical to life. If all possible reactions in a cell were catalyzed simultaneously, macromolecules and metabolites would quickly be broken down to much simpler chemical forms. Instead, cells catalyze only the reactions they need at a given moment. When chemical resources are plentiful, cells synthesize and store glucose and other metabolites. When chemical resources are scarce, cells use these stores to fuel cellular metabolism. Chemical energy is used economically, parceled out to various metabolic pathways as cellular needs dictate. The availability of powerful catalysts, each specific for a given reaction, makes the regulation of these reactions possible. This in turn gives rise to the complex, highly regulated symphony we call life.
SUMMARY 6.5 Regulatory Enzymes

- The activities of metabolic pathways in cells are regulated by control of the activities of certain enzymes.
- In feedback inhibition, the end product of a pathway inhibits the first enzyme of that pathway.
- The activity of an allosteric enzyme is adjusted by reversible binding of a specific modulator to a regulatory site. A modulator may be the substrate itself or some other metabolite, and the effect of the modulator may be inhibitory or stimulatory. The kinetic behavior of allosteric enzymes reflects cooperative interactions among enzyme subunits.
- Other regulatory enzymes are modulated by covalent modification of a specific functional group necessary for activity. The phosphorylation of specific amino acid residues is a particularly common way to regulate enzyme activity.
- Many proteolytic enzymes are synthesized as inactive precursors called zymogens, which are activated by cleavage of small peptide fragments.
- Enzymes at important metabolic intersections may be regulated by complex combinations of effectors, allowing coordination of the activities of interconnected pathways.

Key Terms

Terms in bold are defined in the glossary.

- enzyme 184
- cofactor 184
- coenzyme 184
- prosthetic group 184
- holoenzyme 184
- apoenzyme 184
- apoprotein 184
- active site 186
- substrate 186
- ground state 186
- standard free-energy change (ΔG°) 186
- transition state 187
- activation energy (ΔG‡) 187
- reaction intermediate 187
- rate-limiting step 187
- equilibrium constant (Km) 188
- rate constant 188
- binding energy (ΔGb) 189
- specificity 191
- induced fit 192
- specific acid-base catalysis 192
- general acid-base catalysis 193
- covalent catalysis 193
- enzyme kinetics 194
- initial rate (initial velocity), V₀ 194
- Vₘₐₓ 195
- pre-steady state 195
- steady state 195
- steady-state kinetics 195
- Michaelis constant (Kₘ) 196
- Michaelis-Menten equation 196
- Lineweaver-Burk equation 197
- dissociation constant (Kₐ) 198
- kᵣ 198
- turnover number 198
- reversible inhibition 201
- competitive inhibition 201
- uncompetitive inhibition 203
- mixed inhibition 203
- noncompetitive inhibition 203
- irreversible inhibitors 203
- suicide inactivator 204
- transition state analogs 210
- regulatory enzyme 220
- allosteric enzyme 220
- allosteric modulator 220
- feedback inhibition 221
- protein kinases 224
- zymogen 226

Further Reading

General

- A collection of excellent papers on fundamentals; continues to be very useful.

- A clearly written, concise introduction. More advanced.

- An authoritative and up-to-date resource on the reactions that occur in living systems.

- A collection of classic papers on enzyme chemistry, with historical commentaries by the editor. Extremely interesting.

Principles of Catalysis

- A nice discussion of where binding energy comes from and how it is used.

- A nice discussion of where binding energy comes from and how it is used.

- A good description of the importance of protein motions in catalysis.

- A good place for the beginning student to acquire a better understanding of principles.

Harris, T.K. & Turner, G.J. (2002) Structural basis of perturbed pKₐ values of catalytic groups in enzyme active sites. IUBMB Life 53, 85—98.
- A good summary of the principles of enzymatic catalysis as currently understood, and of what we still do not understand.

Orotidine monophosphate decarboxylase seems to be a reigning champion of catalytic rate enhancement by an enzyme.

Many good illustrations of the principles introduced in this chapter.

**Kinetics**

A clear and concise presentation of the basics.

**Enzyme Examples**

An interesting description of the evolution of enzymes with different catalytic specificities, and the use of a limited repertoire of protein structural motifs.

A nice discussion of the catalytic power of enzymes and the principles underlying it.

**Regulatory Enzymes**

Details of the variety of these important enzymes in a model eukaryote.

A classic paper introducing the concept of allosteric regulation.

**Problems**

1. **Keeping the Sweet Taste of Corn** The sweet taste of freshly picked corn (maize) is due to the high level of sugar in the kernels. Store-bought corn (several days after picking) is not as sweet, because about 50% of the free sugar is converted to starch within one day of picking. To preserve the sweetness of fresh corn, the husked ears can be immersed in boiling water for a few minutes (“blanched”) then cooled in cold water. Corn processed in this way and stored in a freezer maintains its sweetness. What is the biochemical basis for this procedure?

2. **Intracellular Concentration of Enzymes** To approximate the actual concentration of enzymes in a bacterial cell, assume that the cell contains equal concentrations of 1,000 different enzymes in solution in the cytosol and that each protein has a molecular weight of 100,000. Assume also that the bacterial cell is a cylinder (diameter 1.0 μm, height 2.0 μm), that the cytosol (specific gravity 1.20) is 20% soluble protein by weight, and that the soluble protein consists entirely of enzymes. Calculate the average molar concentration of each enzyme in this hypothetical cell.

3. **Rate Enhancement by Urease** The enzyme urease enhances the rate of urea hydrolysis at pH 8.0 and 20 °C by a factor of 10^{14}. If a given quantity of urease can completely hydrolyze a given quantity of urea in 5.0 min at 20 °C and pH 8.0, how long would it take for this amount of urea to be hydrolyzed under the same conditions in the absence of urease? Assume that both reactions take place in sterile systems so that bacteria cannot attack the urea.

4. **Protection of an Enzyme against Denaturation by Heat** When enzyme solutions are heated, there is a progressive loss of catalytic activity over time due to denaturation of the enzyme. A solution of the enzyme hexokinase incubated at 45 °C lost 50% of its activity in 12 min, but when incubated at 45 °C in the presence of a very large concentration of one of its substrates, it lost only 3% of its activity in 12 min. Suggest why thermal denaturation of hexokinase was retarded in the presence of one of its substrates.

5. **Requirements of Active Sites in Enzymes** Carboxypeptidase, which sequentially removes carboxyl-terminal amino acid residues from its peptide substrates, is a single polypeptide of 307 amino acids. The two essential catalytic groups in the active site are furnished by Arg^{145} and Glu^{279}.

(a) If the carboxypeptidase chain were a perfect α helix, how far apart (in Å) would Arg^{145} and Glu^{279} be? (Hint: See Fig. 4.4a.)

(b) Explain how the two amino acid residues can catalyze a reaction occurring in the space of a few angstroms.

6. **Quantitative Assay for Lactate Dehydrogenase** The muscle enzyme lactate dehydrogenase catalyzes the reaction

\[
\text{Pyruvate} \rightarrow \text{Lactate}
\]

\[
\text{CH}_3\text{C}(-)\text{COO}^- + \text{NADH} + \text{H}^+ \rightarrow \text{CH}_3\text{C}(-)\text{COO}^- + \text{NAD}^+
\]

NADH and NAD^{+} are the reduced and oxidized forms, respectively, of the coenzyme NAD. Solutions of NADH, but not NAD^{+},
absorb light at 340 nm. This property is used to determine the concentration of NADH in solution by measuring spectrophotometrically the amount of light absorbed at 340 nm by the solution. Explain how these properties of NADH can be used to design a quantitative assay for lactate dehydrogenase.

7. Effect of Enzymes on Reactions Which of the following effects would be brought about by any enzyme catalyzing the simple reaction

\[ S \xrightarrow{k_1} P \quad \text{where} \quad K_{eq} = \frac{[P]}{[S]} \]

(a) Decreased \( K_{eq} \); (b) Increased \( k_1 \); (c) Increased \( K_{eq} \); (d) Increased \( \Delta G^\circ \); (e) Decreased \( \Delta G^\circ \); (f) More negative \( \Delta G^\circ \); (g) Increased \( k_2 \).

8. Relation between Reaction Velocity and Substrate Concentration: Michaelis-Menten Equation

(a) At what substrate concentration would an enzyme with a \( k_{cat} \) of 30.0 \( \text{s}^{-1} \) and a \( K_m \) of 0.0050 \( M \) operate at one-quarter of its maximum rate?

(b) Determine the fraction of \( V_{max} \) that would be obtained at the following substrate concentrations \([S]\): ¼\( K_m \), 2\( K_m \), and 10\( K_m \).

(c) An enzyme that catalyzes the reaction \( X \rightleftharpoons Y \) is isolated from two bacterial species. The enzymes have the same \( V_{max} \) but different \( K_m \) values for the substrate \( X \). Enzyme A has a \( K_m \) of 2.0 \( \mu M \), while enzyme B has a \( K_m \) of 0.5 \( \mu M \). The plot below shows the kinetics of reactions carried out with the same concentration of each enzyme and with \([X] = 1 \mu M \). Which curve corresponds to which enzyme?

9. Applying the Michaelis-Menten Equation I A research group discovers a new version of happyase, which they call happyase*, that catalyzes the chemical reaction

\[ \text{HAPPY} \rightleftharpoons \text{SAD} \]

The researchers begin to characterize the enzyme.

(a) In the first experiment, with \([E]\) at 4 \( mM \), they find that the \( V_{max} \) is 1.6 \( \mu M \text{s}^{-1} \). Based on this experiment, what is the \( k_{cat} \) for happyase*? (Include appropriate units.)

(b) In another experiment, with \([E]\) at 1 \( mM \) and \([\text{HAPPY}] \) at 30 \( \mu M \), the researchers find that \( V_0 = 300 \mu M \text{s}^{-1} \). What is the measured \( K_m \) of happyase* for its substrate \( \text{HAPPY} \)? (Include appropriate units.)

(c) Further research shows that the purified happyase* used in the first two experiments was actually contaminated with a reversible inhibitor called ANGER. When ANGER is carefully removed from the happyase* preparation, and the two experiments repeated, the measured \( V_{max} \) in (a) is increased to 4.8 \( \mu M \text{s}^{-1} \), and the measured \( K_m \) in (b) is now 15 \( \mu M \). For the inhibitor ANGER, calculate the values of \( a \) and \( a' \).

(d) Based on the information given above, what type of inhibitor is ANGER?

10. Applying the Michaelis-Menten Equation II Another enzyme is found that catalyzes the reaction

\[ A \rightleftharpoons B \]

Researchers find that the \( K_m \) for the substrate \( A \) is 4 \( \mu M \), and the \( k_{cat} \) is 20 \( \text{min}^{-1} \).

(a) In an experiment, \([A] = 6 \mu M \), and the initial velocity, \( V_0 \) was 480 \( \mu M \text{min}^{-1} \). What was the \([E]\) used in the experiment?

(b) In another experiment, \([E] = 0.5 \mu M \), and the measured \( V_0 = 5 \mu M \text{min}^{-1} \). What was the \([A]\) used in the experiment?

(c) The compound \( Z \) is found to be a very strong competitive inhibitor of the enzyme, with an \( a \) of 10. In an experiment with the same \([E]\) as in part (a), but a different \([A]\), an amount of \( Z \) is added that reduces the rate \( V_0 \) to 240 \( \mu M \text{min}^{-1} \). What is the \([A]\) in this experiment?

(d) Based on the kinetic parameters given above, has this enzyme evolved to achieve catalytic perfection? Explain your answer briefly, using the kinetic parameter(s) that define catalytic perfection.

11. Estimation of \( V_{max} \) and \( K_m \) by Inspection Although graphical methods are available for accurate determination of the \( V_{max} \) and \( K_m \) of an enzyme-catalyzed reaction (see Box 6–1), sometimes these quantities can be quickly estimated by inspecting values of \( V_0 \) at increasing \([S]\). Estimate the \( V_{max} \) and \( K_m \) of the enzyme-catalyzed reaction for which the following data were obtained.

<table>

12. Properties of an Enzyme of Prostaglandin Synthesis Prostaglandins are a class of eicosanoids, fatty acid derivatives with a variety of extremely potent actions on vertebrate tissues. They are responsible for producing fever and inflammation and its associated pain. Prostaglandins are derived from the 20-carbon fatty acid arachidonic acid in a reaction catalyzed by the enzyme prostaglandin endoperoxide synthase. This enzyme, a cyclooxygenase, uses oxygen to convert arachidonic acid to \( \text{PGG}_2 \), the immediate precursor of many
different prostaglandins (prostaglandin synthesis is described in Chapter 21).

(a) The kinetic data given below are for the reaction catalyzed by prostaglandin endoperoxide synthase. Focusing here on the first two columns, determine the $V_{\text{max}}$ and $K_m$ of the enzyme.

<table>
<thead>
<tr>
<th>[Arachidonic acid] (mm)</th>
<th>Rate of formation of PGG$_2$ (mm/min)</th>
<th>Rate of formation of PGG$_2$ with 10 mg/mL ibuprofen (mm/min)</th>

(b) Ibuprofen is an inhibitor of prostaglandin endoperoxide synthase. By inhibiting the synthesis of prostaglandins, ibuprofen reduces inflammation and pain. Using the data in the first and third columns of the table, determine the type of inhibition that ibuprofen exerts on prostaglandin endoperoxide synthase.

13. Graphical Analysis of $V_{\text{max}}$ and $K_m$ The following experimental data were collected during a study of the catalytic activity of an intestinal peptidase with the substrate glycylglycine:

Glycylglycine + H$_2$O $\rightarrow$ 2 glycine

<table>
<thead>
<tr>
<th>[S] (mm)</th>

</tbody>
</table>

Use graphical analysis (see Box 6–1 and its associated Living Graph) to determine the $K_m$ and $V_{\text{max}}$ for this enzyme preparation and substrate.

14. The Eadie-Hofstee Equation One transformation of the Michaelis-Menten equation is the Lineweaver-Burk, or double-reciprocal, equation. Multiplying both sides of the Lineweaver-Burk equation by $V_{\text{max}}$ and rearranging gives the Eadie-Hofstee equation:

$$V_0 = \frac{V_{\text{max}}}{S} + \frac{V_{\text{max}}}{K_m}$$

A plot of $V_0$ versus $V_0/[S]$ for an enzyme-catalyzed reaction is shown below. The blue curve was obtained in the absence of inhibitor. Which of the other curves (A, B, or C) shows the enzyme activity when a competitive inhibitor is added to the reaction mixture? Hint: See Equation 6–30.

15. The Turnover Number of Carbonic Anhydrase Carbonic anhydrase of erythrocytes ($M$, 30,000) has one of the highest turnover numbers we know of. It catalyzes the reversible hydration of CO$_2$:

$$H_2O + CO_2 \rightleftharpoons H_2CO_3$$

This is an important process in the transport of CO$_2$ from the tissues to the lungs. If 10.0 $\mu$g of pure carbonic anhydrase catalyzes the hydration of 0.30 g of CO$_2$ in 1 min at 37 °C at $V_{\text{max}}$, what is the turnover number ($k_{\text{cat}}$) of carbonic anhydrase (in units of min$^{-1}$)?

16. Deriving a Rate Equation for Competitive Inhibition The rate equation for an enzyme subject to competitive inhibition is

$$V_0 = \frac{V_{\text{max}} [S]}{K_m + [S]}$$

Beginning with a new definition of total enzyme as

$$[E] = [E] + [ES] + [EI]$$

and the definitions of $\alpha$ and $K_1$ provided in the text, derive the rate equation above. Use the derivation of the Michaelis-Menten equation as a guide.

17. Irreversible Inhibition of an Enzyme Many enzymes are inhibited irreversibly by heavy metal ions such as Hg$^{2+}$, Cu$^{2+}$, or Ag$^+$, which can react with essential sulfhydryl groups to form mercaptides:

$$\text{Enz-SH} + \text{Ag}^+ \rightarrow \text{Enz-S-Ag} + \text{H}^+$$

The affinity of Ag$^+$ for sulfhydryl groups is so great that Ag$^+$ can be used to titrate —SH groups quantitatively. To 10.0 mL of a solution containing 1.0 mg/mL of a pure enzyme, an investigator added just enough AgNO$_3$ to completely inactivate the enzyme. A total of 0.342 pmol of AgNO$_3$ was required. Calculate the minimum molecular weight of the enzyme. Does the value obtained in this way give only the minimum molecular weight?

18. Clinical Application of Differential Enzyme Inhibition Human blood serum contains a class of
enzymes known as acid phosphatases, which hydrolyze biological phosphate esters under slightly acidic conditions (pH 5.0):

\[
\begin{align*}
R-O-P-O^- + H_2O & \rightarrow R-OH + HO-P-O^- \\
\end{align*}
\]

Acid phosphatases are produced by erythrocytes, the liver, kidney, spleen, and prostate gland. The enzyme of the prostate gland is clinically important, because its increased activity in the blood can be an indication of prostate cancer. The phosphatase from the prostate gland is strongly inhibited by tartrate ion, but acid phosphatases from other tissues are not. How can this information be used to develop a specific procedure for measuring the activity of the acid phosphatase of the prostate gland in human blood serum?

19. Inhibition of Carbonic Anhydrase by Acetzolamide Carbonic anhydrase is strongly inhibited by the drug acetazolamide, which is used as a diuretic (i.e., to increase the production of urine) and to lower excessively high pressure in the eye (due to accumulation of intraocular fluid) in glaucoma. Carbonic anhydrase plays an important role in these and other secretory processes, because it participates in regulating the pH and bicarbonate content of several body fluids. The experimental curve of initial reaction velocity (as percentage of \( V_{\text{max}} \)) versus [S] for the carbonic anhydrase reaction is illustrated below (upper curve). When the experiment is repeated in the presence of acetazolamide, the lower curve is obtained. From an inspection of the curves and your knowledge of the kinetic properties of competitive and mixed enzyme inhibitors, determine the nature of the inhibition by acetazolamide. Explain your reasoning.

20. The Effects of Reversible Inhibitors Derive the expression for the effect of a reversible inhibitor on observed \( K_m \) (apparent \( K_m = \alpha K_m / \alpha' \)). Start with Equation 6–30 and the statement that apparent \( K_m \) is equivalent to the [S] at which \( V_0 = V_{\text{max}} / 2 \alpha' \).

21. pH Optimum of Lysozyme The active site of lysozyme contains two amino acid residues essential for catalysis: G135 and A52. The \( pK_a \) values of the carboxyl side chains of these residues are 5.9 and 4.5, respectively. What is the ionization state (protonated or deprotonated) of each residue at pH 5.2, the pH optimum of lysozyme? How can the ionization states of these residues explain the pH-activity profile of lysozyme shown below?

---

Data Analysis Problem

22. Working with Kinetics Go to the Living Graphs for Chapter 6.

(a) Using the Living Graph for Equation 6–9, create a \( V \) versus [S] plot. Use \( V_{\text{max}} = 100 \mu M \cdot s^{-1} \), and \( K_m = 10 \mu M \). How much does \( V_0 \) increase when [S] is doubled, from 0.2 to 0.4 \( \mu M \)? What is \( V_0 \) when [S] = 10 \( \mu M \)? How much does the \( V_0 \) increase when [S] increases from 100 to 200 \( \mu M \)? Observe how the graph changes when the values for \( \alpha \) and \( \alpha' \) are halved or doubled.

(b) Using the Living Graph for Equation 6–30 and the kinetic parameters in (a), create a plot in which both \( \alpha \) and \( \alpha' \) are 1.0. Now observe how the plot changes when \( \alpha \) = 2.0, when \( \alpha' \) = 3.0, and when \( \alpha = 2.0 \) and \( \alpha' = 3.0 \).

(c) Using the Living Graphs for Equation 6–30 and the Lineweaver-Burk equation in Box 6–1, create Lineweaver-Burk (double-reciprocal) plots for all the cases in (a) and (b). When \( \alpha = 2.0 \), does the \( x \) intercept move to the right or to the left? If \( \alpha = 2.0 \) and \( \alpha' = 3.0 \), does the \( x \) intercept move to the right or to the left?

23. Exploring and Engineering Lactate Dehydrogenase Examining the structure of an enzyme results in hypotheses about the relationship between different amino acids in the protein’s structure and the protein’s function. One way to test these hypotheses is to use recombinant DNA technology to generate mutant versions of the enzyme and then examine the structure and function of these altered forms. The technology used to do this is described in Chapter 9.

One example of this kind of analysis is the work of Clarke and colleagues on the enzyme lactate dehydrogenase, published in 1989. Lactate dehydrogenase (LDH) catalyzes the reduction of pyruvate with NADH to form lactate (see Section 14.3). A schematic of the enzyme’s active site is shown below; the pyruvate is in the center:
Lactate dehydrogenase

The reaction mechanism is similar to many NADH reductions (Fig. 13–24); it is approximately the reverse of steps 2 and 3 of Figure 14–7. The transition state involves a strongly polarized carbonyl group of the pyruvate molecule as shown below:

(a) A mutant form of LDH in which Arg\(^{109}\) is replaced with Gln shows only 5% of the pyruvate binding and 0.07% of the activity of wild-type enzyme. Provide a plausible explanation for the effects of this mutation.

(b) A mutant form of LDH in which Arg\(^{171}\) is replaced with Lys shows only 0.05% of the wild-type level of substrate binding. Why is this dramatic effect surprising?

(c) In the crystal structure of LDH, the guanidinium group of Arg\(^{171}\) and the carboxyl group of pyruvate are aligned as shown in a co-planar “forked” configuration. Based on this, provide a plausible explanation for the dramatic effect of substituting Arg\(^{171}\) with Lys.

(d) A mutant form of LDH in which Ile\(^{250}\) is replaced with Gln shows reduced binding of NADH. Provide a plausible explanation for this result.

Clarke and colleagues also set out to engineer a mutant version of LDH that would bind and reduce oxaloacetate rather than pyruvate. They made a single substitution, replacing Gln\(^{102}\) with Arg; the resulting enzyme would reduce oxaloacetate to malate and would no longer reduce pyruvate to lactate. They had therefore converted LDH to malate dehydrogenase.

(e) Sketch the active site of this mutant LDH with oxaloacetate bound.

(f) Provide a plausible explanation for why this mutant enzyme now “prefers” oxaloacetate instead of pyruvate.

(g) The authors were surprised that substituting a larger amino acid in the active site allowed a larger substrate to bind. Provide a plausible explanation for this result.

7.4 Carbohydrates as Informational Molecules: The Sugar Code 257
7.5 Working with Carbohydrates 263

Carbohydrates are the most abundant biomolecules on Earth. Each year, photosynthesis converts more than 100 billion metric tons of CO₂ and H₂O into cellulose and other plant products. Certain carbohydrates (sugar and starch) are a dietary staple in most parts of the world, and the oxidation of carbohydrates is the central energy-yielding pathway in most nonphotosynthetic cells. Carbohydrate polymers (also called glycans) serve as structural and protective elements in the cell walls of bacteria and plants and in the connective tissues of animals. Other carbohydrate polymers lubricate skeletal joints and participate in recognition and adhesion between cells. Complex carbohydrate polymers covalently attached to proteins or lipids act as signals that determine the intracellular location or metabolic fate of these hybrid molecules, called glycoconjugates. This chapter introduces the major classes of carbohydrates and glycoconjugates and provides a few examples of their many structural and functional roles.

Carbohydrates are polyhydroxy aldehydes or ketones, or substances that yield such compounds on hydrolysis. Many, but not all, carbohydrates have the empirical formula (CH₂O)ₙ; some also contain nitrogen, phosphorus, or sulfur.

There are three major size classes of carbohydrates: monosaccharides, oligosaccharides, and polysaccharides (the word “saccharide” is derived from the Greek sakcharon, meaning “sugar”). Monosaccharides, or simple sugars, consist of a single polyhydroxy aldehyde or ketone unit. The most abundant monosaccharide in nature is the six-carbon sugar D-glucose, sometimes referred to as dextrose. Monosaccharides of four or more carbons tend to have cyclic structures.

Oligosaccharides consist of short chains of monosaccharide units, or residues, joined by characteristic linkages called glycosidic bonds. The most abundant are the disaccharides, with two monosaccharide units. Typical is sucrose (cane sugar), which consists of the six-carbon sugars D-glucose and D-fructose. All common monosaccharides and disaccharides have names ending with the suffix “-ose.” In cells, most oligosaccharides consisting of three or more units do not occur as free entities but are joined to nonsugar molecules (lipids or proteins) in glycoconjugates.

The polysaccharides are sugar polymers containing more than 20 or so monosaccharide units; some have hundreds or thousands of units. Some polysaccharides, such as cellulose, are linear chains; others, such as glycogen, are branched. Both glycogen and cellulose consist of recurring units of D-glucose, but they differ in the type of glycosidic linkage and consequently have strikingly different properties and biological roles.

7.1 Monosaccharides and Disaccharides

The simplest of the carbohydrates, the monosaccharides, are either aldehydes or ketones with two or more hydroxyl groups; the six-carbon monosaccharides glucose and fructose have five hydroxyl groups. Many of the carbon atoms to which hydroxyl groups are attached are chiral centers, which give rise to the many sugar stereoisomers found in nature. We begin by describing the families of monosaccharides with backbones of three to seven carbons—their structure and stereoisomeric forms, and the means of representing their three-dimensional structures on paper. We then discuss several chemical reactions of the carbonyl groups of monosaccharides. One such reaction, the addition of a hydroxyl group from within the same molecule, generates cyclic forms having four or more backbone carbons (the forms that predominate in aqueous solution). This ring closure creates a new chiral center, adding further stereochemical complexity to this class of compounds. The nomenclature for unambiguously specifying the configuration about each carbon atom in a cyclic form and the means of representing these structures on paper are therefore
described in some detail; this information will be useful as we discuss the metabolism of monosaccharides in Part II. We also introduce here some important monosaccharide derivatives encountered in later chapters.

The Two Families of Monosaccharides Are Aldoses and Ketoses

Monosaccharides are colorless, crystalline solids that are freely soluble in water but insoluble in nonpolar solvents. Most have a sweet taste. The backbones of common monosaccharides are unbranched carbon chains in which all the carbon atoms are linked by single bonds. In the open-chain form, one of the carbon atoms is double-bonded to an oxygen atom to form a carbonyl group; each of the other carbon atoms has a hydroxyl group. If the carbonyl group is at an end of the carbon chain (that is, in an aldehyde group) the monosaccharide is an aldose; if the carbonyl group is at any other position (in a ketone group) the monosaccharide is a ketose. The simplest monosaccharides are the two three-carbon trioses: glyceraldehyde, an aldotriose, and dihydroxyacetone, a ketotriose (Fig. 7-1a).

Monosaccharides with four, five, six, and seven carbon atoms in their backbones are called, respectively, tetroses, pentoses, hexoses, and heptoses. There are aldoses and ketoses of each of these chain lengths: aldohexoses and ketohexoses, and so on. The hexoses, which include the aldohexose d-glucose and the ketohexose d-fructose (Fig. 7-1b), are the most common monosaccharides in nature. The aldopentoses d-ribose and 2-deoxy-d-ribose (Fig. 7-1c) are components of nucleotides and nucleic acids (Chapter 8).

Monosaccharides Have Asymmetric Centers

All the monosaccharides except dihydroxyacetone contain one or more asymmetric (chiral) carbon atoms and thus occur in optically active isomeric forms (pp. 16–17). The simplest aldose, glyceraldehyde, contains one chiral center (the middle carbon atom) and therefore has two different optical isomers, or enantiomers (Fig. 7–2).

**KEY CONVENTION:** One of the two enantiomers is, by convention, designated the D isomer, the other the L isomer. As for other biomolecules with chiral centers, the absolute configurations of sugars are known from x-ray crystallography. To represent three-dimensional sugar structures on paper, we often use Fischer projection formulas (Fig. 7–2). In Fischer projection formulas, horizontal bonds project out of the plane of the paper, toward the reader; vertical bonds project behind the plane of the paper, away from the reader.

**FIGURE 7–1** Representative monosaccharides. (a) Two trioses, an aldose and a ketose. The carbonyl group in each is shaded. (b) Two common hexoses. (c) The pentose components of nucleic acids. d-Ribose is a component of ribonucleic acid (RNA), and 2-deoxy-d-ribose is a component of deoxyribonucleic acid (DNA).
7.1 Monosaccharides and Disaccharides

FIGURE 7-3 Aldoses and ketoses. The series of (a) \(\alpha\)-aldoses and (b) \(\alpha\)-ketoses having from three to six carbon atoms, shown as projection formulas. The carbon atoms in red are chiral centers. In all these \(\alpha\) isomers, the chiral carbon most distant from the carbonyl carbon has the same configuration as the chiral carbon in \(\alpha\)-glyceraldehyde. The sugars named in boxes are the most common in nature; you will encounter these again in this and later chapters.

In general, a molecule with \(n\) chiral centers can have \(2^n\) stereoisomers. Glyceraldehyde has \(2^1 = 2\); the aldohexoses, with four chiral centers, have \(2^4 = 16\) stereoisomers. The stereoisomers of monosaccharides of each carbon-chain length can be divided into two groups that differ in the configuration about the chiral center most distant from the carbonyl carbon. Those in which the configuration at this reference carbon is the same as that of \(\alpha\)-glyceraldehyde are designated \(\alpha\) isomers, and those with the same configuration as \(\alpha\)-glyceraldehyde are \(\beta\) isomers. When the hydroxyl group on the reference carbon is on the right in a projection formula that has the carbonyl carbon at the top, the sugar is the \(\alpha\) isomer; when on the left, it is the \(\beta\) isomer. Of the 16 possible aldohexoses, eight are \(\alpha\) forms and eight are \(\beta\). Most of the hexoses of living organisms are \(\alpha\) isomers.

Figure 7-3 shows the structures of the \(\alpha\) stereoisomers of all the aldoses and ketoses having three to six carbon atoms. The carbons of a sugar are numbered beginning at the end of the chain nearest the carbonyl group. Each of the eight \(\alpha\)-aldohexoses, which differ in the stereochemistry at C-2, C-3, or C-4, has its own name: \(\alpha\)-glucose, \(\alpha\)-galactose, \(\alpha\)-mannose, and so forth (Fig. 7-3a). The four- and five-carbon ketoses are
designated by inserting “ul” into the name of a corresponding aldose; for example, d-ribulose is the ketopentose corresponding to the aldopentose d-ribose. The ketohexoses are named otherwise: for example, fructose (from the Latin fructus, “fruit”; fruits are one source of this sugar) and sorbose (from Sorbus, the genus of mountain ash, which has berries rich in the related sugar alcohol sorbitol). Two sugars that differ only in the configuration around one carbon atom are called epimers; d-glucose and d-mannose, which differ only in the stereochemistry at C-2, are epimers, as are d-glucose and d-galactose (which differ at C-4) (Fig. 7-4).

Some sugars occur naturally in their L form; examples are L-arabinose and the L isomers of some sugar derivatives that are common components of glycoconjugates (Section 7.3).

The Common Monosaccharides Have Cyclic Structures

For simplicity, we have thus far represented the structures of aldoses and ketoses as straight-chain molecules (Figs 7-3, 7-4). In fact, in aqueous solution, aldotetroses and all monosaccharides with five or more carbon atoms in the backbone occur predominantly as cyclic (ring) structures in which the carbonyl group has formed a covalent bond with the oxygen of a hydroxyl group along the chain. The formation of these ring structures is the result of a general reaction between alcohols and aldehydes or ketones to form derivatives called hemiacetals or hemiketals (Fig. 7-5), which contain an additional asymmetric carbon atom and thus can exist in two stereoisomeric forms. For example, d-glucose exists in solution as an intramolecular hemiacetal in which the free hydroxyl group at C-5 has reacted with the aldehydeic C-1, rendering the latter carbon asymmetric and producing two stereoisomers, designated α and β (Fig. 7-6). The designation α indicates that the hydroxyl group at the anomeric center is, in a Fischer projection, on the same side as the

![FIGURE 7-4 Epimers. d-Glucose and two of its epimers are shown as projection formulas. Each epimer differs from d-glucose in the configuration at one chiral center (shaded pink).](image)

![FIGURE 7-5 Formation of hemiacetals and hemiketals. An aldehyde or ketone can react with an alcohol in a 1:1 ratio to yield a hemiacetal or hemiketal, respectively, creating a new chiral center at the carbonyl carbon. Substitution of a second alcohol molecule produces an acetal or ketal. When the second alcohol is part of another sugar molecule, the bond produced is a glycosidic bond (p. 243).](image)

![FIGURE 7-6 Formation of the two cyclic forms of d-glucose. Reaction between the aldehyde group at C-1 and the hydroxyl group at C-5 forms a hemiacetal linkage, producing either of two stereoisomers, the α and β anomers, which differ only in the stereochemistry around the hemiacetal carbon. The interconversion of α and β anomers is called mutarotation.](image)
hydroxyl attached at the farthest chiral center, whereas β indicates that these hydroxyl groups are on opposite sides. These six-membered ring compounds are called **pyranoses** because they resemble the six-membered ring compound pyran (Fig. 7-7). The systematic names for the two ring forms of d-glucose are α-d-glucopyranose and β-d-glucopyranose.

Aldoses also exist in cyclic forms having five-membered rings, which, because they resemble the five-membered ring compound furan, are called **furanoses**. However, the six-membered aldopyranose ring is much more stable than the aldofuranose ring and predominates in aldohexose and aldotetrose solutions. Only aldoses having five or more carbon atoms can form pyranose rings.

Isomeric forms of monosaccharides that differ only in their configuration about the hemiacetal or hemiketal carbon atom are called **anomers**. The hemiacetal (or carbonyl) carbon atom is called the **anomeric carbon**. The α and β anomers of d-glucose interconvert in aqueous solution by a process called **mutarotation** (Fig. 7-6). Thus, a solution of α-d-glucose and a solution of β-d-glucose eventually form identical equilibrium mixtures having identical optical properties. This mixture consists of about one-third α-d-glucose, two-thirds β-d-glucose, and very small amounts of the linear and five-membered ring (glucofuranose) forms.

Ketohexoses also occur in α and β anomeric forms. In these compounds the hydroxyl group at C-5 (or C-6) reacts with the keto group at C-2, forming a furanose (or pyranose) ring containing a hemiketal linkage (Fig. 7-5). D-Fructose readily forms the furanose ring (Fig. 7-7); the more common anomer of this sugar in combined forms or in derivatives is β-d-fructofuranose.

**Haworth perspective formulas** like those in Figure 7-7 are commonly used to show the stereochemistry of ring forms of monosaccharides. However, the six-membered pyranose ring is not planar, as Haworth perspectives suggest, but tends to assume either of two “chair” conformations (Fig. 7-8). Recall from Chapter 1 (p. 18) that two configurations of a molecule are interconvertible without the breakage of covalent bonds, whereas two conformations can be interconverted only by breaking a covalent bond. To interconvert α and β conformations, the bond involving the ring oxygen atom would have to be broken, but interconversion of the two chair forms does not require bond breakage. The specific three-dimensional structures of the monosaccharide units are important in determining the biological properties and functions of some polysaccharides, as we shall see.

**FIGURE 7-8 Conformational formulas of pyranoses.** (a) Two chair forms of the pyranose ring. Bonds to substituents and hydrogen atoms on the ring carbons may be either axial (ax), projecting parallel to the vertical axis through the ring, or equatorial (eq), projecting roughly perpendicular to this axis. Two conformers such are these are not readily interconvertible without breaking the ring. However, when the molecule is “stretched” (by atomic force microscopy; see Box 11-1), an input of about 46 kJ of energy per mole of sugar can force the interconversion of chair forms. Generally, substituents in the equatorial positions are less sterically hindered by neighboring substituents, and conformers with bulky substituents in equatorial positions are favored. Another conformation, the “boat” (not shown), is seen only in derivatives with very bulky substituents. (b) The preferred chair conformation of α-d-glucopyranose.
Organisms Contain a Variety of Hexose Derivatives

In addition to simple hexoses such as glucose, galactose, and mannose, there are a number of sugar derivatives in which a hydroxyl group in the parent compound is replaced with another substituent, or a carbon atom is oxidized to a carboxyl group (Fig. 7-9). In glucosamine, galactosamine, andmannosamine, the hydroxyl at C-2 of the parent compound is replaced with an amino group. The amino group is nearly always condensed with acetic acid, as in N-acetylglicosamine. This glucosamine derivative is part of many structural polymers, including those of the bacterial cell wall. Bacterial cell walls also contain a derivative of glucosamine, N-acetylmuramic acid, in which lactic acid (a three-carbon carboxylic acid) is ether-linked to the oxygen at C-3 of N-acetylglicosamine. The substitution of a hydrogen for the hydroxyl group at C-6 of L-galactose produces L-fucose or L-rhamnose, respectively. L-Fucose is found in the complex oligosaccharide components of glycoproteins and glycolipids; L-rhamnose is found in plant polysaccharides.

Oxidation of the carbonyl (aldehyde) carbon of glucose to the carboxyl level produces gluconic acid; other aldoses yield other aldonic acids. Oxidation of the carbon at the other end of the carbon chain—C-6 of glucose, galactose, or mannose—forms the corresponding uronic acid: glucuronic, galacturonic, or mannuronic acid. Both aldonic and uronic acids form stable intramolecular esters called lactones (Fig. 7-9, lower left). In addition to these acidic hexose derivatives, one nine-carbon acidic sugar deserves mention: N-acetyleneuraminic acid (a sialic acid, but often referred to simply as “sialic acid”), a derivative of N-acetylmannosamine, is a component of many glycoproteins and glycolipids in animals.

The acidic sugars contain a carboxylate group, which confers a negative charge at neutral pH. D-Glucono-δ-lactone results from formation of an ester linkage between the C-1 carboxylate group and the C-3 (also known as the δ carbon) hydroxyl group of D-gluconate.
carboxylic acid groups of the acidic sugar derivatives are ionized at pH 7, and the compounds are therefore correctly named as the carboxylates—glucuronate, galacturonate, and so forth.

In the synthesis and metabolism of carbohydrates, the intermediates are very often not the sugars themselves but their phosphorylated derivatives. Condensation of phosphoric acid with one of the hydroxyl groups of a sugar forms a phosphate ester, as in glucose 6-phosphate (Fig. 7-9). Sugar phosphates are relatively stable at neutral pH and bear a negative charge. One effect of sugar phosphorylation within cells is to trap the sugar inside the cell; most cells do not have plasma membrane transporters for phosphorylated sugars. Phosphorylation also activates sugars for subsequent chemical transformation. Several important phosphorylated derivatives of sugars are components of nucleotides (discussed in the next chapter).

Monosaccharides Are Reducing Agents

Monosaccharides can be oxidized by relatively mild oxidizing agents such as cupric (Cu++) ion (Fig. 7–10). The carbonyl carbon is oxidized to a carboxyl group. Glucose and other sugars capable of reducing cupric ion are called reducing sugars. They form enediols, which are converted to aldonic acids and then to a complex mixture of 2-, 3-, 4-, and 6-carbon acids. This is the basis of Fehling’s reaction, a qualitative test for the presence of reducing sugar. By measuring the amount of oxidizing agent reduced by a solution of a sugar, it is also possible to estimate the concentration of that sugar. For many years this test was used to detect and measure elevated glucose levels in blood and urine in the diagnosis of diabetes mellitus (Box 7–1).

BOX 7-1 Medicine

Blood Glucose Measurements in the Diagnosis and Treatment of Diabetes

Glucose is the principal fuel for the brain. When the amount of glucose reaching the brain is too low, the consequences can be dire: lethargy, coma, permanent brain damage, and death (see Fig. 23–25). Animals have evolved complex hormonal mechanisms to ensure that the concentration of glucose in the blood remains high enough (about 5 mM) to satisfy the brain’s needs, but not too high, because elevated blood glucose can also have serious physiological consequences.

Individuals with insulin-dependent diabetes mellitus do not produce sufficient insulin, the hormone that normally serves to reduce blood glucose concentration, and if the diabetes is untreated their blood glucose levels may rise to severalfold higher than normal. These high glucose levels are believed to be at least one cause of the serious long-term consequences of untreated diabetes—kidney failure, cardiovascular disease, blindness, and impaired wound healing—so one goal of therapy is to provide just enough insulin (by injection) to keep blood glucose levels near normal. To maintain the correct balance of exercise, diet, and insulin for the individual, blood glucose concentration needs to be measured several times a day, and the amount of insulin injected adjusted appropriately.

The concentrations of glucose in blood and urine can be determined by a simple assay for reducing sugar, such as Fehling’s reaction, which for many years was used as a diagnostic test for diabetes (Fig. 7–10). Modern measurements require just a drop of blood, added to a test strip containing the enzyme glucose oxidase (Fig. 1); a simple photometer measures the color produced when the H2O2 from glucose oxidation reacts with a dye, and reads out the blood glucose concentration. Because blood glucose levels change with the timing of meals and exercise, single-time measurements do not necessarily reflect the average blood glucose over hours and days, so dangerous increases may go undetected. The average glucose concentration can be assessed by looking at its effect on hemoglobin, the oxygen-carrying protein in erythrocytes (p. 158). Transporters in the erythrocyte membrane equilibrate intracellular and plasma glucose.

\[
\text{D-Glucose} + \text{O}_2 \xrightarrow{\text{glucose oxidase}} \text{D-Glucono-6-lactone} + \text{H}_2\text{O}_2
\]

FIGURE 1 The glucose oxidase reaction, used in the measurement of blood glucose. A second enzyme, a peroxidase, catalyzes the reaction of the H2O2 with a colorless compound to produce a colored product, which is measured spectrophotometrically.
glucose concentrations, so hemoglobin is constantly exposed to glucose at whatever concentration is present in the blood. A nonenzymatic reaction occurs between glucose and primary amino groups in hemoglobin (either the amino-terminal Val or the ε-amino groups of Lys residues; see Fig. 2). The rate of this process is proportional to the concentration of glucose, so the reaction can be used as the basis for estimating the average blood glucose level over weeks. The amount of glycated hemoglobin (GHB) present at any time reflects the average blood glucose concentration over the circulating “lifetime” of the erythrocyte (about 120 days), although the concentration in the last two weeks is the most important in setting the level of GHB.

The extent of hemoglobin glycation (so named to distinguish it from glycosylation, the enzymatic transfer of glucose to a protein) is measured clinically by extracting hemoglobin from a small sample of blood and separating GHB from unmodified hemoglobin electrophoretically, taking advantage of the charge difference resulting from modification of the amino group(s). Normal GHB values are about 5% of total hemoglobin (corresponding to blood glucose of 120 mg/100 mL). In people with untreated diabetes, however, this value may be as high as 13%, indicating an average blood glucose level of about 300 mg/100 mL—dangerously high. One criterion for success in an individual program of insulin therapy (the timing, frequency, and amount of insulin injected) is maintaining GHB values at about 7%.

In the hemoglobin glycation reaction, the first step (formation of a Schiff base) is followed by a series of rearrangements, oxidations, and dehydrations of the carbohydrate moiety to produce a heterogeneous mixture of AGEs, advanced glycation end products. These products can leave the erythrocyte and form covalent cross-links between proteins, interfering with normal protein function (Fig. 2). The accumulation of relatively high concentrations of AGEs in people with diabetes may, by cross-linking critical proteins, cause the damage to the kidneys, retinas, and cardiovascular system that characterize the disease. This pathogenic process is a potential target for drug action.

**FIGURE 2** The nonenzymatic reaction of glucose with a primary amino group in hemoglobin begins with ① formation of a Schiff base, which ② undergoes the Amadori rearrangement to generate a stable product; ③ this ketoamine can further cyclize to yield GHB. ④ Subsequent reactions generate advanced glycation end products (AGEs), such as ε-N-carboxymethyllysine and methylglyoxal, compounds that ⑤ can damage other proteins by cross-linking them, causing pathological changes.
Disaccharides Contain a Glycosidic Bond

Disaccharides (such as maltose, lactose, and sucrose) consist of two monosaccharides joined covalently by an **O-glycosidic bond**, which is formed when a hydroxyl group of one sugar reacts with the anomeric carbon of the other (Fig. 7-11). This reaction represents the formation of an acetal from a hemiacetal (such as glucopyranose) and an alcohol (a hydroxyl group of the second sugar molecule) (Fig. 7-5), and the resulting compound is called a glycoside. Glycosidic bonds are readily hydrolyzed by acid but resist cleavage by base. Thus disaccharides can be hydrolyzed to yield their free monosaccharide components by boiling with dilute acid. N-glycosyl bonds join the anomeric carbon of a sugar to a nitrogen atom in glycoproteins (see Fig. 7-29) and nucleotides (see Fig. 8-1).

The oxidation of a sugar by cupric ion (the reaction that defines a reducing sugar) occurs only with the linear form, which exists in equilibrium with the cyclic forms. When the anomeric carbon is involved in a glycosidic bond, that sugar residue cannot take the linear form and therefore becomes a nonreducing sugar. In describing disaccharides or polysaccharides, the end of a chain with a free anomeric carbon (one not involved in a glycosidic bond) is commonly called the **reducing end**.

![Formation of maltose](image)

**FIGURE 7-11 Formation of maltose.** A disaccharide is formed from two monosaccharides (here, two molecules of d-glucose) when an \(-\text{OH}\) (alcohol) of one glucose molecule (right) condenses with the intramolecular hemiacetal of the other glucose molecule (left), with elimination of \(\text{H}_2\text{O}\) and formation of a glycosidic bond. The reversal of this reaction is hydrolysis—attack by \(\text{H}_2\text{O}\) on the glycosidic bond. The maltose molecule, shown here as an illustration, retains a reducing hemiacetal at the C-1 not involved in the glycosidic bond. Because mutarotation interconverts the \(\alpha\) and \(\beta\) forms of the hemiacetal, the bonds at this position are sometimes depicted with wavy lines, as shown here, to indicate that the structure may be either \(\alpha\) or \(\beta\).

The disaccharide maltose (Fig. 7-11) contains two d-glucose residues joined by a glycosidic linkage between C-1 (the anomeric carbon) of one glucose residue and C-4 of the other. Because the disaccharide retains a free anomeric carbon (C-1 of the glucose residue on the right in Fig. 7-11), maltose is a reducing sugar. The configuration of the anomeric carbon atom in the glycosidic linkage is \(\alpha\). The glucose residue with the free anomeric carbon is capable of existing in \(\alpha\)- and \(\beta\)-pyranose forms.

**KEY CONVENTION:** To name reducing disaccharides such as maltose unambiguously, and especially to name more complex oligosaccharides, several rules are followed. By convention, the name describes the compound written with its nonreducing end to the left, and we can “build up” the name in the following order. (1) Give the configuration (\(\alpha\) or \(\beta\)) at the anomeric carbon joining the first monosaccharide unit (on the left) to the second. (2) Name the nonreducing residue; to distinguish five- and six-membered ring structures, insert “furan” or “pyran” into the name. (3) Indicate in parentheses the two carbon atoms joined by the glycosidic bond, with an arrow connecting the two numbers; for example, \((1\rightarrow4)\) shows that C-1 of the first-named sugar residue is joined to C-4 of the second. (4) Name the second residue. If there is a third residue, describe the second glycosidic bond by the same conventions. (To shorten the description of complex polysaccharides, three-letter abbreviations or colored symbols for the monosaccharides are often used, as given in Table 7-1.) Following this convention for naming oligosaccharides, maltose is \(\alpha\)-D-glucopyranosyl-(1\(\rightarrow4\))-D-glucopyranose. Because most sugars encountered in this book are the \(\beta\) enantiomers and the pyranose form of hexoses predominates, we generally use a shortened version of the formal name of

Note: In a commonly used convention, hexoses are represented as circles, N-acetylhexosamines as squares, and hexosamines as squares divided diagonally. All sugars with the “gluco” configuration are blue, those with the “galacto” configuration are yellow, and “manno” sugars are green. Other substituents can be added as needed: sulfate (S), phosphate (P), O-acetyl (OAc), or O-methyl (Ome).
such compounds, giving the configuration of the anomeric carbon and naming the carbons joined by the glycosidic bond. In this abbreviated nomenclature, maltose is Glc(α1→4)Glc.

The disaccharide lactose (Fig. 7-12), which yields D-galactose and D-glucose on hydrolysis, occurs naturally in milk. The anomeric carbon of the glucose residue is available for oxidation, and thus lactose is a reducing disaccharide. Its abbreviated name is Gal(β1→4)Glc. Sucrose (table sugar) is a disaccharide of glucose and fructose. It is formed by plants but not by animals. In contrast to maltose and lactose, sucrose contains no free anomeric carbon atom; the anomeric carbons of both monosaccharide units are involved in the glycosidic bond (Fig. 7-12). Sucrose is therefore a nonreducing sugar. In the abbreviated nomenclature, a double-headed arrow connects the symbols specifying the anomeric carbons and their configurations. For example, the abbreviated name of sucrose is either Glc(α1→2β)Fru or Fru(2β→1α)Glc. Sucrose is a major intermediate product of photosynthesis; in many plants it is the principal form in which sugar is transported from the leaves to other parts of the plant body. Trehalose, Glc(α1→1α)Glc (Fig. 7-12)—a disaccharide of D-glucose that, like sucrose, is a nonreducing sugar—is a major constituent of the circulating fluid (hemolymph) of insects, serving as an energy-storage compound. Fungi also contain trehalose and are used as a commercial source of this sugar.

**SUMMARY 7.1 Monosaccharides and Disaccharides**

- Sugars (also called saccharides) are compounds containing an aldehyde or ketone group and two or more hydroxyl groups.
- Monosaccharides generally contain several chiral carbons and therefore exist in a variety of stereochemical forms, which may be represented on paper as Fischer projections. Epimers are sugars that differ in configuration at only one carbon atom.
- Monosaccharides commonly form internal hemiacetals or hemiketals, in which the aldehyde or ketone group joins with a hydroxyl group of the same molecule, creating a cyclic structure; this can be represented as a Haworth perspective formula. The carbon atom originally found in the aldehyde or ketone group joins with a hydroxyl group of the same molecule, creating a cyclic structure; this can be represented as a Haworth perspective formula.
- A hydroxyl group of one monosaccharide can add to the anomeric carbon of a second monosaccharide to form an acetal. In this disaccharide, the glycosidic bond protects the anomeric carbon from oxidation.
- Oligosaccharides are short polymers of several monosaccharides joined by glycosidic bonds. At one end of the chain, the reducing end, is a monosaccharide unit with its anomeric carbon not involved in a glycosidic bond.
- The common nomenclature for di- or oligosaccharides specifies the order of monosaccharide units, the configuration at each anomeric carbon, and the carbon atoms involved in the glycosidic linkage(s).

**7.2 Polysaccharides**

Most carbohydrates found in nature occur as polysaccharides, polymers of medium to high molecular weight. Polysaccharides, also called glycans, differ from each other in the identity of their recurring monosaccharide units, in the length of their chains, in the types of bonds linking the units, and in the degree of branching. Homopolysaccharides contain only a single monomeric species; heteropolysaccharides contain two or more different kinds (Fig. 7-13). Some homopolysaccharides serve as storage forms of monosaccharides that are used as fuels; starch and glycogen are homopolysaccharides of this type. Other homopolysaccharides (cellulose and chitin, for example) serve as structural elements in plant
Homopolysaccharides | Heteropolysaccharides
---|---
Unbranched | Branched
Two monomer types, unbranched | Multiple monomer types, branched

FIGURE 7-13 Homo- and heteropolysaccharides. Polysaccharides may be composed of one, two, or several different monosaccharides, in straight or branched chains of varying length.

Cell walls and animal exoskeletons. Heteropolysaccharides provide extracellular support for organisms of all kingdoms. For example, the rigid layer of the bacterial cell envelope (the peptidoglycan) is composed in part of a heteropolysaccharide built from two alternating monosaccharide units. In animal tissues, the extracellular space is occupied by several types of heteropolysaccharides, which form a matrix that holds individual cells together and provides protection, shape, and support to cells, tissues, and organs.

Unlike proteins, polysaccharides generally do not have defining molecular weights. This difference is a consequence of the mechanisms of assembly of the two types of polymer. As we shall see in Chapter 27, proteins are synthesized on a template (messenger RNA) of defined sequence and length, by enzymes that follow the template exactly. For polysaccharide synthesis there is no template; rather, the program for polysaccharide synthesis is intrinsic to the enzymes that catalyze the polymerization of the monomeric units, and there is no specific stopping point in the synthetic process.

Some Homopolysaccharides Are Stored Forms of Fuel

The most important storage polysaccharides are starch in plant cells and glycogen in animal cells. Both polysaccharides occur intracellularly as large clusters or granules. Starch and glycogen molecules are heavily hydrated, because they have many exposed hydroxyl groups available to hydrogen-bond with water. Most plant cells have the ability to form starch (see Fig. 20-2), and starch storage is especially abundant in tubers (underground stems), such as potatoes, and in seeds.

Starch contains two types of glucose polymer, amylose and amylopectin (Fig. 7-14). The former consists

FIGURE 7-14 Glycogen and starch. (a) A short segment of amylose, a linear polymer of α-glucose residues in (α1→4) linkage. A single chain can contain several thousand glucose residues. Amylopectin has stretches of similarly linked residues between branch points. Glycogen has the same basic structure, but has more branching than amylopectin. (b) An (α1→6) branch point of glycogen or amylopectin. (c) A cluster of amylose and amylopectin like that believed to occur in starch granules. Strands of amylopectin (red) form double-helical structures with each other or with amylose strands (blue). Glucose residues at the nonreducing ends of the outer branches are removed enzymatically during the mobilization of starch for energy production. Glycogen has a similar structure but is more highly branched and more compact.
of long, unbranched chains of D-glucose residues connected by (α1→4) linkages (as in maltose). Such chains vary in molecular weight from a few thousand to more than a million. Amylopectin also has a high molecular weight (up to 200 million) but unlike amylose is highly branched. The glycosidic linkages joining successive glucose residues in amylopectin chains are (α1→4); the branch points (occurring every 24 to 30 residues) are (α1→6) linkages.

Glycogen is the main storage polysaccharide of animal cells. Like amylopectin, glycogen is a polymer of (α1→4)-linked subunits of glucose, with (α1→6)-linked branches, but glycogen is more extensively branched (on average, every 8 to 12 residues) and more compact than starch. Glycogen is especially abundant in the liver, where it may constitute as much as 7% of the wet weight; it is also present in skeletal muscle. In hepatocytes glycogen is found in large granules, which are themselves clusters of smaller granules composed of single, highly branched glycogen molecules with an average molecular weight of several million. Such glycogen granules also contain, in tightly bound form, the enzymes responsible for the synthesis and degradation of glycogen.

Because each branch in glycogen ends with a nonreducing sugar unit, a glycogen molecule with $n$ branches has $n + 1$ nonreducing ends, but only one reducing end. When glycogen is used as an energy source, glucose units are removed one at a time from the nonreducing ends. Degradative enzymes that act only at nonreducing ends can work simultaneously on the many branches, speeding the conversion of the polymer to monosaccharides.

Why not store glucose in its monomeric form? It has been calculated that hepatocytes store glycogen equivalent to a glucose concentration of 0.4 M. The actual concentration of glycogen, which is insoluble and contributes little to the osmolarity of the cytosol, is about 0.01 μM. If the cytosol contained 0.4 M glucose, the osmolarity would be threateningly elevated, leading to osmotic entry of water that might rupture the cell (see Fig. 2–12). Furthermore, with an intracellular glucose concentration of 0.4 M and an external concentration of about 5 mM (the concentration in the blood of a mammal), the free-energy change for glucose uptake into cells against this very high concentration gradient would be prohibitively large.

DextranS are bacterial and yeast polysaccharides made up of (α1→6)-linked poly-D-glucose; all have (α1→3) branches, and some also have (α1→2) or (α1→4) branches. Dental plaque, formed by bacteria growing on the surface of teeth, is rich in dextranS. Synthetic dextranS are used in several commercial products (for example, Sephadex) that serve in the fractionation of proteins by size-exclusion chromatography (see Fig. 3–17b). The dextranS in these products are chemically cross-linked to form insoluble materials of various porosities, admitting macromolecules of various sizes.

Some Homopolysaccharides Serve Structural Roles

Cellulose, a fibrous, tough, water-insoluble substance, is found in the cell walls of plants, particularly in stalks, stems, trunks, and all the woody portions of the plant body. Cellulose constitutes much of the mass of wood, and cotton is almost pure cellulose. Like amylose, the cellulose molecule is a linear, unbranched homopolysaccharide, consisting of 10,000 to 15,000 D-glucose units. But there is a very important difference: in cellulose the glucose residues have the β configuration (Fig. 7–15), whereas in amylose the glucose is in the α configuration. The glucose residues in cellulose are linked by (β1→4) glycosidic bonds, in contrast to the (α1→4) bonds of amylose. This difference gives cellulose and amylose very different structures and physical properties.

Glycogen and starch ingested in the diet are hydrolyzed by α-amylases and glycosidases, enzymes in saliva and the intestine that break (α1→4) glycosidic bonds between glucose units. Most animals cannot use cellulose as a fuel source, because they lack an enzyme to hydrolyze the (β1→4) linkages. Termites readily digest cellulose (and therefore wood), but only because their intestinal tract harbors a symbiotic microorganism,
Trichonympha, that secretes cellulase, which hydrolyzes the (β1→4) linkages. Wood-rot fungi and bacteria also produce cellulase (Fig. 7-16).

Chitin is a linear homopolysaccharide composed of N-acetylglucosamine residues in (β1→4) linkage (Fig. 7-17). The only chemical difference from cellulose is the replacement of the hydroxyl group at C-2 with an acetylated amino group. Chitin forms extended fibers similar to those of cellulose, and like cellulose cannot be digested by vertebrates. Chitin is the principal component of the hard exoskeletons of nearly a million species of arthropods— insects, lobsters, and crabs, for example—and is probably the second most abundant polysaccharide, next to cellulose, in nature; an estimated 1 billion tons of chitin are produced each year in the biosphere!

Steric Factors and Hydrogen Bonding Influence Homopolysaccharide Folding

The folding of polysaccharides in three dimensions follows the same principles as those governing polypeptide structure: subunits with a more-or-less rigid structure dictated by covalent bonds form three-dimensional macromolecular structures that are stabilized by weak interactions within or between molecules: hydrogen bonds and hydrophobic and van der Waals interactions, and, for polymers with charged subunits, electrostatic interactions. Because polysaccharides have so many hydroxyl groups, hydrogen bonding has an especially important influence on their structure. Glycogen, starch, and cellulose are composed of pyranoside subunits (having six-membered rings), as are the oligosaccharides of glycoproteins and glycolipids to be discussed later. Such molecules can be represented as a series of rigid pyranose rings connected by an oxygen atom bridging two carbon atoms (the glycosidic bond). There is, in principle, free rotation about both C—O bonds linking the residues (Fig. 7-15a), but as in polypeptides (see Figs 4-2, 4-8), rotation about each bond is limited by steric hindrance by substituents. The three-dimensional structures of these molecules can be
described in terms of the dihedral angles, $\phi$ and $\Psi$, about the glycosidic bond (Fig. 7-18), analogous to angles $\phi$ and $\Psi$ made by the peptide bond (see Fig. 4-2).

The bulkiness of the pyranose ring and its substituents, and electronic effects at the anomeric carbon, place constraints on the angles $\phi$ and $\Psi$; thus certain conformations are much more stable than others, as can be shown on a map of energy as a function of $\phi$ and $\Psi$ (Fig. 7-19).

The most stable three-dimensional structure for the ($\alpha1\rightarrow4$)-linked chains of starch and glycogen is a tightly coiled helix (Fig. 7-20), stabilized by interchain hydrogen bonds. In amylose (with no branches) this structure is regular enough to allow crystallization and thus determination of the structure by x-ray diffraction. The average plane of each residue along the amylose chain forms a 60° angle with the average plane of the preceding residue, so the helical structure has six residues per turn. For amylose, the core of the helix is of precisely the right dimensions to accommodate iodine as complex ions ($I^-$ and $I^-$), giving an intensely blue complex. This interaction is a common qualitative test for amylose.

For cellulose, the most stable conformation is that in which each chair is turned 180° relative to its neighbors, yielding a straight, extended chain. All $\text{--OH}$ groups are available for hydrogen bonding with neighboring chains. With several chains lying side by side, a stabilizing network of interchain and intrachain hydrogen bonds produces straight, stable supramolecular fibers of great tensile strength (Fig. 7-15b). This property of cellulose has made it a useful substance for civilizations for millennia. Many manufactured products, including papyrus, paper, cardboard, rayon, insulating tiles, and a variety of other useful materials, are derived from cellulose. The water content of these materials is low because extensive interchain hydrogen bonding between cellulose molecules satisfies their capacity for hydrogen-bond formation.

**Figure 7-19** A map of favored conformations for oligosaccharides and polysaccharides. The torsion angles $\Psi$ and $\phi$ (see Fig. 7-18), which define the spatial relationship between adjacent rings, can in principle have any value from 0° to 360°. In fact, some of the torsion angles would give conformations that are sterically hindered, whereas others give conformations that maximize hydrogen bonding. (a) When the relative energy (E) is plotted for each value of $\phi$ and $\Psi$, with isoenergy (“same energy”) contours drawn at intervals of 1 kcal/mol above the minimum energy state, the result is a map of preferred conformations. This is analogous to the Ramachandran plot for peptides (see Figs 4-3, 4-8). (b) Two energetic extremes for the disaccharide Gal($\beta1\rightarrow3$)Gal; these values fall on the energy diagram (a) as shown by the red and blue dots. The red dot indicates the least favored conformation, the blue dot the most favored conformation. The known conformations of the three polysaccharides shown in Figure 7-18 have been determined by x-ray crystallography, and all fall within the lowest-energy regions of the map.
FIGURE 7-20 Starch (amylose). (a) In the most stable conformation, with adjacent rigid chairs, the polysaccharide chain is curved, rather than linear as in cellulose (see Fig. 7-15). (b) A model of a segment of amylose; for clarity, the hydroxyl groups have been omitted from all but one of the glucose residues. Compare the two residues shaded in pink with the chemical structures in (a). The conformation of $(\alpha 1 \rightarrow 4)$ linkages in amylose, amylopectin, and glycogen causes these polymers to assume tightly coiled helical structures. These compact structures produce the dense granules of stored starch or glycogen seen in many cells (see Fig. 20-2).

Bacterial and Algal Cell Walls Contain Structural Heteropolysaccharides

The rigid component of bacterial cell walls (peptidoglycan) is a heteropolymer of alternating $(\beta 1 \rightarrow 4)$-linked $N$-acetylglucosamine and $N$-acetylmuramic acid residues (see Fig. 20-31). The linear polymers lie side by side in the cell wall, cross-linked by short peptides, the exact structure of which depends on the bacterial species. The peptide cross-links weld the polysaccharide chains into a strong sheath that envelopes the entire cell and prevents cellular swelling and lysis due to the osmotic entry of water. The enzyme lysozyme kills bacteria by hydrolyzing the $(\beta 1 \rightarrow 4)$ glycosidic bond between $N$-acetylglucosamine and $N$-acetylmuramic acid (see Fig. 6-24). Lysozyme is notably present in tears, presumably as a defense against bacterial infections of the eye. It is also produced by certain bacterial viruses to ensure their release from the host bacterial cell, an essential step of the viral infection cycle. Penicillin and related antibiotics kill bacteria by preventing synthesis of the cross-links, leaving the cell wall too weak to resist osmotic lysis (see pp. 216–217).

Certain marine red algae, including some of the seaweeds, have cell walls that contain agar, a mixture of sulfated heteropolysaccharides made up of $D$-galactose and an $L$-galactose derivative ether-linked between C-3 and C-6. Agar is a complex mixture of polysaccharides, all with the same backbone structure, but substituted to varying degrees with sulfate and pyruvate. Agarose ($M_t \sim 150,000$) is the agar component with the fewest charged groups (sulfates, pyruvates) (Fig. 7-21). The remarkable gel-forming property of agarose makes it useful in the biochemistry laboratory. When a suspension of agarose in water is heated and cooled, the agarose forms a double helix: two molecules in parallel orientation twist together with a helix repeat of three residues; water molecules are trapped in the central cavity. These structures in turn associate with each other to form a gel—a three-dimensional matrix that traps large amounts of water. Agarose gels are used as inert supports for the electrophoretic separation of nucleic acids, an essential part of the DNA sequencing process (p. 292). Agar is also used to form a surface for the growth of bacterial colonies. Another commercial use of agar is for the capsules in which some vitamins and drugs are packaged; the dried agar material dissolves readily in the stomach and is metabolically inert.

Glycosaminoglycans Are Heteropolysaccharides of the Extracellular Matrix

The extracellular space in the tissues of multicellular animals is filled with a gel-like material, the extracellular matrix (ECM), also called ground substance, which holds the cells together and provides a porous pathway for the diffusion of nutrients and oxygen to individual cells. The reticular ECM that surrounds fibroblasts and other connective tissue cells is composed of an interlocking meshwork of heteropolysaccharides and fibrous proteins such as fibrillar collagens, elastin, and fibronectin. Basement membrane is a specialized ECM that underlies epithelial cells; it consists of specialized collagens, laminin, and heteropolysaccharides. These heteropolysaccharides, the glycosaminoglycans, are a family of linear polymers composed of repeating disaccharide units (Fig. 7-22). They are unique to animals and bacteria and are not found in plants. One of the two monosaccharides is always either $N$-acetylglucosamine or $N$-acetylgalactosamine; the other is in most cases a uronic acid, usually $\alpha$-glucuronic or $\beta$-iduronic acid. Some glycosaminoglycans contain esterified sulfate groups. The combination of sulfate groups and the carboxylate groups of the uronic acid residues gives glycosaminoglycans a very high density of negative charge. To minimize the repulsive forces among neighboring charged groups, these molecules assume an

Extended conformation in solution, forming a rodlike helix in which the negatively charged carboxylate groups occur on alternate sides of the helix (as shown for heparin in Fig. 7–22). The extended rod form also provides maximum separation between the negatively charged sulfate groups. The specific patterns of sulfated and nonsulfated sugar residues in glycosaminoglycans provide for specific recognition by a variety of protein ligands that bind electrostatically to these molecules. The sulfated glycosaminoglycans are attached to extracellular proteins to form proteoglycans (Section 7.3).

**Figure 7–22** Repeating units of some common glycosaminoglycans of extracellular matrix. The molecules are copolymers of alternating uronic acid and amino sugar residues (keratan sulfate is the exception), with sulfate esters in any of several positions, except in hyaluronan. The ionized carboxylate and sulfate groups (red in the perspective formulas) give these polymers their characteristic high negative charge. Therapeutic heparin contains primarily iduronic acid (IdoA) and a smaller proportion of glucuronic acid (GlcA, not shown), and is generally highly sulfated and heterogeneous in length. The space-filling model shows a heparin segment as its solution structure, as determined by NMR spectroscopy (PDB ID 1HPN). The carbons in the iduronic acid sulfate are colored blue; those in glucosamine sulfate are green. Oxygen and sulfur atoms are shown in their standard colors of red and yellow, respectively. The hydrogen atoms are not shown (for clarity). Heparan sulfate (not shown) is similar to heparin but has a higher proportion of GlcA and fewer sulfate groups, arranged in a less regular pattern.

The glycosaminoglycan **hyaluronan** (hyaluronic acid) contains alternating residues of D-glucuronic acid and N-acetylglucosamine (Fig. 7–22). With up to 50,000 repeats of the basic disaccharide unit, hyaluronan has a molecular weight of several million; it forms clear, highly viscous solutions that serve as lubricants in the synovial fluid of joints and give the vitreous humor of the vertebrate eye its jellylike consistency (the Greek hyalos means “glass”; hyaluronan can have a glassy or translucent appearance). Hyaluronan is also a component of the extracellular matrix of cartilage and tendons, to which it contributes tensile strength and elasticity as a result of its strong interactions with other components of the matrix. Hyaluronidase, an enzyme secreted by some pathogenic bacteria, can hydrolyze the glycosidic linkages of hyaluronan, rendering tissues more susceptible to bacterial invasion. In many species, a similar enzyme in sperm hydrolyzes an outer glycosaminoglycan coat around the ovum, allowing sperm penetration.

Other glycosaminoglycans differ from hyaluronan in three respects: they are generally much shorter polymers, they are covalently linked to specific proteins (proteoglycans), and one or both monomeric units differ from those of hyaluronan. **Chondroitin sulfate** (Greek chondros, “cartilage”) contributes to the tensile strength of cartilage, tendons, ligaments, and the walls of the aorta. **Dermatan sulfate** (Greek derma, “skin”) contributes to the pliability of skin and is also present in blood vessels and heart valves. In this polymer, many of the glucuronate residues present in chondroitin sulfate are replaced by their 5-epimer, l-iduronate.
Keratan sulfates (Greek κέρας, “horn”) have no uronic acid and their sulfate content is variable. They are present in cornea, cartilage, bone, and a variety of horny structures formed of dead cells: horn, hair, hoofs, nails, and claws. Heparan sulfate (Greek ἰεπάρ, “liver”) is produced by all animal cells and contains variable arrangements of sulfated and nonsulfated sugars. The sulfated segments of the chain allow it to interact with a large number of proteins, including growth factors and ECM components, as well as various enzymes and factors present in plasma. Heparin is a fractionated form of heparan sulfate derived mostly from mast cells (a type of leukocyte). Heparin is a therapeutic agent used to inhibit coagulation through its capacity to bind the protease inhibitor antithrombin. Heparin binding causes antithrombin to bind to and inhibit thrombin, a protease essential to blood clotting. The interaction is strongly electrostatic; heparin has the highest negative charge density of any known biological macromolecule (Fig. 7-23). Purified heparin is routinely added to blood samples obtained for clinical analysis, and to blood donated for transfusion, to prevent clotting.

Table 7-2 summarizes the composition, properties, roles, and occurrence of the polysaccharides described in Section 7.2.

*Each polymer is classified as a homopolysaccharide (homo-) or heteropolysaccharide (hetero-).
†The abbreviated names for the peptidoglycan, agarose, and hyaluronan repeating units indicate that the polymer contains repeats of this disaccharide unit. For example, in peptidoglycan, the GlcNAc of one disaccharide unit is (β1→4)-linked to the first residue of the next disaccharide unit.
SUMMARY 7.2 Polysaccharides

- Polysaccharides (glycans) serve as stored fuel and as structural components of cell walls and extracellular matrix.
- The homopolysaccharides starch and glycogen are stored fuels in plant, animal, and bacterial cells. They consist of D-glucose with (α1→4) linkages, and both contain some branches.
- The homopolysaccharides cellulose, chitin, and dextran serve structural roles. Cellulose, composed of (β1→4)-linked D-glucose residues, lends strength and rigidity to plant cell walls. Chitin, a polymer of (β1→4)-linked N-acetylgalactosamine, strengthens the exoskeletons of arthropods. Dextran forms an adhesive coat around certain bacteria.
- Homopolysaccharides fold in three dimensions. The chair form of the pyranose ring is essentially rigid, so the conformation of the polymers is determined by rotation about the bonds from the rings to the oxygen atom in the glycosidic linkage. Starch and glycogen form helical structures with intrachain hydrogen bonding; cellulose and chitin form long, straight strands that interact with neighboring strands.
- Bacterial and algal cell walls are strengthened by heteropolysaccharides—peptidoglycan in bacteria, agar in red algae. The repeating disaccharide in peptidoglycan is GlcNAc(β1→4)Mur2Ac; in sugar, it is D-Gal(β1→4)3,6-anhydro-1-Gal.
- Glycosaminoglycans are extracellular heteropolysaccharides in which one of the two monosaccharide units is a uronic acid (keratan sulfate is an exception) and the other an N-acetylated amino sugar. Sulfate esters on some of the hydroxyl groups and on the amino group of some glucosamine residues in heparin and in heparan sulfate give these polymers a high density of negative charge, forcing them to assume extended conformations. These polymers (hyaluronan, chondroitin sulfate, dermatan sulfate, and keratan sulfate) provide viscosity, adhesiveness, and tensile strength to the extracellular matrix.

7.3 Glycoconjugates: Proteoglycans, Glycoproteins, and Glycolipids

In addition to their important roles as stored fuels (starch, glycogen, dextran) and as structural materials (cellulose, chitin, peptidoglycans), polysaccharides and oligosaccharides are information carriers. Some provide communication between cells and their extracellular surroundings; others label proteins for transport to and localization in specific organelles, or for destruction when the protein is malformed or superfluous; and others serve as recognition sites for extracellular signal molecules (growth factors, for example) or extracellular parasites (bacteria or viruses). On almost every eukaryotic cell, specific oligosaccharide chains attached to components of the plasma membrane form a carbohydrate layer (the glycocalyx), several nanometers thick, that serves as an information-rich surface that a cell shows to its surroundings. These oligosaccharides are central players in cell-cell recognition and adhesion, cell migration during development, blood clotting, the immune response, wound healing, and other cellular processes. In most of these cases, the informational carbohydrate is covalently joined to a protein or a lipid to form a glycoconjugate, which is the biologically active molecule.

Proteoglycans are macromolecules of the cell surface or extracellular matrix in which one or more sulfated glycosaminoglycan chains are joined covalently to a membrane protein or a secreted protein. The glycosaminoglycan chain can bind to extracellular proteins through electrostatic interactions with the negatively charged groups on the polysaccharide. Proteoglycans are major components of all extracellular matrices.

Glycoproteins have one or several oligosaccharides of varying complexity joined covalently to a protein. They are usually found on the outer face of the plasma membrane (as part of the glycocalyx), in the extracellular matrix, and in the blood. Inside cells they are found in specific organelles such as Golgi complexes, secretory granules, and lysosomes. The oligosaccharide portions of glycoproteins are very heterogeneous and, like glycosaminoglycans, they are rich in information, forming highly specific sites for recognition and high-affinity binding by carbohydrate-binding proteins called lectins. Some cytosolic and nuclear proteins can be glycosylated as well.

Glycolipids are membrane sphingolipids in which the hydrophilic head groups are oligosaccharides. As in glycoproteins, the oligosaccharides act as specific sites for recognition by lectins. The brain and neurons are rich in glycolipids, which help in nerve conduction and myelin formation. Glycolipids also play a role in signal transduction in cells.

Proteoglycans Are Glycosaminoglycan-Containing Macromolecules of the Cell Surface and Extracellular Matrix

Mammalian cells can produce 40 types of proteoglycans. These molecules act as tissue organizers, and they influence various cellular activities, such as growth factor activation and adhesion. The basic proteoglycan unit consists of a “core protein” with covalently attached glycosaminoglycan(s). The point of attachment is a Ser residue, to which the glycosaminoglycan is joined through a tetrasaccharide bridge (Fig. 7-24). The Ser residue is generally in the sequence -Ser–Gly–X–Gly– (where X is any amino acid residue), although not every protein with this sequence has an attached glycosaminoglycan.
Many proteoglycans are secreted into the extracellular matrix, but some are integral membrane proteins (see Fig. 11–6). For example, the sheet-like extracellular matrix (basal lamina) that separates organized groups of cells from other groups contains a family of core proteins (M, 20,000 to 40,000), each with several covalently attached heparan sulfate chains. There are two major families of membrane heparan sulfate proteoglycans. **Syndecans** have a single transmembrane domain and an extracellular domain bearing three to five chains of heparan sulfate and in some cases chondroitin sulfate (Fig. 7–25a). **Glypicans** are attached to the membrane by a lipid anchor, a derivative of the membrane lipid phosphatidylinositol (Chapter 11). Both syndecans and glypicans can be shed into the extracellular space. A protease in the ECM that cuts close to the membrane surface releases syndecan ectodomains (those domains outside the plasma membrane), and a phospholipase that breaks the connection to the membrane lipid releases glypicans. Numerous chondroitin sulfate and dermatan sulfate proteoglycans also exist, some as membrane-bound entities, others as secreted products in the ECM.

The glycosaminoglycan chains can bind to a variety of extracellular ligands and thereby modulate the ligands' interaction with specific receptors of the cell surface. Detailed studies of heparan sulfate demonstrate a domain structure that is not random; some domains (typically 3 to 8 disaccharide units long) differ from neighboring domains in sequence and in ability to bind to specific proteins. Highly sulfated domains (called NS domains) alternate with domains having unmodified GlcNAc and GlcA residues (N-acetylated, or NA, domains) (Fig. 7–25b). The exact pattern of sulfation in the NS domain depends on the particular proteoglycan; given the number of possible modifications of the GlcNAc–IdoA dimer, at least 32 different disaccharide units are possible. Furthermore, the same core protein can display different heparan sulfate structures when synthesized in different cell types.

The NS domains bind specifically to extracellular proteins and signaling molecules to alter their activities. The change in activity may result from a conformational change in the protein that is induced by the binding...
A conformational change induced in the protein antithrombin (AT) on binding a specific pentasaccharide NS domain allows its interaction with blood clotting factor Xa, preventing clotting.

Binding of AT and thrombin to two adjacent NS domains brings the two proteins into close proximity, favoring their interaction, which inhibits blood clotting.

NS domains interact with both the fibroblast growth factor (FGF) and its receptor, bringing the oligomeric complex together and increasing the effectiveness of a low concentration of FGF.

The high density of negative charges in heparan sulfate attracts positively charged lipoprotein lipase molecules and holds them by electrostatic and sequence-specific interactions with NS domains.

**FIGURE 7–26** Four types of protein interactions with NS domains of heparan sulfate.

(Fig. 7–26a), or it may be due to the ability of adjacent domains of heparan sulfate to bind to two different proteins, bringing them into close proximity and enhancing protein-protein interactions (Fig. 7–26b). A third general mechanism of action is the binding of extracellular signal molecules (growth factors, for example) to heparan sulfate, which increases their local concentrations and enhances their interaction with growth factor receptors in the cell surface; in this case, the heparan sulfate acts as a coreceptor (Fig. 7–26c). For example, fibroblast growth factor (FGF), an extracellular protein signal that stimulates cell division, first binds to heparan sulfate moieties of syndecan molecules in the target cell's plasma membrane. Syndecan presents FGF to the FGF plasma membrane receptor, and only then can FGF interact productively with its receptor to trigger cell division. Finally, in another type of mechanism, the NS domains interact—electrostatically and otherwise—with a variety of soluble molecules outside the cell, maintaining high local concentrations at the cell surface (Fig. 7–26d).

The importance of correctly synthesizing sulfated domains in heparan sulfate is demonstrated in mutant (“knockout”) mice lacking the enzyme that sulfates the C-2 hydroxyl of IdooA. These animals are born without kidneys and with very severe developmental abnormalities of the skeleton and eyes. Other studies demonstrate that membrane proteoglycans are important in lipoprotein clearance in the liver. There is growing evidence that the path taken by developing axons in the nervous system, and thus the wiring circuitry, is influenced by proteoglycans containing heparan sulfates and chondroitin sulfate, which provide directional cues for axon outgrowth.

Some proteoglycans can form proteoglycan aggregates, enormous supramolecular assemblies of many core proteins all bound to a single molecule of hyaluronan. Aggrecan core protein (Mᵣ ~250,000) has multiple chains of chondroitin sulfate and keratan sulfate, joined to Ser residues in the core protein through trisaccharide linkers, to give an aggrecan monomer of 

\[ Mᵣ \approx 2 \times 10^6 \]

When a hundred or more of these “decorated” core proteins bind a single, extended molecule of hyaluronate (Fig. 7–27), the resulting proteoglycan aggregate (Mᵣ > 2 x 10⁸) and its associated water of hydration occupy a volume about equal to that of a bacterial cell! Aggrecan interacts strongly with collagen in the extracellular matrix of cartilage, contributing to the development, tensile strength, and resiliency of this connective tissue.

Interwoven with these enormous extracellular proteoglycans are fibrous matrix proteins such as collagen, elastin, and fibronectin, forming a cross-linked meshwork that gives the whole extracellular matrix strength and resilience. Some of these proteins are multiahesive, a single protein having binding sites for several different matrix molecules. Fibronectin, for example, has separate domains that bind fibrin, heparan sulfate, collagen, and a family of plasma membrane proteins called integrins that mediate signaling between the cell interior and the extracellular matrix (see Fig. 12–28). The overall picture of cell-matrix interactions that emerges
Figure 7-27 Proteoglycan aggregate of the extracellular matrix. Schematic drawing of a proteoglycan with many aggrecan molecules. One very long molecule of hyaluronan is associated noncovalently with about 100 molecules of the core protein aggrecan. Each aggrecan molecule contains many covalently bound chondroitin sulfate and keratan sulfate chains. Link proteins at the junction between each core protein and the hyaluronan backbone mediate the core protein-hyaluronan interaction. The micrograph shows a single molecule of aggrecan, viewed with the atomic force microscope (see Box 11-1).

(Fig. 7-28) shows an array of interactions between cellular and extracellular molecules. These interactions serve not only to anchor cells to the extracellular matrix but also to provide paths that direct the migration of cells in developing tissue and to convey information in both directions across the plasma membrane.

Figure 7-28 Interactions between cells and the extracellular matrix. The association between cells and the proteoglycan of the extracellular matrix is mediated by a membrane protein (integrin) and by an extracellular protein (fibronectin in this example) with binding sites for both integrin and the proteoglycan. Note the close association of collagen fibers with the fibronectin and proteoglycan.

Glycoproteins Have Covalently Attached Oligosaccharides
Glycoproteins are carbohydrate-protein conjugates in which the glycans are smaller, branched, and more structurally diverse than the glycosaminoglycans of proteoglycans. The carbohydrate is attached at its anomeric carbon through a glycosidic link to the —OH of a Ser or Thr residue (O-linked), or through an N-glycosyl link to the amide nitrogen of an Asn residue (N-linked) (Fig. 7-29). Some glycoproteins have a single
oligosaccharide chain, but many have more than one; the carbohydrate may constitute from 1% to 70% or more of the glycoprotein by mass. **Mucins** are secreted or membrane glycoproteins that can contain large numbers of *O*-linked oligosaccharide chains. Mucins are present in most secretions; they give mucus its characteristic slipperiness. About half of all proteins of mammals are glycosylated, and about 1% of all mammalian genes encode enzymes involved in the synthesis and attachment of these oligosaccharide chains. Sequences for the attachment of *O*-linked chains tend to be rich in Gly, Val, and Pro residues. In contrast the attachment of *N*-linked chains depends on the consensus sequence N-{P}-[ST] (see Box 3–3 for the conventions on representing consensus sequences). As with proteoglycans, not all potential sites are used.

One class of glycoproteins found in the cytoplasm and the nucleus is unique in that the glycosylated positions in the protein carry only single residues of *N*-acetylglucosamine, in *O*-glycosidic linkage to the hydroxyl group of Ser side chains. This modification is reversible and often occurs on the same Ser residues that are phosphorylated at some stage in the protein's activity. The two modifications are mutually exclusive, and this type of glycosylation may prove to be important in the regulation of protein activity. We discuss it in the context of protein phosphorylation in Chapter 12.

As we shall see in Chapter 11, the external surface of the plasma membrane has many membrane glycoproteins with arrays of covalently attached oligosaccharides of varying complexity. The first well-characterized membrane glycoprotein was glycophorin A of the erythrocyte membrane (see Fig. 11–7). It contains 60% carbohydrate by mass, in the form of 16 oligosaccharide chains (totaling 60 to 70 monosaccharide residues) covalently attached to amino acid residues near the amino terminus of the polypeptide chain. Fifteen of the oligosaccharide chains are *O*-linked to Ser or Thr residues, and one is *N*-linked to an Asn residue.

**Glycomics** is the systematic characterization of all of the carbohydrate components of a given cell or tissue, including those attached to proteins and to lipids. For glycoproteins, this also means determining which proteins are glycosylated and where in the amino acid sequence each oligosaccharide is attached. This is a challenging undertaking, but worthwhile because of the potential insights it offers into normal patterns of glycosylation and the ways in which they are altered during development or in genetic diseases or cancer. Current methods of characterizing the whole carbohydrate complement of cells depend heavily on sophisticated application of mass spectroscopy (see Fig. 7–37).

The structures of a large number of *O* - and *N*-linked oligosaccharides from a variety of glycoproteins are known; Figure 7–29 shows a few typical examples. We consider the mechanisms by which specific proteins acquire specific oligosaccharide moieties in Chapter 27.

Many of the proteins secreted by eukaryotic cells are glycoproteins, including most of the proteins of blood. For example, immunoglobulins (antibodies) and certain hormones, such as follicle-stimulating hormone, luteinizing hormone, and thyroid-stimulating hormone, are glycoproteins. Many milk proteins, including lactalbumin, and some of the proteins secreted by the pancreas (such as ribonuclease) are glycosylated, as are most of the proteins contained in lysosomes.

The biological advantages of adding oligosaccharides to proteins are slowly being uncovered. The very hydrophilic clusters of carbohydrate alter the polarity and solubility of the proteins with which they are conjugated. Oligosaccharide chains that are attached to newly synthesized proteins in the endoplasmic reticulum (ER) and elaborated in the Golgi complex serve as destination labels and also act in protein quality control, targeting misfolded proteins for degradation (see Fig. 27–39). When numerous negatively charged oligosaccharide chains are clustered in a single region of a protein, the charge repulsion among them favors the formation of an extended, rodlike structure in that region. The bulkiness and negative charge of oligosaccharide chains also protect some proteins from attack by proteolytic enzymes. Beyond these global physical effects on protein structure, there are also more specific biological effects of oligosaccharide chains in glycoproteins (Section 7.4). The importance of normal protein glycosylation is clear from the finding of at least 18 different genetic disorders of glycosylation in humans, all causing severely defective physical or mental development; some of these disorders are fatal.

**Glycolipids and Lipopolysaccharides Are Membrane Components**

Glycoproteins are not the only cellular components that bear complex oligosaccharide chains; some lipids, too, have covalently bound oligosaccharides. **Gangliosides** are membrane lipids of eukaryotic cells in which the polar head group, the part of the lipid that forms the outer surface of the membrane, is a complex oligosaccharide containing a sialic acid (Fig. 7–9) and other monosaccharide residues. Some of the oligosaccharide moieties of gangliosides, such as those that determine human blood groups (see Fig. 10–15), are identical with those found in certain glycoproteins, which therefore also contribute to blood group type. Like the oligosaccharide moieties of glycoproteins, those of membrane lipids are generally, perhaps always, found on the outer face of the plasma membrane.

**Lipopolysaccharides** are the dominant surface feature of the outer membrane of gram-negative bacteria such as *Escherichia coli* and *Salmonella typhimurium*. These molecules are prime targets of the antibodies produced by the vertebrate immune system in response to bacterial infection and are therefore
7.4 Carbohydrates as Informational Molecules: The Sugar Code

SUMMARY 7.3 Glycoconjugates: Proteoglycans, Glycoproteins, and Glycolipids

- Proteoglycans are glycoconjugates in which one or more large glycans, called sulfated glycosaminoglycans (heparan sulfate, chondroitin sulfate, dermatan sulfate, or keratan sulfate) are covalently attached to a core protein. Bound to the outside of the plasma membrane by a transmembrane peptide or a covalently attached lipid, proteoglycans provide points of adhesion, recognition, and information transfer between cells, or between the cell and the extracellular matrix.

- Glycoproteins contain oligosaccharides covalently linked to Asp or Ser/Thr residues. The glycans are typically branched and smaller than glycosaminoglycans. Many cell surface or extracellular proteins are glycoproteins, as are most secreted proteins. The covalently attached oligosaccharides influence the folding and stability of the proteins, provide critical information about the targeting of newly synthesized proteins, and allow for specific recognition by other proteins.

- Glycomics is the determination of the full complement of sugar-containing molecules in a cell or tissue, and the determination of the function of each such molecule.

- Glycolipids in plants and animals and lipopolysaccharides in bacteria are components of the cell envelope with covalently attached oligosaccharide chains exposed on the cell's outer surface.

7.4 Carbohydrates as Informational Molecules: The Sugar Code

Glycobiology, the study of the structure and function of glycoconjugates, is one of the most active and exciting areas of biochemistry and cell biology. As is becoming increasingly clear, cells use specific oligosaccharides to encode important information about intracellular targeting of proteins, cell-cell interactions, cell differentiation and tissue development, and extracellular signals. Our discussion uses just a few examples to illustrate the diversity of structure and the range of biological activity of the glycoconjugates. In Chapter 20 we discuss the biosynthesis of polysaccharides, including peptidoglycan; and in Chapter 27, the assembly of oligosaccharide chains on glycoproteins.

Improved methods for the analysis of oligosaccharide and polysaccharide structure have revealed remarkable complexity and diversity in the oligosaccharides of glycoproteins and glycolipids. Consider the oligosaccharide chains in Figure 7-29, typical of those found in many glycoproteins. The most complex of those shown...
contains 14 monosaccharide residues of four different kinds, variously linked as (1→2), (1→3), (1→4), (1→6), (2→3), and (2→6), some with the α and some with the β configuration. Branched structures, not found in nucleic acids or proteins, are common in oligosaccharides. With the reasonable assumption that 20 different monosaccharide subunits are available for construction of oligosaccharides, we can calculate that many billions of different hexameric oligosaccharides are possible; this compares with $6.4 \times 10^7$ ($20^6$) different hexapeptides possible with the 20 common amino acids, and 4,096 ($4^6$) different hexanucleotides with the four nucleotide subunits. If we also allow for variations in oligosaccharides resulting from sulfation of one or more residues, the number of possible oligosaccharides increases by two orders of magnitude. In reality, only a subset of possible combinations is found, given the restrictions imposed by the biosynthetic enzymes and the availability of precursors. Nevertheless, the enormously rich structural information in glycans does not merely rival but far surpasses that of nucleic acids in the density of information contained in a molecule of modest size. Each of the oligosaccharides represented in Figure 7–29 presents a unique, three-dimensional face—a word in the sugar code—readable by the proteins that interact with it.

**Lectins Are Proteins That Read the Sugar Code and Mediate Many Biological Processes**

Lectins, found in all organisms, are proteins that bind carbohydrates with high specificity and with moderate to high affinity (Table 7–3). Lectins serve in a wide variety of cell-cell recognition, signaling, and adhesion processes and in intracellular targeting of newly synthesized proteins. Plant lectins, abundant in seeds, probably serve as deterrents to insects and other predators. In the laboratory, purified plant lectins are useful reagents for detecting and separating glycans and glycoproteins with different oligosaccharide moieties. Here we discuss just a few examples of the roles of lectins in animal cells.

Some peptide hormones that circulate in the blood have oligosaccharide moieties that strongly influence their circulatory half-life. Luteinizing hormone and thyrotropin (polypeptide hormones produced in the adrenal cortex) have N-linked oligosaccharides that end with the disaccharide GalNAc4S(β1→4)GlcNAc, which is recognized by a lectin (receptor) of hepatocytes. (GalNAc4S is N-acetylgalactosamine sulfated on the –OH group at C-4.) Receptor-hormone interaction mediates the uptake and destruction of luteinizing hormone and thyrotropin, reducing their concentration in the blood. Thus the blood levels of these hormones undergo a periodic rise (due to pulsatile secretion by the adrenal cortex) and fall (due to continual destruction by hepatocytes).

The residues of Neu5Ac (a sialic acid) situated at the ends of the oligosaccharide chains of many plasma glycoproteins (Fig. 7–29) protect those proteins from uptake and degradation in the liver. For example, ceruloplasmin, a copper-containing serum glycoprotein, has several oligosaccharide chains ending in Neu5Ac. The mechanism that removes sialic acid residues from serum glycoproteins is unclear. It may be due to the activity of the enzyme sialidase (also called neuraminidase) produced by invading organisms or to a steady, slow release by extracellular enzymes. The plasma membrane of hepatocytes has lectin molecules (asialoglycoprotein receptors; “asialo-” indicating “without sialic acid”) that specifically bind oligosaccharide chains with galactose residues no longer “protected” by a terminal Neu5Ac.

\]

A similar mechanism is apparently responsible for removing “old” erythrocytes from the mammalian bloodstream. Newly synthesized erythrocytes have several membrane glycoproteins with oligosaccharide chains that end in Neu5Ac. When the sialic acid residues are removed by withdrawing a sample of blood from experimental animals, treating it with sialidase in vitro, and reintroducing it into the circulation, the treated erythrocytes disappear from the bloodstream within a few hours; erythrocytes with intact oligosaccharides (withdrawn and reintroduced without sialidase treatment) continue to circulate for days.

Cell surface lectins are important in the development of some human diseases—both human lectins and the lectins of infectious agents. Selectins are a family of plasma membrane lectins that mediate cell-cell recognition and adhesion in a wide range of cellular processes. One such process is the movement of immune cells (neutrophils) through the capillary wall, from blood to tissues, at sites of infection or inflammation (Fig. 7-31). At an infection site, P-selectin on the surface of capillary endothelial cells interacts with a specific oligosaccharide of the glycoproteins of circulating neutrophils. This interaction slows the neutrophils as they adhere to and roll along the endothelial lining of the capillaries. A second interaction, between integrin molecules (p. 455) in the neutrophil plasma membrane and an adhesion protein on the endothelial cell surface, now stops the neutrophil and allows it to move through the capillary wall into the infected tissues to initiate the immune attack. Two other selectins participate in this “lymphocyte homing”: E-selectin on the endothelial cell and L-selectin on the neutrophil bind their cognate oligosaccharides on the neutrophil and endothelial cell, respectively.

Selectins mediate the inflammatory responses in rheumatoid arthritis, asthma, psoriasis, multiple sclerosis, and the rejection of transplanted organs, and thus there is great interest in developing drugs that inhibit selectin-mediated cell adhesion. Many carcinomas express an antigen normally present only in fetal cells (sialyl Lewis x, or sialyl Le\(^x\)) that, when shed into the circulation, facilitates tumor cell survival and metastasis. Carbohydrate derivatives that mimic the sialyl Le\(^x\) portion of sialoglycoproteins or that alter the biosynthesis of the oligosaccharide might prove effective as selectin-specific drugs for treating chronic inflammation or metastatic disease.

Several animal viruses, including the influenza virus, attach to their host cells through interactions with oligosaccharides displayed on the host cell surface. The lectin of the influenza virus, known as the HA (hemagglutinin) protein, is essential for viral entry and infection. After the virus has entered a host cell and has been replicated, the newly synthesized viral particles bud out of the cell, wrapped in a portion of its plasma membrane. A viral sialidase (neuraminidase) trims the terminal sialic acid residue from the host cell’s oligosaccharides, releasing the viral particles from their interaction with the cell and preventing their aggregation with one another. Another round of infection can now begin. The antiviral drugs oseltamivir (Tamiflu) and zanamivir (Relenza) (next page) are used clinically in the treatment of influenza. These drugs are sugar analogs; they inhibit the viral sialidase by competing with the host cell’s oligosaccharides for binding. This prevents the release of viruses from the infected cell.
and also causes viral particles to aggregate, both of which block another cycle of infection.

Lectins on the surface of the herpes simplex viruses HSV-1 and HSV-2 (the causative agents of oral and genital herpes, respectively) bind specifically to heparan sulfate on the host cell surface as a first step in the infection cycle; infection requires precisely the right pattern of sulfation on this polymer. Analogs of heparan sulfate that mimic its interaction with the viruses are being investigated as possible antiviral drugs, interfering with interactions between virus and cell.

Some microbial pathogens have lectins that mediate bacterial adhesion to host cells or the entry of toxin into cells. For example, Helicobacter pylori—shown by Barry J. Marshall and J. Robin Warren in the 1980s to be responsible for most gastric ulcers—adheres to the inner surface of the stomach as bacterial membrane lectins interact with specific oligosaccharides of membrane glycoproteins of the gastric epithelial cells (Fig. 7-32). Among the binding sites recognized by H. pylori is the oligosaccharide Lewis b (Le\(^b\)), when it is part of the type O blood group determinant. This observation helps to explain the severalfold greater incidence of gastric ulcers in people of blood type O than in those of type A or B. Chemically synthesized analogs of the Le\(^b\) oligosaccharide may prove useful in treating this type of ulcer. Administered orally, they could prevent bacterial adhesion (and thus infection) by competing with the gastric glycoproteins for binding to the bacterial lectin.

Some of the most devastating of the human parasitic diseases, widespread in much of the developing world, are caused by eukaryotic microorganisms that display unusual surface oligosaccharides, which in some cases are known to be protective for the parasites. These organisms include the trypanosomes, responsible for African sleeping sickness and Chagas disease; Plasmodium falciparum, the malaria parasite; and Entamoeba histolytica, the causative agent of amoebic dysentery. The prospect of finding drugs that interfere with the synthesis of these unusual oligosaccharide chains, and therefore with the replication of the parasites, has inspired much recent work on the biosynthetic pathways of these oligosaccharides.

The cholera toxin molecule (produced by the bacterium Vibrio cholerae) triggers diarrhea after entering intestinal cells responsible for water absorption from the intestine. The toxin attaches to its target cell through the oligosaccharide moiety of ganglioside GM1, a membrane phospholipid (for the structure of GM1 see Box 10-2, Fig. 1), on the surface of intestinal epithelial cells. Similarly, the pertussis toxin produced by Bordetella pertussis, the bacterium that causes whooping cough, enters target cells only after interacting with a host cell oligosaccharide (or perhaps several oligosaccharides) bearing a terminal sialic acid residue. Understanding the details of the oligosaccharide-binding sites of these toxins (lectins) may allow the development of genetically engineered toxin analogs for use in vaccines. Toxin analogs engineered to lack the carbohydrate binding site would be harmless because they could not bind to and enter cells, but they might elicit an immune response that would protect against later exposure to the natural toxin. It is also possible to imagine drugs that would act by mimicking cell surface oligosaccharides, binding to the bacterial lectins or toxins and preventing their productive binding to cell surfaces.

Lectins also act intracellularly. An oligosaccharide containing mannose 6-phosphate marks newly synthesized proteins in the Golgi complex for transfer to the lysosome (see Fig. 27-39). A common structural feature on the surface of these glycoproteins, the signal patch, is recognized by an enzyme that phosphorylates (in a two-step process) a mannose residue at the terminus of an oligosaccharide chain. The resulting mannose 6-phosphate residue is then recognized by the cation-dependent mannose 6-phosphate receptor, a membrane-
associated lectin with its mannose phosphate binding site on the luminal side of the Golgi complex. When a section of the Golgi complex containing this receptor buds off to form a transport vesicle, proteins containing mannose phosphate residues are dragged into the forming bud by interaction of their mannose phosphates with the receptor; the vesicle then moves to and fuses with a lysosome, depositing its cargo therein. Many, perhaps all, of the degradative enzymes (hydrolases) of the lysosome are targeted and delivered by this mechanism. Some of the mannose 6-phosphate receptors can capture enzymes containing the mannose 6-phosphate residue and direct them to the lysosome. This process is the basis for "enzyme replacement therapy" to correct lysosomal storage disorders in humans.

Other lectins act in other kinds of protein sorting. Any newly synthesized protein in the endoplasmic reticulum already has a complex oligosaccharide attached, which can be bound by either of two ER lectins that are also chaperones: calnexin (membrane-bound) or calreticulin (soluble). These lectins link the new protein with an enzyme that brings about rapid disulfide exchange as the protein tries various ways to fold, leading eventually to the native conformation. At this point, enzymes in the ER trim the oligosaccharide moiety to a form recognized by another lectin, ERGIC53, which draws the folded protein (glycoprotein) into the Golgi complex for further maturation. If a protein has not folded effectively, the oligosaccharide is trimmed to another form, this one recognized by a lectin, EDEM, that initiates movement of the defectively folded protein into the cytosol, where it will be degraded. Thus, protein glycosylation serves in the ER as a kind of quality control signal, allowing the cell to eliminate improperly folded proteins. (This process is described in greater detail in Chapter 27.)

**Lectin-Carbohydrate Interactions Are Highly Specific and Often Polyvalent**

In all the functions of lectins described above, and in many more known to involve lectin-oligosaccharide interactions, it is essential that the oligosaccharide have a unique structure, so that recognition by the lectin is highly specific. The high density of information in oligosaccharides provides a sugar code with an essentially unlimited number of unique "words" small enough to be read by a single protein. In their carbohydrate-binding sites, lectins have a subtle molecular complementarity that allows interaction only with their correct carbohydrate cognates. The result is an extraordinarily high specificity in these interactions. The affinity between an oligosaccharide and each carbohydrate binding domain (CBD) of a lectin is sometimes modest (micromolar to millimolar $K_d$ values), but the effective affinity is in many cases greatly increased by lectin multivalency, in which a single lectin molecule has multiple CBDs. In a cluster of oligosaccharides—as is commonly found on a membrane surface, for example—each oligosaccharide can engage one of the lectin's CBDs, strengthening the interaction. When cells express multiple receptors, the avidity of the interaction can be very high, enabling highly cooperative events such as cell attachment and rolling (see Fig. 7-3I).

X-ray crystallographic studies of the structures of several lectin-carbohydrate complexes have provided rich details of the lectin-sugar interaction (Fig. 7-33). In humans, a family of 11 lectins that bind to oligosaccharide chains ending in sialic acid residues plays some important biological roles. All of these lectins bind sialic acids at $\beta$ sandwich domains like those found in immunoglobulins (Igs; see this motif in the CD8 protein in Fig. 4-21), and the proteins are therefore called siglecs 1 to 11 (sialic bonded to Arg$^{111}$ and coordinated with the manganese ion (shown smaller than its van der Waals radius for clarity). Each hydroxyl group of mannose is hydrogen-bonded to the protein. The His$^{105}$ hydroxyl-bonded to a phosphate oxygen of mannose 6-phosphate may be the residue that, when protonated at low pH, causes the receptor to release mannose 6-phosphate into the lysosome.

**FIGURE 7-33** Details of a lectin-carbohydrate interaction. Structure of the bovine mannose 6-phosphate receptor complexed with mannose 6-phosphate (PDB ID 1M6P). The protein is represented as a surface contour image, showing the surface as predominantly negatively charged (red) or positively charged (blue). Mannose 6-phosphate is shown as a stick structure; a manganese ion is shown in violet. (b) An enlarged view of the binding site. Mannose 6-phosphate is hydrogen-bonded to Arg$^{111}$ and coordinated with the manganese ion (shown smaller than its van der Waals radius for clarity). Each hydroxyl group of mannose is hydrogen-bonded to the protein. Carbohydrates and Glycobiology

acid-recognizing Ig-superfamily lectins), or sometimes sialoadhesins. The interaction of a siglec with sialic acid (Neu5Ac) involves each of the ring substituents unique to Neu5Ac: the acetyl group at C-5 undergoes both hydrogen-bond and van der Waals interactions with the protein; the carboxyl group makes a salt bridge with a conserved Arg residue; and the hydroxyls of the glycerol moieties hydrogen-bond with the protein. Siglec-7, for example, by binding to a specific ganglioside (GD3) containing two sialic acid residues, suppresses the activity of NK (natural killer) cells in the immune system, sparing cells targeted for immune destruction from the NK killing activity. The elevated GD3 levels in tumors such as malignant melanoma and neuroblastoma may be a mechanism for evading the protective action of the immune system.

The structure of the mannose 6-phosphate receptor/lectin reveals details of its interaction with mannose 6-phosphate that explain the specificity of the binding and the role for a divalent cation in the lectin-sugar interaction (Fig. 7-33a). His105 is hydrogen-bonded to one of the oxygen atoms of the phosphate (Fig. 7-33b).

When the protein tagged with mannose 6-phosphate reaches the lysosome (which has a lower internal pH than the Golgi complex), the receptor loses its affinity for mannose 6-phosphate. Protonation of His105 may be responsible for this change in binding.

In addition to these very specific interactions, there are more general interactions that contribute to the binding of many carbohydrates to their lectins. For example, many sugars have a more polar and a less polar side (Fig. 7-34); the more polar side hydrogen-bonds with the lectin, while the less polar side undergoes hydrophobic interactions with nonpolar amino acid residues. The sum of all these interactions produces high-affinity binding and high specificity of lectins for their carbohydrates. This represents a kind of information transfer that is clearly central in many processes within and between cells. Figure 7-35 summarizes some of the biological interactions mediated by the sugar code.
SUMMARY 7.4 Carbohydrates as Informational Molecules: The Sugar Code

- Monosaccharides can be assembled into an almost limitless variety of oligosaccharides, which differ in the stereochemistry and position of glycosidic bonds, the type and orientation of substituent groups, and the number and type of branches. Glycans are far more information-dense than nucleic acids or proteins.

- Lectins, proteins with highly specific carbohydrate-binding domains, are commonly found on the outer surface of cells, where they initiate interaction with other cells. In vertebrates, oligosaccharide tags “read” by lectins govern the rate of degradation of certain peptide hormones, circulating proteins, and blood cells.

- Bacterial and viral pathogens and some eukaryotic parasites adhere to their animal-cell targets by the binding of lectins in the pathogens to oligosaccharides on the target cell surface.

- Intracellular lectins mediate intracellular protein targeting to specific organelles or to the secretory pathway.

- X-ray crystallography of lectin-sugar complexes shows the detailed complementarity between the two molecules, which accounts for the strength and specificity of lectin interactions with carbohydrates.

7.5 Working with Carbohydrates

The growing appreciation of the importance of oligosaccharide structure in biological recognition has been the driving force behind the development of methods for analyzing the structure and stereochemistry of complex oligosaccharides. Oligosaccharide analysis is complicated by the fact that, unlike nucleic acids and proteins, oligosaccharides can be branched and are joined by a variety of linkages. The high charge density of many oligosaccharides and polysaccharides, and the relative lability of the sulfate esters in glycosaminoglycans, present further difficulties.

For simple, linear polymers such as amylose, the positions of the glycosidic bonds are determined by the classical method of exhaustive methylation: treating the intact polysaccharide with methyl iodide in a strongly basic medium to convert all free hydroxyls to acid-stable methyl ethers, then hydrolyzing the methylated polysaccharide in acid. The only free hydroxyls present in the monosaccharide derivatives so produced are those that were involved in the glycosidic bonds. To determine the sequence of monosaccharide residues, including any branches that are present, exoglycosidases of known specificity are used to remove residues one at a time from the nonreducing end(s). The known specificity of these exoglycosidases often allows deduction of the position and stereochemistry of the linkages.

For analysis of the oligosaccharide moieties of glycoproteins and glycolipids, the oligosaccharides are released by purified enzymes—glycosidases that specifically cleave O- or N-linked oligosaccharides or lipases that remove lipid head groups. Alternatively, O-linked glycans can be released from glycoproteins by treatment with hydrazine.

The resulting mixtures of carbohydrates are resolved into their individual components by a variety of methods (Fig. 7–36), including the same techniques used in protein and amino acid separation: fractional precipitation by solvents, and ion-exchange and size-exclusion chromatography (see Fig. 3–17). Highly purified lectins, attached covalently to an insoluble support, are commonly used in affinity chromatography of carbohydrates (see Fig. 3–17c).

Hydrolysis of oligosaccharides and polysaccharides in strong acid yields a mixture of monosaccharides, which may be identified and quantified by chromatographic techniques to yield the overall composition of the polymer.

Oligosaccharide analysis relies increasingly on mass spectrometry and high-resolution NMR spectroscopy. Matrix-assisted laser desorption/ionization mass spectrometry (MALDI MS) and tandem mass spectrometry (MS/MS), both described in Box 3–2, are readily applicable to polar compounds such as oligosaccharides. MALDI MS is a very sensitive method for determining the mass of a molecular ion (in this case, the entire oligosaccharide chain; Fig. 7–37). MS/MS reveals the mass of the molecular ion and many of its fragments, which are usually the result of breakage of the glycosidic bonds. NMR analysis alone (see Box 4–5), especially for oligosaccharides of moderate size, can yield much information about sequence, linkage position, and anomeric carbon configuration. For example, the structure of the heparin segment shown as a space-filling model in Figure 7–22 was obtained entirely by NMR spectroscopy. Automated procedures and commercial instruments are used for the routine determination of oligosaccharide structure, but the sequencing of branched oligosaccharides joined by more than one type of bond remains a far more formidable task than determining the linear sequences of proteins and nucleic acids.

Another important tool in working with carbohydrates is chemical synthesis, which has proved to be a powerful approach to understanding the biological functions of glycosaminoglycans and oligosaccharides. The chemistry involved in such syntheses is difficult, but carbohydrate chemists can now synthesize short segments of almost any glycosaminoglycan, with correct stereochemistry, chain length, and sulfation pattern, and oligosaccharides significantly more complex than those shown in Figure 7–29. Solid-phase oligosaccharide synthesis is based on the same principles (and has the same advantages) as peptide synthesis (see Fig. 3–29), but requires a set of tools unique to carbohydrate chemistry: blocking groups and activating groups that allow the synthesis of glycosidic linkages with the correct hydroxyl.
FIGURE 7-36 Methods of carbohydrate analysis. A carbohydrate purified in the first stage of the analysis often requires all four analytical routes for its complete characterization.

FIGURE 7-37 Separation and quantification of the oligosaccharides in a group of glycoproteins. In this experiment, the mixture of proteins extracted from kidney tissue was treated to release oligosaccharides from glycoproteins, and the oligosaccharides were analyzed by matrix-assisted laser desorption/ionization mass spectrometry (MALDI MS). Each distinct oligosaccharide produces a peak at its molecular mass, and the area under the curve reflects the quantity of that oligosaccharide. The most prominent oligosaccharide here (mass 2837.4 u) is composed of 13 sugar residues; in this sample, other oligosaccharides containing as few as 7 and as many as 19 residues are also resolved by this method.
group. Highly purified enzymes (glycosyltransferases) should greatly aid in the preparation of pure synthetic compounds. Synthetic approaches like this represent a current area of great interest since it is difficult to purify in adequate quantity defined oligosaccharides from natural sources. Glycan microarrays of defined oligosaccharides, analogous to the DNA arrays described in Chapter 9, can be probed with fluorescently tagged lectins to determine their binding specificity.

**SUMMARY 7.5  Working with Carbohydrates**

- Establishing the complete structure of oligosaccharides and polysaccharides requires determination of linear sequence, branching positions, the configuration of each monosaccharide unit, and the positions of the glycosidic linkages—a more complex problem than protein and nucleic acid analysis.

- The structures of oligosaccharides and polysaccharides are usually determined by a combination of methods: specific enzymatic hydrolysis to determine stereochemistry at the glycosidic bond and produce smaller fragments for further analysis; methylation to locate glycosidic bonds; and stepwise degradation to determine sequence and configuration of anomeric carbons.

- Mass spectrometry and high-resolution NMR spectroscopy, applicable to small samples of carbohydrate, yield essential information about sequence, configuration at anomeric and other carbons, and positions of glycosidic bonds.

- Solid-phase synthetic methods yield defined oligosaccharides that are of great value in exploring lectin-oligosaccharide interactions and may prove clinically useful.

**Key Terms**

Terms in bold are defined in the glossary.

- glycoconjugate 235
- monosaccharide 235
- oligosaccharide 235
- disaccharide 235
- polysaccharide 235
- allose 236
- ketose 236
- Fischer projection formulas 236
- epimer 238
- hemiacetal 238
- hemiketal 238
- pyranose 239
- furanose 239
- anomers 239
- anomic carbon 239
- mutarotation 239
- Haworth perspective formulas 239
- reducing sugar 241
- hemoglobin glycation 242
- glycosidic bonds 243
- reducing end 243
- glycan 244
- starch 245
- glycogen 246
- extracellular matrix (ECM) 249
- glycosaminoglycan 249
- hyaluronan 250
- chondroitin sulfate 250
- heparan sulfate 251
- proteoglycan 252
- glycoprotein 252
- glycolipid 252
- syndecan 253
- glypican 253
- glycomics 256
- lectin 258
- selectin 259
- siglec 261
- sialoadhesin 262

**Further Reading**

**General**

A comprehensive text at the graduate level.

Chapters 34 and 35 cover the structure, stereochemistry, nomenclature, and chemical reactions of carbohydrates.

Brief introduction to some very useful materials on carbohydrate structure, synthesis, chemistry, and biology on the Internet.

Structure, biosynthesis, metabolism, and function of glycosaminoglycans, proteoglycans, glycoproteins, and glycolipids, all presented at an intermediate level and very well illustrated.

**Glycosaminoglycans and Proteoglycans**

Advanced review of recent studies on glycosaminoglycan defects in human disease and of the use of model organisms to study glycosaminoglycan biology.

Intermediate-level review.

Intermediate-level review.

Intermediate review of the use of chemically synthesized glycosaminoglycans in exploring the functions of these glycoconjugates.

Intermediate review of the roles of proteoglycans in development.

Brief, intermediate-level review of the possible role of glycosaminoglycans in directing the outgrowth of axons in the developing nervous system.

A review focusing on genetic and molecular biological studies of the matrix proteoglycans. The structure-function relationships of some paradigmatic proteoglycans are discussed in depth, and novel aspects of their biology are examined.

A masterful review of the history of carbohydrate and glycosaminoglycan studies, by one of the major contributors to this field.

Advanced review, including the methodology of glycosaminoglycan analysis.

Glycoproteins

Short, intermediate review of the consequences of genetic defects in glycoprotein synthesis.

Intermediate review of the medical consequences of defective protein glycosylation.

Short, intermediate-level review of the structures of parasite glycoprotein oligosaccharides.

Intermediate-level review, including both structure and biology.

Intermediate-level review of the biosynthetic process of protein glycosylation.

Glycobiology and the Sugar Code

Excellent review of the structural basis for the specificity of sugar-binding proteins.

How the oligosaccharides that determine blood type affect the adherence of Helicobacter pylori to the stomach lining.

Analogs of recognition oligosaccharides are used to block adhesion of a pathogen to its host-cell target.

Description of the basis for the high information density in oligosaccharides, with examples of the importance of the sugar code.

This review examines the reasons for the relatively late appreciation of the informational roles of oligosaccharides and polysaccharides.

Intermediate-level review.

Evidence for roles of sulfated oligosaccharides in peptide hormone half-life, symbiotic interactions in nitrogen-fixing legumes, and lymphocyte homing.

Introduction to a series of papers on heparan sulfates published in the same issue of the journal; all are rewarding reading.

Intermediate-level review.

Introduction to a series of excellent reviews on lectins and their biological roles, all published in the same issue of the journal.

Intermediate-level review of the role of protein glycosylation in quality control in the endoplasmic reticulum.

Excellent review of the structural basis for the high information density in oligosaccharides, with examples of the importance of the sugar code.

Excellent review of the chemical diversity of oligosaccharides and polysaccharides and of biological processes dependent on protein-carbohydrate recognition.

Working with Carbohydrates

Problems

1. Sugar Alcohols In the monosaccharide derivatives known as sugar alcohols, the carbonyl oxygen is reduced to a hydroxyl group. For example, d-glyceraldeldehyde can be reduced to glycerol. However, this sugar alcohol is no longer designated D or L. Why?

2. Recognizing Epimers Using Figure 7–3, identify the epimers of (a) d-allose, (b) d-gulose, and (c) d-ribose at C-2, C-3, and C-4.

3. Melting Points of Monosaccharide Osazone Derivatives Many carbohydrates react with phenylhydrazine (C₆H₅NHNH₂) to form bright yellow crystalline derivatives known as osazones:

The melting temperatures of these derivatives are easily determined and are characteristic for each osazone. This information was used to help identify monosaccharides before the development of HPLC or gas-liquid chromatography. Listed below are the melting points (MPs) of some aldose-osazone derivatives:

<table>
<thead>
<tr>
<th>Monosaccharide</th>
<th>MP of anhydrous monosaccharide (°C)</th>
<th>MP of osazone derivative (°C)</th>
</tr>
</thead>
<tbody>
<tr>
<td>Glucose</td>
<td>146</td>
<td>205</td>
</tr>
<tr>
<td>Mannose</td>
<td>132</td>
<td>205</td>
</tr>
<tr>
<td>Galactose</td>
<td>165–168</td>
<td>201</td>
</tr>
<tr>
<td>Talose</td>
<td>128–130</td>
<td>201</td>
</tr>
</tbody>
</table>

As the table shows, certain pairs of derivatives have the same melting points, although the underivatized monosaccharides do not. Why do glucose and mannose, and similarly galactose and talose, form osazone derivatives with the same melting points?

4. Interconversion of D-Glucose Forms A solution of one enantiomer of a given monosaccharide rotates plane-polarized light to the left (counterclockwise) and is called the levorotatory isomer, designated (−); the other enantiomer rotates plane-polarized light to the same extent but to the right (clockwise) and is called the dextrorotatory isomer, designated (+). An equimolar mixture of the (+) and (−) forms does not rotate plane-polarized light.

The optical activity of a stereoisomer is expressed quantitatively by its optical rotation, the number of degrees by which plane-polarized light is rotated on passage through a given path length of a solution of the compound at a given concentration. The specific rotation [α]₀ of an optically active compound is defined thus:

\[ [\alpha]_0 = \frac{\text{observed optical rotation} (\degree)}{\text{optical path length (dm)} \times \text{concentration (g/mL)}} \]

The temperature (T) and the wavelength of the light (λ) employed (usually, as here, the D line of sodium, 589 nm) must be specified.

A freshly prepared solution of α-D-glucose shows a specific rotation of +112°. Over time, the rotation of the solution...
gradually decreases and reaches an equilibrium value corresponding to $[\alpha]_D^{20} = +52.5^\circ$. In contrast, a freshly prepared solution of $\beta$-D-glucose has a specific rotation of $+19^\circ$. The rotation of this solution increases over time to the same equilibrium value as that shown by the $\alpha$ anomer.

(a) Draw the Haworth perspective formulas of the $\alpha$ and $\beta$ forms of D-glucose. What feature distinguishes the two forms?

(b) Why does the specific rotation of a freshly prepared solution of the $\alpha$ form gradually decrease with time? Why do solutions of the $\alpha$ and $\beta$ forms reach the same specific rotation at equilibrium?

(c) Calculate the percentage of each of the two forms of D-glucose present at equilibrium.

5. Configuration and Conformation Which bond(s) in $\alpha$-D-glucose must be broken to change its configuration to $\beta$-D-glucose? Which bond(s) to convert $\alpha$-D-glucose to $\alpha$-mannose? Which bond(s) to convert one “chair” form of $\beta$-glucose to the other?

6. Deoxysugars Is $\beta$-2-deoxygalactose the same chemical as D-2-deoxyglucose? Explain.

7. Sugar Structures Describe the common structural features and the differences for each pair: (a) cellulose and glycogen; (b) D-glucose and D-fructose; (c) maltose and sucrose.

8. Reducing Sugars Draw the structural formula for $\alpha$-D-glucosyl-(1→6)-D-mannosamine and circle the part of this structure that makes the compound a reducing sugar.

9. Hemiacetal and Glycosidic Linkages Explain the difference between a hemiacetal and a glycoside.

10. A Taste of Honey The fructose in honey is mainly in the $\beta$-D-pyranose form. This is one of the sweetest carbohydrates known, about twice as sweet as glucose; the $\beta$-D-furanose form of fructose is much less sweet. The sweetness of honey gradually decreases at a high temperature. Also, high-fructose corn syrup (a commercial product in which much of the glucose in corn syrup is converted to fructose) is used for sweetening cold but not hot drinks. What chemical property of fructose could account for both these observations?

11. Reducing Disaccharide A disaccharide, which you know to be either maltose or sucrose, is treated with Fehling’s solution, and a red color is formed. Which sugar is it, and how do you know?

12. Glucose Oxidase in Determination of Blood Glucose The enzyme glucose oxidase isolated from the mold Penicillium notatum catalyzes the oxidation of $\beta$-D-glucose to D-glucono-6-lactone. This enzyme is highly specific for the $\beta$ anomer of glucose and does not affect the $\alpha$ anomer. In spite of this specificity, the reaction catalyzed by glucose oxidase is commonly used in a clinical assay for total blood glucose—that is, for solutions consisting of a mixture of $\beta$- and $\alpha$-D-glucose. What are the circumstances required to make this possible? Aside from allowing the detection of smaller quantities of glucose, what advantage does glucose oxidase offer over Fehling’s reagent for measuring blood glucose?

13. Invertase “Inverts” Sucrose The hydrolysis of sucrose (specific rotation $+66.5^\circ$) yields an equimolar mixture of $\alpha$-glucose (specific rotation $+52.5^\circ$) and $\beta$-fructose (specific rotation $-92^\circ$). (See Problem 4 for details of specific rotation.)

(a) Suggest a convenient way to determine the rate of hydrolysis of sucrose by an enzyme preparation extracted from the lining of the small intestine.

(b) Explain why, in the food industry, an equimolar mixture of $\alpha$-glucose and $\beta$-fructose formed by hydrolysis of sucrose is called invert sugar.

(c) The enzyme invertase (now commonly called sucrase) is allowed to act on a 10% (0.1 g/mL) solution of sucrose until hydrolysis is complete. What will be the observed optical rotation of the solution in a 10 cm cell? (Ignore a possible small contribution from the enzyme.)

14. Manufacture of Liquid-Filled Chocolates The manufacture of chocolates containing a liquid center is an interesting application of enzyme engineering. The flavored liquid center consists largely of an aqueous solution of sugars rich in fructose to provide sweetness. The technical dilemma is the following: the chocolate coating must be prepared by pouring hot melted chocolate over a solid (or almost solid) core, yet the final product must have a liquid, fructose-rich center. Suggest a way to solve this problem. (Hint: Sucrose is much less soluble than a mixture of glucose and fructose.)

15. Anomers of Sucrose? Lactose exists in two anomeric forms, but no anomeric forms of sucrose have been reported. Why?

16. Gentiobiose Gentiobiose (D-Glc(1→6)D-Glc) is a disaccharide found in some plant glycosides. Draw the structure of gentiobiose based on its abbreviated name. Is it a reducing sugar? Does it undergo mutarotation?

17. Identifying Reducing Sugars Is N-acetyl-$\beta$-D-glucosamine (Fig. 7–9) a reducing sugar? What about D-glucurate? Is the disaccharide GlcN(\(\alpha\)1→1\(\alpha\))Glc a reducing sugar?

18. Cellulose Digestion Cellulose could provide a widely available and cheap form of glucose, but humans cannot digest it. Why not? If you were offered a procedure that allowed you to acquire this ability, would you accept? Why or why not?

19. Physical Properties of Cellulose and Glycogen The almost pure cellulose obtained from the seed threads of Gossypium (cotton) is tough, fibrous, and completely insoluble in water. In contrast, glycogen obtained from muscle or liver disperses readily in hot water to make a turbid solution. Despite their markedly different physical properties, both substances are (1→4)-linked $\beta$-glucose polymers of comparable molecular weight. What structural features of these two polysaccharides underlie their different physical properties? Explain the biological advantages of their respective properties.

20. Dimensions of a Polysaccharide Compare the dimensions of a molecule of cellulose and a molecule of amylose, each of $\mathcal{M}_r$ 200,000.
21. Growth Rate of Bamboo The stems of bamboo, a tropical grass, can grow at the phenomenal rate of 0.3 m/day under optimal conditions. Given that the stems are composed almost entirely of cellulose fibers oriented in the direction of growth, calculate the number of sugar residues per second that must be added enzymatically to growing cellulose chains to account for the growth rate. Each D-glucose unit contributes ~0.5 nm to the length of a cellulose molecule.

22. Glycogen as Energy Storage: How Long Can a Game Bird Fly? Since ancient times it has been observed that certain game birds, such as grouse, quail, and pheasants, are easily fatigued. The Greek historian Xenophon wrote, "The bustards... can be caught if one is quick in starting them up, for they will fly only a short distance, like partridges, and soon tire; and their flesh is delicious." The flight muscles of game birds rely almost entirely on the use of glucose 1-phosphate for energy, in the form of ATP (Chapter 14). The glucose 1-phosphate is formed by the breakdown of stored muscle glycogen, catalyzed by the enzyme glycogen phosphorylase. The rate of ATP production is limited by the rate at which glycogen can be broken down. During a "panic flight," the game bird's rate of glycogen breakdown is quite high, approximately 120 μmol/min of glucose 1-phosphate produced per gram of fresh tissue. Given that the flight muscles usually contain about 0.35% glycogen by weight, calculate how long a game bird can fly. (Assume the average molecular weight of a glucose residue in glycogen is 162 g/mol.)

23. Relative Stability of Two Conformers Explain why the two structures shown in Figure 7–19 are so different in energy (stability). Hint: See Figure 1–21.

24. Volume of Chondroitin Sulfate in Solution One critical function of chondroitin sulfate is to act as a lubricant in skeletal joints by creating a gel-like medium that is resilient to friction and shock. This function seems to be related to a distinctive property of chondroitin sulfate: the volume occupied by the molecule is much greater in solution than in the dehydrated solid. Why is the volume so much larger in solution?

25. Heparin Interactions Heparin, a highly negatively charged glycosaminoglycan, is used clinically as an anticoagulant. It acts by binding several plasma proteins, including antithrombin III, an inhibitor of blood clotting. The 1:1 binding of heparin to antithrombin III seems to cause a conformational change in the protein that greatly increases its ability to inhibit clotting. What amino acid residues of antithrombin III are likely to interact with heparin?

26. Permutations of a Trisaccharide Think about how one might estimate the number of possible trisaccharides composed of N-acetylglucosamine 4-sulfate (GlcNAc4S) and glucuronic acid (GlcA), and draw 10 of them.

27. Effect of Sialic Acid on SDS Polyacrylamide Gel Electrophoresis Suppose you have four forms of a protein, all with identical amino acid sequence but containing zero, one, two, or three oligosaccharide chains, each ending in a single sialic acid residue. Draw the gel pattern you would expect when a mixture of these four glycoproteins is subjected to SDS polyacrylamide gel electrophoresis (see Fig. 3–18) and stained for protein. Identify any bands in your drawing.

28. Information Content of Oligosaccharides The carbohydrate portion of some glycoproteins may serve as a cellular recognition site. To perform this function, the oligosaccharide moiety must have the potential to exist in a large variety of forms. Which can produce a greater variety of structures: oligopeptides composed of five different amino acid residues or oligosaccharides composed of five different monosaccharide residues? Explain.

29. Determination of the Extent of Branching in Amylopectin The amount of branching (number of (α1→6) glycosidic bonds) in amylopectin can be determined by the following procedure. A sample of amylopectin is exhaustively methylated—treated with a methylating agent (methyl iodide) that replaces the hydrogen of every sugar hydroxyl with a methyl group, converting —OH to —OCH₃. All the glycosidic bonds in the treated sample are then hydrolyzed in aqueous acid, and the amount of 2,3-di-O-methylglucose so formed is determined.

(a) Explain the basis of this procedure for determining the number of (α1→6) branch points in amylopectin. What happens to the unbranched glucose residues in amylopectin during the methylation and hydrolysis procedure?

(b) A 258 mg sample of amylopectin treated as described above yielded 12.4 mg of 2,3-di-O-methylglucose. Determine what percentage of the glucose residues in the amylopectin contained an (α1→6) branch. (Assume that the average molecular weight of a glucose residue in amylopectin is 162 g/mol.)

30. Structural Analysis of a Polysaccharide A polysaccharide of unknown structure was isolated, subjected to exhaustive methylation, and hydrolyzed. Analysis of the products revealed three methylated sugars: 2,3,4-tri-O-methyl-o-glucose, 2,4-di-O-methyl-o-glucose, and 2,3,4,6-tetra-O-methyl-d-glucose, in the ratio 20:1:1. What is the structure of the polysaccharide?

31. Determining the Structure of ABO Blood Group Antigens The human ABO blood group system was first discovered in 1901, and in 1924 this trait was shown to be inherited at a single gene locus with three alleles. In 1960, W. T. J. Morgan published a paper summarizing what was known at that time about the structure of the ABO antigen molecules. When the paper was published, the complete structures of the A, B, and O
antigens were not yet known; this paper is an example of what scientific knowledge looks like "in the making."

In any attempt to determine the structure of an unknown biological compound, researchers must deal with two fundamental problems: (1) If you don’t know what it is, how do you know if it is pure? (2) If you don’t know what it is, how do you know that your extraction and purification conditions have not changed its structure? Morgan addressed problem 1 through several methods. One method is described in his paper as observing “constant analytical values after fractional solubility tests” (p. 312). In this case, “analytical values” are measurements of chemical composition, melting point, and so forth.

(a) Based on your understanding of chemical techniques, what could Morgan mean by “fractional solubility tests”?

(b) Why would the analytical values obtained from fractional solubility tests of a pure substance be constant, and those of an impure substance not be constant?

Morgan addressed problem 2 by using an assay to measure the immunological activity of the substance present in different samples.

(c) Why was it important for Morgan’s studies, and especially for addressing problem 2, that this activity assay be quantitative (measuring a level of activity) rather than simply qualitative (measuring only the presence or absence of a substance)?

The structure of the blood group antigens is shown in Figure 10–15. In his paper (p. 314), Morgan listed several properties of the three antigens, A, B, and O, that were known at that time:

1. Type B antigen has a higher content of galactose than A or O.
2. Type A antigen contains more total amino sugars than B or O.
3. The glucosamine/galactosamine ratio for the A antigen is roughly 1.2; for B, it is roughly 2.5.

(d) Which of these findings is (are) consistent with the known structures of the blood group antigens?

(e) How do you explain the discrepancies between Morgan’s data and the known structures?

In later work, Morgan and his colleagues used a clever technique to obtain structural information about the blood group antigens. Enzymes had been found that would specifically degrade the antigens. However, these were available only as crude enzyme preparations, perhaps containing more than one enzyme of unknown specificity. Degradation of the blood type antigens by these crude enzymes could be inhibited by the addition of particular sugar molecules to the reaction. Only sugars found in the blood type antigens would cause this inhibition. One enzyme preparation, isolated from the protozoan Trichomonas foetus, would degrade all three antigens and was inhibited by the addition of particular sugars. The results of these studies are summarized in the table below, showing the percentage of substrate remaining unchanged when the T. foetus enzyme acted on the blood group antigens in the presence of sugars.

For the O antigen, a comparison of the control and L-fucose results shows that L-fucose inhibits the degradation of the antigen. This is an example of product inhibition, in which an excess of reaction product shifts the equilibrium of the reaction, preventing further breakdown of substrate.

(f) Although the O antigen contains galactose, N-acetylglucosamine, and N-acetylgalactosamine, none of these sugars inhibited the degradation of this antigen. Based on these data, is the enzyme preparation from T. foetus an endo- or exoglycosidase? (Endoglycosidases cut bonds between interior residues; exoglycosidases remove one residue at a time from the end of a polymer.) Explain your reasoning.

(g) Fucose is also present in the A and B antigens. Based on the structure of these antigens, why does fucose fail to prevent their degradation by the T. foetus enzyme? What structure would be produced?

(h) Which of the results in (f) and (g) are consistent with the structures shown in Figure 10–15? Explain your reasoning.

Reference
Nucleotides have a variety of roles in cellular metabolism. They are the energy currency in metabolic transactions, the essential chemical links in the response of cells to hormones and other extracellular stimuli, and the structural components of an array of enzyme cofactors and metabolic intermediates. And, last but certainly not least, they are the constituents of nucleic acids: deoxyribonucleic acid (DNA) and ribonucleic acid (RNA), the molecular repositories of genetic information. The structure of every protein, and ultimately of every biomolecule and cellular component, is a product of information programmed into the nucleotide sequence of a cell’s nucleic acids. The ability to store and transmit genetic information from one generation to the next is a fundamental condition for life.

This chapter provides an overview of the chemical nature of the nucleotides and nucleic acids found in most cells; a more detailed examination of the function of nucleic acids is the focus of Part III of this text.

8.1 Some Basics

Nucleotides, Building Blocks of Nucleic Acids

The amino acid sequence of every protein in a cell, and the nucleotide sequence of every RNA, is specified by a nucleotide sequence in the cell’s DNA. A segment of a DNA molecule that contains the information required for the synthesis of a functional biological product, whether protein or RNA, is referred to as a gene. A cell typically has many thousands of genes, and DNA molecules, not surprisingly, tend to be very large. The storage and transmission of biological information are the only known functions of DNA.

RNAs have a broader range of functions, and several classes are found in cells. Ribosomal RNAs (rRNAs) are components of ribosomes, the complexes that carry out the synthesis of proteins. Messenger RNAs (mRNAs) are intermediaries, carrying genetic information from one or a few genes to a ribosome, where the corresponding proteins can be synthesized. Transfer RNAs (tRNAs) are adapter molecules that faithfully translate the information in mRNA into a specific sequence of amino acids. In addition to these major classes there is a wide variety of RNAs with special functions, described in depth in Part III.

Nucleotides and Nucleic Acids Have Characteristic Bases and Pentoses

Nucleotides have three characteristic components: (1) a nitrogenous (nitrogen-containing) base, (2) a pentose, and (3) a phosphate (Fig. 8–1). The molecule

![FIGURE 8–1 Structure of nucleotides. (a) General structure showing the numbering convention for the pentose ring. This is a ribonucleotide. In deoxyribonucleotides the —OH group on the 2’ carbon (in red) is replaced with —H. (b) The parent compounds of the pyrimidine and purine bases of nucleotides and nucleic acids, showing the numbering conventions.](image)
without the phosphate group is called a **nucleoside**. The nitrogenous bases are derivatives of two parent compounds, **pyrimidine** and **purine**. The bases and pentoses of the common nucleotides are heterocyclic compounds.

**KEY CONVENTION:** The carbon and nitrogen atoms in the parent structures are conventionally numbered to facilitate the naming and identification of the many derivative compounds. The convention for the pentose ring follows rules outlined in Chapter 7, but in the pentoses of nucleotides and nucleosides the carbon numbers are given a prime (') designation to distinguish them from the numbered atoms of the nitrogenous bases.

The base of a nucleotide is joined covalently (at N-1 of pyrimidines and N-9 of purines) in an N-β-glycosyl bond to the 1' carbon of the pentose, and the phosphate is esterified to the 5' carbon. The N-β-glycosyl bond is formed by removal of the elements of water (a hydroxyl group from the pentose and hydrogen from the base), as in O-glycosidic bond formation (see Fig. 7–29).

Both DNA and RNA contain two major purine bases, **adenine** (A) and **guanine** (G), and two major pyrimidines. In both DNA and RNA one of the pyrimidines is **cytosine** (C), but the second major pyrimidine is not the same in both: it is **thymine** (T) in DNA and **uracil** (U) in RNA. Only rarely does thymine occur in RNA or uracil in DNA. The structures of the five major bases are shown in Figure 8–2, and the nomenclature of their corresponding nucleotides and nucleosides is summarized in Table 8–1.

Nucleic acids have two kinds of pentoses. The recurring deoxyribonucleotide units of DNA contain 2'-deoxy-D-ribose, and the ribonucleotide units of RNA contain D-ribose. In nucleotides, both types of pentoses are in their β-furanose (closed five-membered ring) form. As Figure 8–3 shows, the pentose ring is not planar but occurs in one of a variety of conformations generally described as “puckered.”

**KEY CONVENTION:** Although DNA and RNA seem to have two distinctions—different pentoses and the presence of uracil in RNA and thymine in DNA—it is the pentoses that define the identity of a nucleic acid. If the nucleic acid contains 2'-deoxy-D-ribose, it is DNA by definition even though it may contain some uracil. Similarly, if the nucleic acid contains D-ribose, it is RNA regardless of its base composition.

*Note: “Nucleoside” and “nucleotide” are generic terms that include both ribo- and deoxyribo- forms. Also, ribonucleosides and ribonucleotides are here designated simply as nucleosides and nucleotides (e.g., riboadenosine as adenosine), and deoxyribonucleosides and deoxyribonucleotides as deoxyribonucleosides and deoxyribonucleotides (e.g., deoxyriboadenosine as deoxyadenosine). Both forms of naming are acceptable, but the shortened names are more commonly used. Thymine is an exception; “ribothymidine” is used to describe its unusual occurrence in RNA.*
**Figure 8-3** Conformations of ribose. (a) In solution, the straight-chain (aldehyde) and ring (β-furanose) forms of free ribose are in equilibrium. RNA contains only the ring form, β-β-ribofuranose. Deoxyribose undergoes a similar interconversion in solution, but in DNA exists solely as β-2′-deoxy-β-ribofuranose. (b) Ribofuranose rings in nucleotides can exist in four different puckered conformations. In all cases, four of the five atoms are in a single plane. The fifth atom (C-2′ or C-3′) is on either the same (endo) or the opposite (exo) side of the plane relative to the C-5′ atom.

**Figure 8-4** gives the structures and names of the four major deoxyribonucleotides (deoxyribonucleoside 5′-monophosphates), the structural units of DNAs, and the four major ribonucleotides (ribonucleoside 5′-monophosphates), the structural units of RNAs.

All nucleotides are shown in their free form at pH 7.0. The nucleotide units of DNA (a) are usually symbolized as A, G, T, and C, sometimes as dA, dG, dT, and dC; those of RNA (b) as A, G, U, and C. In their free form the deoxyribonucleotides are commonly abbreviated dAMP, dGMP, dTMP, and dCMP; the ribonucleotides, AMP, GMP, UMP, and CMP. For each nucleotide, the more common name is followed by the complete name in parentheses. All abbreviations assume that the phosphate group is at the 5′ position. The nucleoside portion of each molecule is shaded in pink. In this and the following illustrations, the ring carbons are not shown.
Figure 8-5 Some minor purine and pyrimidine bases, shown as the nucleosides. (a) Minor bases of DNA. 5-Methylcytidine occurs in the DNA of animals and higher plants, \( N^\beta \)-methyladenosine in bacterial DNA, and 5-hydroxymethylcytidine in the DNA of bacteria infected with certain bacteriophages. (b) Some minor bases of tRNAs. Inosine contains the base hypoxanthine. Note that pseudouridine, like uridine, contains uracil; they are distinct in the point of attachment to the ribose—in uridine, uracil is attached through N-1, the usual attachment point for pyrimidines; in pseudouridine, through C-5.

Although nucleotides bearing the major purines and pyrimidines are most common, both DNA and RNA also contain some minor bases (Fig. 8-5). In DNA the most common of these are methylated forms of the major bases; in some viral DNAs, certain bases may be hydroxymethylated or glucosylated. Altered or unusual bases in DNA molecules often have roles in regulating or protecting the genetic information. Minor bases of many types are also found in RNAs, especially in tRNAs (see Fig. 8-25 and Fig. 26-23).

**KEY CONVENTION:** The nomenclature for the minor bases can be confusing. Like the major bases, many have common names—hypoxanthine, for example, shown as its nucleoside inosine in Figure 8-5. When an atom in the purine or pyrimidine ring is substituted, the usual convention (used here) is simply to indicate the ring position of the substituent by its number—for example, 5-methylcytosine, 7-methylguanine, and 5-hydroxymethylcytosine (shown as the nucleosides in Fig. 8-5). The element to which the substituent is attached (N, C, O) is not identified. The convention changes when the substituted atom is exocyclic (not within the ring structure), in which case the type of atom is identified and the ring position to which it is attached is denoted with a superscript. The amino nitrogen attached to C-6 of adenine is \( N^\alpha \); similarly, the carbonyl oxygen and amino nitrogen at C-6 and C-2 of guanine are \( O^\beta \) and \( N^\beta \), respectively. Examples of this nomenclature are \( N^\beta \)-methyladenosine and \( N^\alpha \)-methylguanosine (Fig. 8-5). 

Cells also contain nucleotides with phosphate groups in positions other than on the 5' carbon (Fig. 8-6). **Ribonucleoside 2',3'-cyclic monophosphates** are isolatable intermediates, and **ribonucleoside 3'-monophosphates** are end products of the hydrolysis of RNA by certain ribonucleases. Other variations are adenosine 3',5'-cyclic monophosphate (cAMP) and guanosine 3',5'-cyclic monophosphate (cGMP), considered at the end of this chapter.

**Phosphodiester Bonds Link Successive Nucleotides in Nucleic Acids**

The successive nucleotides of both DNA and RNA are covalently linked through phosphate-group "bridges," in
which the 5'-phosphate group of one nucleotide unit is joined to the 3'-hydroxyl group of the next nucleotide, creating a **phosphodiester linkage** (Fig. 8–7). Thus the covalent backbones of nucleic acids consist of alternating phosphate and pentose residues, and the nitrogenous bases may be regarded as side groups joined to the backbone at regular intervals. The backbones of both DNA and RNA are hydrophilic. The hydroxyl groups of the sugar residues form hydrogen bonds with water. The phosphate groups, with a $pK_a$ near 0, are completely ionized and negatively charged at pH 7, and the negative charges are generally neutralized by ionic interactions with positive charges on proteins, metal ions, and polyamines.

**KEY CONVENTION:** All the phosphodiester linkages in DNA and RNA have the same orientation along the chain (Fig. 8–7), giving each linear nucleic acid strand a specific polarity and distinct 5' and 3' ends. By definition, the **5' end** lacks a nucleotide at the 5' position and the **3' end** lacks a nucleotide at the 3' position. Other groups (most often one or more phosphates) may be present on one or both ends. The 5' to 3' orientation of a strand of nucleic acid refers to the ends of the strand, not the orientation of the individual phosphodiester bonds linking its constituent nucleotides.

The covalent backbone of DNA and RNA is subject to slow, nonenzymatic hydrolysis of the phosphodiester bonds. In the test tube, RNA is hydrolyzed rapidly under alkaline conditions, but DNA is not; the 2'-hydroxyl groups in RNA (absent in DNA) are directly involved in the process. Cyclic 2',3'-monophosphate nucleotides are the first products of the action of alkali on RNA and are rapidly hydrolyzed further to yield a mixture of 2'- and 3'-nucleoside monophosphates (Fig. 8–8).

**FIGURE 8–7** Phosphodiester linkages in the covalent backbone of DNA and RNA. The phosphodiester bonds (one of which is shaded in the DNA) link successive nucleotide units. The backbone of alternating pentose and phosphate groups in both types of nucleic acid is highly polar. The 5' end of the macromolecule lacks a nucleotide at the 5' position, and the 3' end lacks a nucleotide at the 3' position.

**FIGURE 8–8** Hydrolysis of RNA under alkaline conditions. The 2' hydroxyl acts as a nucleophile in an intramolecular displacement. The 2',3'-cyclic monophosphate derivative is further hydrolyzed to a mixture of 2'- and 3'-monophosphates. DNA, which lacks 2' hydroxyls, is stable under similar conditions.
The nucleotide sequences of nucleic acids can be represented schematically, as illustrated below by a segment of DNA with five nucleotide units. The phosphate groups are symbolized by $\mathbb{P}$, and each deoxyribose is symbolized by a vertical line, from C-1' at the top to C-5' at the bottom (but keep in mind that the sugar is always in its closed-ring $\beta$-furanose form in nucleic acids). The connecting lines between nucleotides (which pass through $\mathbb{P}$) are drawn diagonally from the middle (C-3') of the deoxyribose of one nucleotide to the bottom (C-5') of the next.

Some simpler representations of this pentadeoxyribonucleotide are $\text{pA-C-G-T-ASH}$, $\text{pApCpGpTpA}$, and $\text{pACGTA}$.

**KEY CONVENTION:** The sequence of a single strand of nucleic acid is always written with the 5' end at the left and the 3' end at the right—that is, in the 5' → 3' direction.

A short nucleic acid is referred to as an oligonucleotide. The definition of "short" is somewhat arbitrary, but polymers containing 50 or fewer nucleotides are generally called oligonucleotides. A longer nucleic acid is called a polynucleotide.

The Properties of Nucleotide Bases Affect the Three-Dimensional Structure of Nucleic Acids

Free pyrimidines and purines are weakly basic compounds and thus are called bases. The purines and pyrimidines common in DNA and RNA are aromatic molecules (Fig. 8–2), a property with important consequences for the structure, electron distribution, and light absorption of nucleic acids. Electron delocalization among atoms in the ring gives most of the bonds partial double-bond character. One result is that pyrimidines are planar molecules and purines are very nearly planar, with a slight pucker. Free pyrimidine and purine bases may exist in two or more tautomeric forms depending on the pH. Uracil, for example, occurs in lactam, lactim, and double lactim forms (Fig. 8–9). The structures shown in Figure 8–2 are the tautomers that predominate at pH 7.0. All nucleotide bases absorb UV light, and nucleic acids are characterized by a strong absorption at wavelengths near 260 nm (Fig. 8–10).

The purine and pyrimidine bases are hydrophobic and relatively insoluble in water at the near-neutral pH of the cell. At acidic or alkaline pH the bases become charged and their solubility in water increases. Hydrophobic stacking interactions in which two or more bases are positioned with the planes of their rings parallel (like a stack of coins) are one of two important modes of interaction between bases in nucleic acids. The stacking also involves a combination of van der Waals and dipole-dipole interactions between the bases. Base stacking helps to minimize contact of the bases with water, and base-stacking interactions are very important in stabilizing the three-

![Figure 8-9 Tautomeric forms of uracil.](image)

![Figure 8-10 Absorption spectra of the common nucleotides.](image)
The functional groups of pyrimidines and purines are ring nitrogens, carbonyl groups, and exocyclic amino groups. Hydrogen bonds involving the amino and carbonyl groups are the most important mode of interaction between two (and occasionally three or four) complementary strands of nucleic acid. The most common hydrogen-bonding patterns are those defined by James D. Watson and Francis Crick in 1953, in which A bonds specifically to T (or U) and G bonds to C (Fig. 8-11). These two types of base pairs predominate in double-stranded DNA and RNA, and the tautomers shown in Figure 8-2 are responsible for these patterns. It is this specific pairing of bases that permits the duplication of genetic information, as we shall discuss later in this chapter.

**SUMMARY 8.1 Some Basics**

- A nucleotide consists of a nitrogenous base (purine or pyrimidine), a pentose sugar, and one or more phosphate groups. Nucleic acids are polymers of nucleotides, joined together by phosphodiester linkages between the 5’-hydroxyl group of one pentose and the 3’-hydroxyl group of the next.

- There are two types of nucleic acid: RNA and DNA. The nucleotides in RNA contain ribose, and the common pyrimidine bases are uracil and cytosine. In DNA, the nucleotides contain 2’-deoxyribose, and the common pyrimidine bases are thymine and cytosine. The primary purines are adenine and guanine in both RNA and DNA.

**8.2 Nucleic Acid Structure**

The discovery of the structure of DNA by Watson and Crick in 1953 was a momentous event in science, an event that gave rise to entirely new disciplines and influenced the course of many established ones. In this section we focus on DNA structure, some of the events that led to its discovery, and more recent refinements in our understanding of DNA. RNA structure is also introduced.

As in the case of protein structure (Chapter 4), it is sometimes useful to describe nucleic acid structure in terms of hierarchical levels of complexity (primary, secondary, tertiary). The primary structure of a nucleic acid is its covalent structure and nucleotide sequence. Any regular, stable structure taken up by some or all of

---

**Figure 8-11** Hydrogen-bonding patterns in the base pairs defined by Watson and Crick. Here as elsewhere, hydrogen bonds are represented by three blue lines.
the nucleotides in a nucleic acid can be referred to as secondary structure. All structures considered in the remainder of this chapter fall under the heading of secondary structure. The complex folding of large chromosomes within eukaryotic chromatin and bacterial nucleoids is generally considered tertiary structure; this is discussed in Chapter 24.

DNA Is a Double Helix That Stores Genetic Information

DNA was first isolated and characterized by Friedrich Miescher in 1868. He called the phosphorus-containing substance “nuclein.” Not until the 1940s, with the work of Oswald T. Avery, Colin MacLeod, and Maclyn McCarty, was there any compelling evidence that DNA was the genetic material. Avery and his colleagues found that DNA extracted from a virulent (disease-causing) strain of the bacterium *Streptococcus pneumoniae* and injected into a nonvirulent strain of the same bacterium transformed the nonvirulent strain into a virulent strain. They concluded that the DNA from the virulent strain carried the genetic information for virulence. Then in 1952, experiments by Alfred D. Hershey and Martha Chase, in which they studied the infection of bacterial cells by a virus (bacteriophage) with radioactively labeled DNA or protein, removed any remaining doubt that DNA, not protein, carried the genetic information.

Another important clue to the structure of DNA came from the work of Erwin Chargaff and his colleagues in the late 1940s. They found that the four nucleotide bases of DNA occur in different ratios in the DNAs of different organisms and that the amounts of certain bases are closely related. These data, collected from DNAs of a great many different species, led Chargaff to the following conclusions:

1. The base composition of DNA generally varies from one species to another.
2. DNA specimens isolated from different tissues of the same species have the same base composition.
3. The base composition of DNA in a given species does not change with an organism’s age, nutritional state, or changing environment.
4. In all cellular DNAs, regardless of the species, the number of adenosine residues is equal to the number of thymidine residues (that is, *A* = *T*), and the number of guanosine residues is equal to the number of cytidine residues (*G* = *C*). From these relationships it follows that the sum of the purine residues equals the sum of the pyrimidine residues, that is, *A* + *G* = *T* + *C*.

These quantitative relationships, sometimes called “Chargaff’s rules,” were confirmed by many subsequent researchers. They were a key to establishing the three-dimensional structure of DNA and yielded clues to how genetic information is encoded in DNA and passed from one generation to the next.

To shed more light on the structure of DNA, Rosalind Franklin and Maurice Wilkins used the powerful method of x-ray diffraction (see Box 4-5) to analyze DNA fibers. They showed in the early 1950s that DNA produces a characteristic x-ray diffraction pattern (Fig. 8-12). From this pattern it was deduced that DNA molecules are helical with two periodicities along their long axis, a primary one of 3.4 Å and a secondary one of 34 Å. The problem then was to formulate a three-dimensional model of the DNA molecule that could account not only for the x-ray diffraction data but also for the specific *A* = *T* and *G* = *C* base equivalences discovered by Chargaff and for the other chemical properties of DNA.

James Watson and Francis Crick relied on this accumulated information about DNA to set about deducing its structure. In 1953 they postulated a three-dimensional model of DNA structure that accounted for all the available data. It consists of two helical DNA chains wound around the same axis to form a right-handed double helix (see Box 4-1 for an explanation of the right- or left-handed sense of a helical structure). The hydrophilic backbones of alternating deoxyribose and phosphate groups are on the outside of the double helix, facing the surrounding water. The furanose ring of each deoxyribose is in the C-2’ endo conformation. The purine and pyrimidine bases of both strands are stacked inside the
FIGURE 8-13 Watson-Crick model for the structure of DNA. The original model proposed by Watson and Crick had 10 base pairs, or 34 Å (3.4 nm), per turn of the helix; subsequent measurements revealed 10.5 base pairs, or 36 Å (3.6 nm), per turn. (a) Schematic representation, showing dimensions of the helix. (b) Stick representation showing the backbone and stacking of the bases. (c) Space-filling model.

The DNA double helix, with their hydrophobic and nearly planar ring structures very close together and perpendicular to the long axis. The offset pairing of the two strands creates a major groove and minor groove on the surface of the duplex (Fig. 8–13). Each nucleotide base of one strand is paired in the same plane with a base of the other strand. Watson and Crick found that the hydrogen-bonded base pairs illustrated in Figure 8–11, G with C and A with T, are those that fit best within the structure, providing a rationale for Chargaff’s rule that in any DNA, G : C and A : T. It is important to note that three hydrogen bonds can form between G and C, symbolized G=C, but only two can form between A and T, symbolized A=T. This is one reason for the finding that the separation of paired DNA strands is more difficult the higher the ratio of G=C to A=T base pairs. Other pairings of bases tend (to varying degrees) to destabilize the double-helical structure.

When Watson and Crick constructed their model, they had to decide at the outset whether the strands of DNA should be parallel or antiparallel—whether their 3' ,5'-phosphodiester bonds should run in the same or opposite directions. An antiparallel orientation produced the most convincing model, and later work with DNA polymerases (Chapter 25) provided experimental evidence that the strands are indeed antiparallel, a finding ultimately confirmed by x-ray analysis.

To account for the periodicities observed in the x-ray diffraction patterns of DNA fibers, Watson and Crick manipulated molecular models to arrive at a structure in which the vertically stacked bases inside the double helix would be 3.4 Å apart; the secondary repeat distance of about 34 Å was accounted for by the presence of 10 base pairs in each complete turn of the double helix. In aqueous solution the structure differs slightly from that in fibers, having 10.5 base pairs per helical turn (Fig. 8–13).

As Figure 8–14 shows, the two antiparallel polynucleotide chains of double-helical DNA are not identical in either base sequence or composition. Instead they are complementary to each other. Wherever adenine occurs in one chain, thymine is found in the other; similarly, wherever guanine occurs in one chain, cytosine is found in the other.

The DNA double helix, or duplex, is held together by two forces, as described earlier: hydrogen bonding between complementary base pairs (Fig. 8–11) and base-stacking interactions. The complementarity between the DNA strands is attributable to the hydrogen bonding between base pairs. The base-stacking interactions, which are largely nonspecific with respect to the identity of the stacked bases, make the major contribution to the stability of the double helix.

The important features of the double-helical model of DNA structure are supported by much chemical and biological evidence. Moreover, the model immediately suggested a mechanism for the transmission of genetic information. The essential feature of the model is the complementarity of the two DNA strands. As Watson and Crick were able to see, well before confirmatory data became available, this structure could logically be replicated by (1) separating the two strands and (2) synthesizing a complementary strand for each. Because nucleotides in each new strand are joined in a sequence specified by the base-pairing rules stated above, each preexisting strand

FIGURE 8-14 Complementarity of strands in the DNA double helix. The complementary antiparallel strands of DNA follow the pairing rules proposed by Watson and Crick. The base-paired antiparallel strands differ in base composition: the left strand has the composition A2 T2 G3 C1; the right, A2 T1 G3 C1. They also differ in sequence when each chain is read in the 5' → 3' direction. Note the base equivalences: A = T and G = C in the duplex.
functions as a template to guide the synthesis of a complementary strand (Fig. 8-15). These expectations were experimentally confirmed, inaugurating a revolution in our understanding of biological inheritance.

**WORKED EXAMPLE 8–1  Base Pairing in DNA**

In samples of DNA isolated from two unidentified species of bacteria, X and Y, adenine makes up 32% and 17%, respectively, of the total bases. What relative proportions of adenine, guanine, thymine, and cytosine would you expect to find in the two DNA samples? What assumptions have you made? One of these species was isolated from a hot spring (64°C). Which species is most likely the thermophilic bacterium, and why?

**Solution:** For any double-helical DNA, A = T and G = C. The DNA from species X has 32% A and therefore must contain 32% T. This accounts for 64% of the bases and leaves 36% as G=C pairs: 18% G and 18% C. The sample from species Y, with 17% A, must contain 17% T, accounting for 34% of the base pairs. The remaining 66% of the bases are thus equally distributed as 33% G and 33% C. This calculation is based on the assumption that both DNA molecules are double-stranded.

The higher the G + C content of a DNA molecule, the higher the melting temperature. Species Y, having the DNA with the higher G + C content (66%), most likely is the thermophilic bacterium; its DNA has a higher melting temperature and thus is more stable at the temperature of the hot spring.

**DNA Can Occur in Different Three-Dimensional Forms**

DNA is a remarkably flexible molecule. Considerable rotation is possible around several types of bonds in the sugar–phosphate (phosphodeoxyribose) backbone, and thermal fluctuation can produce bending, stretching, and unpairing (melting) of the strands. Many significant deviations from the Watson-Crick DNA structure are found in cellular DNA, some or all of which may be important in DNA metabolism. These structural variations generally do not affect the key properties of DNA defined by Watson and Crick: strand complementarity, antiparallel strands, and the requirement for A=T and G=C base pairs.

Structural variation in DNA reflects three things: the different possible conformations of the deoxyribose, rotation about the contiguous bonds that make up the phosphodeoxyribose backbone (Fig. 8–16a), and free rotation about the C-1'-N-glycosyl bond (Fig. 8–16b). Because of steric constraints, purines in purine nucleotides are restricted to two stable conformations with respect to deoxyribose, called syn and
anti (Fig. 8–16b). Pyrimidines are generally restricted to the anti conformation because of steric interference between the sugar and the carbonyl oxygen at C-2 of the pyrimidine.

The Watson-Crick structure is also referred to as **B-form DNA**, or B-DNA. The B form is the most stable structure for a random-sequence DNA molecule under physiological conditions and is therefore the standard point of reference in any study of the properties of DNA. Two structural variants that have been well characterized in crystal structures are the **A** and **Z** forms. These three DNA conformations are shown in **Figure 8–17**, with a summary of their properties. The A form is favored in many solutions that are relatively devoid of water. The DNA is still arranged in a right-handed double helix, but the helix is wider and the number of base pairs per helical turn is 11, rather than 10.5 as in B-DNA. The plane of the base pairs in A-DNA is tilted about 20° with respect to the helix axis. These structural changes deepen the major groove while making the minor groove shallower. The reagents used to promote crystallization of DNA tend to dehydrate it, and thus most short DNA molecules tend to crystallize in the A form.

Z-form DNA is a more radical departure from the B structure; the most obvious distinction is the left-handed helical rotation. There are 12 base pairs per helical turn, and the structure appears more slender and elongated. The DNA backbone takes on a zigzag appearance. Certain nucleotide sequences fold into left-handed Z helices much more readily than others. Prominent examples are sequences in which pyrimidines alternate with purines, especially alternating C and G or 5-methyl-C and G residues. To form the left-handed helix in Z-DNA, the purine residues flip to the syn conformation, alternating with pyrimidines in the anti conformation. The major groove is barely apparent in Z-DNA, and the minor groove is narrow and deep.

Whether A-DNA occurs in cells is uncertain, but there is evidence for some short stretches (tracts) of Z-DNA in both bacteria and eukaryotes. These Z-DNA tracts may play a role (as yet undefined) in regulating the expression of some genes or in genetic recombination.

**Certain DNA Sequences Adopt Unusual Structures**

Other sequence-dependent structural variations found in larger chromosomes may affect the function and metabolism of the DNA segments in their immediate vicinity. For example, bends occur in the DNA helix wherever four or more adenosine residues appear sequentially in one strand. Six adenosines in a row produce a bend of about 18°. The bending observed with this and other sequences may be important in the binding of some proteins to DNA.

A rather common type of DNA sequence is a palindrome. A palindrome is a word, phrase, or sentence that is spelled identically read either forward or backward; two examples are ROTATOR and NURSES RUN. The term is applied to regions of DNA with inverted repeats of base sequence having twofold symmetry over two

---

strands of DNA (Fig. 8–18). Such sequences are self-complementary within each strand and therefore have the potential to form hairpin or cruciform (cross-shaped) structures (Fig. 8–19). When the inverted repeat occurs within each individual strand of the DNA, the sequence is called a mirror repeat. Mirror repeats do not have complementary sequences within the same strand and cannot form hairpin or cruciform structures. Sequences of these types are found in virtually every large DNA molecule and can encompass a few base pairs or thousands. The extent to which palindromes occur as cruciforms in cells is not known, although some cruciform structures have been demonstrated in vivo in *Escherichia coli*. Self-complementary sequences cause isolated single strands of DNA (or RNA) in solution to fold into complex structures containing multiple hairpins.

Several unusual DNA structures involve three or even four DNA strands. Nucleotides participating in a Watson-Crick base pair (Fig. 8–11) can form additional hydrogen bonds, particularly with functional groups arrayed in the major groove. For example, a cytidine residue (if protonated) can pair with the guanosine residue of a G:C nucleotide pair (Fig. 8–20); a thymidine can pair with the adenosine of an A:T pair. The N-7, O6, and N6 of purines, the atoms that participate in the hydrogen bonding of triplex DNA, are often referred to as Hoogsteen positions, and the non-Watson-Crick pairing is called Hoogsteen pairing, after Karst Hoogsteen, who in 1963 first recognized the potential for these unusual pairings. Hoogsteen pairing allows the formation of triplex DNAs. The triplexes shown in Figure 8–20 (a, b) are most stable at low pH because the C=G ∙ C+ triplet requires a protonated cytosine. In the triplex, the pKa of this cytosine is >7.5, altered from its normal value of 4.2. The triplexes also form most readily within long sequences containing only pyrimidines or only purines in a given strand. Some triplex DNAs contain two pyrimidine strands and one purine strand; others contain two purine strands and one pyrimidine strand.

Four DNA strands can also pair to form a tetraplex (quadruplex), but this occurs readily only for DNA sequences with a very high proportion of guanosine residues (Fig. 8–20c, d). The guanosine tetraplex, or G tetraplex, is quite stable over a wide range of conditions. The orientation of strands in the tetraplex can vary as shown in Figure 8–20e.

In the DNA of living cells, sites recognized by many sequence-specific DNA-binding proteins (Chapter 28) are arranged as palindromes, and polyuridine or poly-purine sequences that can form triple helices are found within regions involved in the regulation of expression of some eukaryotic genes. In principle, synthetic DNA strands designed to pair with these sequences to form
Messenger RNAs Code for Polypeptide Chains

We now turn our attention to the expression of the genetic information that DNA contains. RNA, the second major form of nucleic acid in cells, has many functions. In gene expression, RNA acts as an intermediary by using the information encoded in DNA to specify the amino acid sequence of a functional protein.

Given that the DNA of eukaryotes is largely confined to the nucleus whereas protein synthesis occurs on ribosomes in the cytoplasm, some molecule other than DNA must carry the genetic message from the nucleus to the cytoplasm. As early as the 1950s, RNA was considered the logical candidate: RNA is found in both the nucleus and the cytoplasm, and an increase in protein synthesis is accompanied by an increase in the amount of cytoplasmic RNA and an increase in its rate of turnover. These and other observations led several researchers to suggest that RNA carries genetic information from DNA to the protein biosynthetic machinery of the ribosome. In 1961 François Jacob and Jacques Monod presented a unified (and essentially correct) picture of many aspects of this process. They proposed the name "messenger RNA" (mRNA) for that portion of the total cellular RNA carrying the genetic information. 

FIGURE 8–20 DNA structures containing three or four DNA strands.

(a) Base-pairing patterns in one well-characterized form of triplex DNA. The Hoogsteen pair in each case is shown in red. (b) Triple-helical DNA containing two pyrimidine strands (poly(C)) and one purine strand (poly(G)) (derived from PDB ID 1BCE). The dark blue and light blue strands are antiparallel and paired by normal Watson-Crick base-pairing patterns. The third (all-pyrimidine) strand (purple) is parallel to the purine strand and paired through non-Watson-Crick hydrogen bonds. The triplex is viewed end-on, with five triplets shown. Only the triplet closest to the viewer is colored. (c) Base-pairing pattern in the guanosine tetraplex structure. (d) Two successive tetraplets from a G tetraplex structure, viewed end-on with the one closest to the viewer in color. (e) Possible variants in the orientation of strands in a G tetraplex.

FIGURE 8-21 Bacterial mRNA. Schematic diagrams show (a) monocistronic and (b) polycistronic mRNAs of bacteria. Red segments represent RNA coding for a gene product; gray segments represent noncoding RNA. In the polycistronic transcript, noncoding RNA separates the three genes.

information from DNA to the ribosomes, where the messengers provide the templates that specify amino acid sequences in polypeptide chains. Although mRNAs from different genes can vary greatly in length, the mRNAs from a particular gene generally have a defined size. The process of forming mRNA on a DNA template is known as transcription.

In bacteria and archaea, a single mRNA molecule may code for one or several polypeptide chains. If it carries the code for only one polypeptide, the mRNA is monocistronic; if it codes for two or more different polypeptides, the mRNA is polycistronic. In eukaryotes, most mRNAs are monocistronic. (For the purposes of this discussion, “cistron” refers to a gene. The term itself has historical roots in the science of genetics, and its formal genetic definition is beyond the scope of this text.) The minimum length of an mRNA is set by the length of the polypeptide chain for which it codes. For example, a polypeptide chain of 100 amino acid residues requires an RNA coding sequence of at least 300 nucleotides, because each amino acid is coded by a nucleotide triplet (this and other details of protein synthesis are discussed in Chapter 27). However, mRNAs transcribed from DNA are always somewhat longer than the length needed simply to code for a polypeptide sequence (or sequences). The additional, noncoding RNA includes sequences that regulate protein synthesis. Figure 8–21 summarizes the general structure of bacterial mRNAs.

Many RNAs Have More Complex Three-Dimensional Structures

Messenger RNA is only one of several classes of cellular RNA. Transfer RNAs are adapter molecules in protein synthesis; covalently linked to an amino acid at one end, they pair with the mRNA in such a way that amino acids are joined to a growing polypeptide in the correct sequence. Ribosomal RNAs are components of ribosomes. There is also a wide variety of special-function RNAs, including some (called ribozymes) that have enzymatic activity. All the RNAs are considered in detail in Chapter 26. The diverse and often complex functions of these RNAs reflect a diversity of structure much richer than that observed in DNA molecules.

The product of transcription of DNA is always single-stranded RNA. The single strand tends to assume a right-handed helical conformation dominated by base-stacking interactions (Fig. 8–22), which are stronger between two purines than between a purine and pyrimidine or between two pyrimidines. The purine-purine interaction is so strong that a pyrimidine separating two purines is often displaced from the stacking pattern so that the purines can interact. Any self-complementary sequences in the molecule produce more complex structures. RNA can base-pair with complementary regions of either RNA or DNA. Base pairing matches the pattern for DNA: G pairs with C and A pairs with U (or with the occasional T residue in some RNAs). One difference is that base pairing between G and U residues—unusual in DNA—is fairly common in RNA (see Fig. 8–24). The paired strands in RNA or RNA-DNA duplexes are antiparallel, as in DNA.

RNA has no simple, regular secondary structure that serves as a reference point, as does the double helix for DNA. The three-dimensional structures of many RNAs, like those of proteins, are complex and unique. Weak interactions, especially base-stacking interactions, help stabilize RNA structures, just as they do in DNA. Where complementary sequences are present, the predominant double-stranded structure is an A-form right-handed double helix. Z-form helices have been made in the laboratory (under very high-salt or

FIGURE 8–22 Typical right-handed stacking pattern of single-stranded RNA. The bases are shown in gray, the phosphate atoms in yellow, and the riboses and phosphate oxygens in green. Green is used to represent RNA strands in succeeding chapters, just as blue is used for DNA.
high-temperature conditions). The B form of RNA has not been observed. Breaks in the regular A-form helix caused by mismatched or unmatched bases in one or both strands are common and result in bulges or internal loops (Fig. 8-23). Hairpin loops form between nearby self-complementary sequences. The potential for base-paired helical structures in many RNAs is extensive (Fig. 8-24), and the resulting hairpins are the most common type of secondary structure in RNA. Specific short base sequences (such as UUCG) are often found at the ends of RNA hairpins and are known to form particularly tight and stable loops. Such sequences may act as starting points for the folding of an RNA molecule into its precise three-dimensional structure. Other contributions are made by hydrogen bonds that are not part of standard Watson-Crick base pairs. For example, the 2'-hydroxyl group of ribose can hydrogen-bond with other groups. Some of these properties are evident in the structure of the phenylalanine transfer RNA of yeast—the tRNA responsible for inserting Phe residues into polypeptides—and in two RNA enzymes, or ribozymes, whose functions, like those of

**FIGURE 8-24 Base-paired helical structures in an RNA.** Shown here is the possible secondary structure of the M1 RNA component of the enzyme RNase P of _E. coli_, with many hairpins, RNase P, which also contains a protein component (not shown), functions in the processing of transfer RNAs (see Fig. 26-27). The two brackets indicate additional complementary sequences that may be paired in the three-dimensional structure. The blue dots indicate non-Watson-Crick G=U base pairs (boxed inset). Note that G=U base pairs are allowed only when presynthesized strands of RNA fold up or anneal with each other. There are no RNA polymerases (the enzymes that synthesize RNAs on a DNA template) that insert a U opposite a template G, or vice versa, during RNA synthesis.
protein enzymes, depend on their three-dimensional structures (Fig. 8–25).

The analysis of RNA structure and the relationship between structure and function is an emerging field of inquiry that has many of the same complexities as the analysis of protein structure. The importance of understanding RNA structure grows as we become increasingly aware of the large number of functional roles for RNA molecules.

SUMMARY 8.2 Nucleic Acid Structure

- Many lines of evidence show that DNA bears genetic information. In particular, the Avery-MacLeod-McCarty experiment showed that DNA isolated from one bacterial strain can enter and transform the cells of another strain, endowing it with some of the inheritable characteristics of the donor. The Hershey-Chase experiment showed that...
the DNA of a bacterial virus, but not its protein coat, carries the genetic message for replication of the virus in a host cell.

Putting together the available data, Watson and Crick postulated that native DNA consists of two antiparallel chains in a right-handed double-helical arrangement. Complementary base pairs, A=T and G=C, are formed by hydrogen bonding within the helix. The base pairs are stacked perpendicular to the long axis of the double helix, 3.4 Å apart, with 10.5 base pairs per turn.

DNA can exist in several structural forms. Two variations of the Watson-Crick form, or B-DNA, are A- and Z-DNA. Some sequence-dependent structural variations cause bends in the DNA molecule. DNA strands with appropriate sequences can form hairpin/cruciform structures or triplex or tetraplex DNA.

Messenger RNA transfers genetic information from DNA to ribosomes for protein synthesis. Transfer RNA and ribosomal RNA are also involved in protein synthesis. RNA can be structurally complex; single RNA strands can fold into hairpins, double-stranded regions, or complex loops.

8.3 Nucleic Acid Chemistry

The role of DNA as a repository of genetic information depends in part on its inherent stability. The chemical transformations that do occur are generally very slow in the absence of an enzyme catalyst. The long-term storage of information without alteration is so important to a cell, however, that even very slow reactions that alter DNA structure can be physiologically significant. Processes such as carcinogenesis and aging may be intimately linked to slowly accumulating, irreversible alterations of DNA. Other, nondestructive alterations also occur and are essential to function, such as the strand separation that must precede DNA replication or transcription. In addition to providing insights into physiological processes, our understanding of nucleic acid chemistry has given us a powerful array of technologies that have applications in molecular biology, medicine, and forensic science. We now examine the chemical properties of DNA and some of these technologies.

Double-Helical DNA and RNA Can Be Denatured

Solutions of carefully isolated, native DNA are highly viscous at pH 7.0 and room temperature (25 °C). When such a solution is subjected to extremes of pH or to temperatures above 80 °C, its viscosity decreases sharply, indicating that the DNA has undergone a physical change. Just as heat and extremes of pH denature globular proteins, they also cause denaturation, or melting, of double-helical DNA. Disruption of the hydrogen bonds between paired bases and of base stacking causes unwinding of the double helix to form two single strands, completely separate from each other along the entire length or part of the length (partial denaturation) of the molecule. No covalent bonds in the DNA are broken (Fig. 8–26).

Renaturation of a DNA molecule is a rapid one-step process, as long as a double-helical segment of a dozen or more residues still unites the two strands. When the temperature or pH is returned to the range in which most organisms live, the unwound segments of the two strands spontaneously rewind, or anneal, to yield the intact duplex (Fig. 8–26). However, if the two strands are completely separated, renaturation occurs in two steps. In the first, relatively slow step, the two strands “find” each other by random collisions and form a short segment of complementary double helix. The second step is much faster: the remaining unpaired bases successively come into register as base pairs, and the two strands “zipper” themselves together to form the double helix.

The close interaction between stacked bases in a nucleic acid has the effect of decreasing its absorption of UV light relative to that of a solution with the same concentration of free nucleotides, and the absorption is decreased further when two complementary nucleic acid strands are paired. This is called the hypochromic effect. Denaturation of a double-stranded nucleic acid

![Diagram of nucleic acid denaturation and renaturation](image-url)
produces the opposite result: an increase in absorption called the hyperchromic effect. The transition from double-stranded DNA to the single-stranded, denatured form can thus be detected by monitoring UV absorption at 260 nm.

Viral or bacterial DNA molecules in solution denature when they are heated slowly (Fig. 8-27). Each species of DNA has a characteristic denaturation temperature, or melting point \( t_m \); formally, the temperature at which half the DNA is present as separated single strands): the higher its content of G=C base pairs, the higher the melting point of the DNA. This is because G=C base pairs, with three hydrogen bonds, require more heat energy to dissociate than A=T base pairs. Thus the melting point of a DNA molecule, determined under fixed conditions of pH and ionic strength, can yield an estimate of its base composition. If denaturation conditions are carefully controlled, regions that are rich in A=T base pairs will specifically denature while most of the DNA remains double-stranded. Such denatured regions (called bubbles) can be visualized with electron microscopy (Fig. 8-28). Note that in the strand separation of DNA that occurs in vivo during processes such as DNA replication and transcription, the sites where these processes are initiated are often rich in A=T base pairs, as we shall see.

Duplexes of two RNA strands or one RNA strand and one DNA strand (RNA-DNA hybrids) can also be denatured. Notably, RNA duplexes are more stable than DNA duplexes. At neutral pH, denaturation of a double-helical RNA often requires temperatures 20 °C or more higher than those required for denaturation of a DNA molecule with a comparable sequence. The stability of an RNA-DNA hybrid is generally intermediate between that of RNA and that of DNA. The physical basis for these differences in thermal stability is not known.

**Nucleic Acids from Different Species Can Form Hybrids**

The ability of two complementary DNA strands to pair with one another can be used to detect similar DNA sequences in two different species or within the genome of a single species. If duplex DNAs isolated from human cells and from mouse cells are completely denatured by heating, then mixed and kept at about 25 °C below their \( t_m \) for many hours, much of the DNA will anneal. The rate of DNA annealing is affected by temperature, the length and concentration of the DNA fragments being annealed, the concentration of salts in the reaction mixture, and properties of the sequence itself.
Temperature is especially important. If the temperature is too low, short sequences with coincidental similarity from distant, heterologous parts of the DNA molecules will anneal unproductively and interfere with the more general alignment of complementary DNA strands. Temperatures that are too high will favor denaturation. Most of the reannealing occurs between complementary mouse DNA strands to form mouse duplex DNA; similarly, most human DNA strands anneal with complementary human DNA strands. However, some strands of the mouse DNA will associate with human DNA strands to yield hybrid duplexes, in which segments of a mouse DNA strand form base-paired regions with segments of a human DNA strand (Fig. 8–29). This reflects a common evolutionary heritage; different organisms generally have many proteins and RNAs with similar functions and, often, similar structures. In many cases, the DNAs encoding these proteins and RNAs have similar sequences. The closer the evolutionary relationship between two species, the more extensively their DNAs will hybridize. For example, human DNA hybridizes much more extensively with mouse DNA than with DNA from yeast.

The hybridization of DNA strands from different sources forms the basis for a powerful set of techniques essential to the practice of modern molecular genetics. A specific DNA sequence or gene can be detected in the presence of many other sequences if one already has an appropriate complementary DNA strand (usually labeled in some way) to hybridize with it (Chapter 9). The complementary DNA can be from a different species or from the same species, or it can be synthesized chemically in the laboratory using techniques described later in this chapter. Hybridization techniques can be varied to detect a specific RNA rather than DNA. The isolation and identification of specific genes and RNAs rely on these hybridization techniques. Applications of this technology make possible the identification of an individual on the basis of a single hair left at the scene of a crime or the prediction of the onset of a disease decades before symptoms appear (see Box 9–1).

Nucleotides and Nucleic Acids Undergo Nonenzymatic Transformations

Purines and pyrimidines, along with the nucleotides of which they are a part, undergo spontaneous alterations in their covalent structure. The rate of these reactions is generally very slow, but they are physiologically significant because of the cell’s very low tolerance for alterations in its genetic information. Alterations in DNA structure that produce permanent changes in the genetic information encoded therein are called mutations, and much evidence suggests an intimate link between the accumulation of mutations in an individual organism and the processes of aging and carcinogenesis.

Several nucleotide bases undergo spontaneous loss of their exocyclic amino groups (deamination) (Fig. 8–30a). For example, under typical cellular conditions, deamination of cytosine (in DNA) to uracil occurs in about one of every 10$^6$ cytosine residues in 24 hours. This corresponds to about 100 spontaneous events per day, on average, in a mammalian cell. Deamination of adenine and guanine occurs at about 1/100th this rate.

The slow cytosine deamination reaction seems innocuous enough, but is almost certainly the reason why DNA contains thymine rather than uracil. The product of cytosine deamination (uracil) is readily recognized as foreign in DNA and is removed by a repair system (Chapter 25). If DNA normally contained uracil, recognition of uracils resulting from cytosine deamination would be more difficult, and unrepaired uracils would lead to permanent sequence changes as they were paired with adenines during replication. Cytosine deamination would gradually lead to a decrease in G=C base pairs and an increase in A=U base pairs in the DNA of all cells. Over the millennia, cytosine deamination could eliminate G=C base pairs and the genetic code that depends on them. Establishing thymine as one of the four bases in DNA may well have been one of the crucial
turning points in evolution, making the long-term storage of genetic information possible.

Another important reaction in deoxyribonucleotides is the hydrolysis of the N-β-glycosyl bond between the base and the pentose, to create a DNA lesion called an AP (apurinic, apyrimidinic) site or abasic site (Fig. 8–30b). This occurs at a higher rate for purines than for pyrimidines. As many as one in $10^6$ purines (10,000 per mammalian cell) are lost from DNA every 24 hours under typical cellular conditions. Depurination of ribonucleotides and RNA is much slower and generally is not considered physiologically significant. In the test tube, loss of purines can be accelerated by dilute acid. Incubation of DNA at pH 3 causes selective removal of the purine bases, resulting in a derivative called apurinic acid.

Other reactions are promoted by radiation. UV light induces the condensation of two ethylene groups to form a cyclobutane ring. In the cell, the same reaction between adjacent pyrimidine bases in nucleic acids forms cyclobutane pyrimidine dimers. This happens most frequently between adjacent thymidine residues on the same DNA strand (Fig. 8–31). A second type of pyrimidine dimer, called a 6-4 photoproduct, is also formed during UV irradiation. Ionizing radiation (x rays and gamma rays) can cause ring opening and fragmentation of bases as well as breaks in the covalent backbone of nucleic acids.

Virtually all forms of life are exposed to energy-rich radiation capable of causing chemical changes in DNA. Near-UV radiation (with wavelengths of 200 to 400 nm), which makes up a significant portion of the solar spectrum, is known to cause pyrimidine dimer formation and other chemical changes in the DNA of bacteria and of human skin cells. We are subject to a constant field of ionizing radiation in the form of cosmic rays, which can penetrate deep into the earth, as well as radiation emitted from radioactive elements, such as radium, plutonium, uranium, radon, $^{14}$C, and $^3$H. X rays used in medical and dental examinations and in radiation therapy of cancer and other diseases are another form of ionizing radiation. It is estimated that UV and ionizing radiations are responsible for about 10% of all DNA damage caused by environmental agents.
DNA also may be damaged by reactive chemicals introduced into the environment as products of industrial activity. Such products may not be injurious per se but may be metabolized by cells into forms that are. There are two prominent classes of such agents (Fig. 8-32): (1) deaminating agents, particularly nitrous acid ($\text{HNO}_2$) or compounds that can be metabolized to nitrous acid or nitrites, and (2) alkylating agents.

Nitrous acid, formed from organic precursors such as nitrosamines and from nitrite and nitrate salts, is a potent accelerator of the deamination of bases. Bisulfite has similar effects. Both agents are used as preservatives in processed foods to prevent the growth of toxic bacteria. They do not seem to increase cancer risks significantly when used in this way, perhaps because they are used in small amounts and make only a minor contribution to the overall levels of DNA damage. (The potential health risk from food spoilage if these preservatives were not used is much greater.)
Alkylating agents can alter certain bases of DNA. For example, the highly reactive chemical dimethylsulphate (Fig. 8–32b) can methylate a guanine to yield O6-methylguanine, which cannot base-pair with cytosine.

\[
\begin{align*}

\text{H}_2\text{N} \hspace{1cm} \text{H} \\
\end{array}
\end{align*}
\]

\[
\text{O}^6-\text{Methylguanine}
\]

Many similar reactions are brought about by alkylating agents normally present in cells, such as S-adenosylmethionine.

The most important source of mutagenic alterations in DNA is oxidative damage. Excited-oxygen species such as hydrogen peroxide, hydroxyl radicals, and superoxide radicals arise during irradiation or as a byproduct of aerobic metabolism. Of these species, the hydroxyl radicals are responsible for most oxidative DNA damage. Cells have an elaborate defense system to destroy reactive oxygen species, including enzymes such as catalase and superoxide dismutase that convert reactive oxygen species to harmless products. A fraction of these oxidants inevitably escape cellular defenses, however, and damage to DNA occurs through any of a large, complex group of reactions ranging from oxidation of deoxyribose and base moieties to strand breaks. Accurate estimates for the extent of this damage are not yet available, but every day the DNA of each human cell is subjected to thousands of damaging oxidative reactions.

This is merely a sampling of the best-understood reactions that damage DNA. Many carcinogenic compounds in food, water, or air exert their cancer-causing effects by modifying bases in DNA. Nevertheless, the integrity of DNA as a polymer is better maintained than that of either RNA or protein, because DNA is the only macromolecule that has the benefit of biochemical repair systems. These repair processes (described in Chapter 25) greatly lessen the impact of damage to DNA.

**Some Bases of DNA Are Methylated**

Certain nucleotide bases in DNA molecules are enzymatically methylated. Adenine and cytosine are methylated more often than guanine and thymine. Methylations is generally confined to certain sequences or regions of a DNA molecule. In some cases the function of methylation is well understood; in others the function remains unclear. All known DNA methylases use S-adenosylmethionine as a methyl group donor (Fig. 8–32b).

**E. coli** has two prominent methylation systems. One serves as part of a defense mechanism that helps the cell to distinguish its DNA from foreign DNA by marking its own DNA with methyl groups and destroying (foreign) DNA without the methyl groups (this is known as a restriction-modification system; see p. 305). The other system methylates adenosine residues within the sequence (5')(GATC(3')) to N6-methyladenosine (Fig. 8–5a). This is mediated by the Dam (DNA adenine methylation) methylase, a component of a system that repairs mismatched base pairs formed occasionally during DNA replication (see Fig. 25–22).

In eukaryotic cells, about 5% of cytidine residues in DNA are methylated to 5-methylcytidine (Fig. 8–5a). Methylation is most common at CpG sequences, producing methyl-CpG symmetrically on both strands of the DNA. The extent of methylation of CpG sequences varies by molecular region in large eukaryotic DNA molecules.

**The Sequences of Long DNA Strands Can Be Determined**

In its capacity as a repository of information, a DNA molecule's most important property is its nucleotide sequence. Until the late 1970s, determining the sequence of a nucleic acid containing even five or ten nucleotides was very laborious. The development of two new techniques in 1977, one by Alan Maxam and Walter Gilbert and the other by Frederick Sanger, made possible the sequencing of larger DNA molecules with an ease unimaginable just a few years before. The techniques depend on an improved understanding of nucleotide chemistry and DNA metabolism, and on electrophoretic methods for separating DNA strands differing in size by one nucleotide. Electrophoresis of DNA is similar to that of proteins (see Fig. 3–18). Polyacrylamide is often used as the gel matrix in work with short DNA molecules (up to a few hundred nucleotides); agarose is generally used for longer pieces of DNA.

In both Sanger and Maxam-Gilbert sequencing, the general principle is to reduce the DNA to four sets of labeled fragments. The reaction producing each set is base-specific, so the lengths of the fragments correspond to positions in the DNA sequence where a certain base occurs. For example, for an oligonucleotide with the sequence pAATCGACT, labeled at the 5' end (the left end), a reaction that breaks the DNA after each G residue will generate two labeled fragments: a four-nucleotide and a seven-nucleotide fragment; a reaction that breaks the DNA after each C residue will generate two labeled fragments: a four-nucleotide and a seven-nucleotide fragment. Because the fragments are radioactively labeled at their 5' ends, only the fragment to the 5' side of the break is visualized. The fragment sizes correspond to the relative positions of C and G residues in the sequence. When the sets of fragments corresponding to each of the four bases are electrophoretically separated side by side, they produce a ladder of bands from which the sequence can be read directly (Fig. 8–33). We illustrate only the Sanger
FIGURE 8-33 DNA sequencing by the Sanger method. This method makes use of the mechanism of DNA synthesis by DNA polymerases (Chapter 25). (a) DNA polymerases require both a primer (a short oligonucleotide strand), to which nucleotides are added, and a template strand to guide selection of each new nucleotide. In cells, the 3'-hydroxyl group of the primer reacts with an incoming deoxynucleoside triphosphate (dNTP) to form a new phosphodiester bond. (b) The Sanger sequencing procedure uses dideoxynucleoside triphosphate (ddNTP) analogs to interrupt DNA synthesis. (The Sanger method is also known as the dideoxy method.) When a ddNTP is inserted in place of a dNTP, strand elongation is halted after the analog is added, because it lacks the 3'-hydroxyl group needed for the next step. (c) The DNA to be sequenced is used as the template strand, and a short primer, radioactively or fluorescently labeled, is annealed to it. By addition of small amounts of a single ddNTP, for example ddCTP, to an otherwise normal reaction system, the synthesized strands will be prematurely terminated at some locations where dC normally occurs. Given the excess of dCTP over ddCTP, the chance that the analog will be incorporated whenever a dC is to be added is small. However, ddCTP is present in sufficient amounts to ensure that each new strand has a high probability of acquiring at least one ddC at some point during synthesis. The result is a solution containing a mixture of labeled fragments, each ending with a C residue. Each C residue in the sequence generates a set of fragments of a particular length, such that the different-sized fragments, separated by electrophoresis, reveal the location of C residues. This procedure is repeated separately for each of the four ddNTPs, and the sequence can be read directly from an autoradiogram of the gel. Because shorter DNA fragments migrate faster, the fragments near the bottom of the gel represent the nucleotide positions closest to the primer (the 5' end), and the sequence is read (in the 5' → 3' direction) from bottom to top. Note that the sequence obtained is that of the strand complementary to the strand being analyzed.
method, because it has proved to be technically easier and is in more widespread use. It requires the enzymatic synthesis of a DNA strand complementary to the strand under analysis, using a radioactively labeled “primer” and dideoxynucleotides.

DNA sequencing is now automated by a variation of Sanger’s sequencing method in which the dideoxynucleotides used for each reaction are labeled with a differently colored fluorescent tag (Fig. 8-34). With this technology, researchers can sequence DNA molecules containing thousands of nucleotides in a few hours. The entire genomes of more than a thousand organisms have now been sequenced in this way (see Table 1-2), and many very large DNA-sequencing projects have been completed or are in progress. For example, in the Human Genome Project, researchers have sequenced all 3.2 billion base pairs of the DNA in a human cell (Chapter 9).

![Diagram of DNA sequencing](image)

**FIGURE 8-34 Strategy for automating DNA sequencing reactions.**

Each dideoxynucleotide used in the Sanger method can be linked to a fluorescent molecule that gives all the fragments terminating in that nucleotide a particular color. All four labeled ddNTPs are added to a single tube. The resulting colored DNA fragments are then separated by size in a single electrophoretic gel contained in a capillary tube (a refinement of gel electrophoresis that allows for faster separations). All fragments of a given length migrate through the capillary gel in a single peak, and the color associated with each peak is detected using a laser beam. The DNA sequence is read by determining the sequence of colors in the peaks as they pass the detector. This information is fed directly to a computer, which determines the sequence.

The Chemical Synthesis of DNA Has Been Automated

Also important in nucleic acid chemistry is the rapid and accurate synthesis of short oligonucleotides of known sequence. The methods were pioneered by H. Gobind Khorana and his colleagues in the 1970s. Refinements by Robert Letsinger and Marvin Caruthers led to the chemistry now in widest use, called the phosphoramidite method (Fig. 8–35). The synthesis is carried out with the growing strand attached to a solid support, using principles similar to those used by Merrifield for peptide synthesis (see Fig. 3–29), and is readily automated. The efficiency of each addition step is very high, allowing the routine synthesis of polymers containing 70 or 80 nucleotides and, in some laboratories, much longer strands. The availability of relatively inexpensive DNA polymers with predesigned sequences is having a powerful impact on all areas of biochemistry (Chapter 9).
FIGURE 8-35 Chemical synthesis of DNA by the phosphoramidite method. Automated DNA synthesis is conceptually similar to the synthesis of polypeptides on a solid support. The oligonucleotide is built up on the solid support (silica), one nucleotide at a time, in a repeated series of chemical reactions with suitably protected nucleotide precursors.  

1. The first nucleoside (which will be the 3' end) is attached to the silica support at the 3' hydroxyl (through a linking group, R) and is protected at the 5' hydroxyl with an acid-labile dimethoxytrityl group (DMT). The reactive groups on all bases are also chemically protected.  

2. The protecting DMT group is removed by washing the column with acid (the DMT group is colored, so this reaction can be followed spectrophotometrically).  

3. The next nucleotide has a reactive phosphoramidite at its 3' position: a trivalent phosphite (as opposed to the more oxidized pentavalent phosphate normally present in nucleic acids) with one linked oxygen replaced by an amino group or substituted amine. In the common variant shown, one of the phosphoramidite oxygens is bonded to the deoxyribose, the other is protected by a cyanoethyl group, and the third position is occupied by a readily displaced diisopropylamino group. Reaction with the immobilized nucleotide forms a 5',3' linkage, and the diisopropylamino group is eliminated. In step 4, the phosphite linkage is oxidized with iodine to produce a phosphotriester linkage. Reactions 2 through 4 are repeated until all nucleotides are added. At each step, excess nucleotide is removed before addition of the next nucleotide. In steps 5 and 6 the remaining protecting groups on the bases and the phosphates are removed, and in 7 the oligonucleotide is separated from the solid support and purified. The chemical synthesis of RNA is somewhat more complicated because of the need to protect the 2' hydroxyl of ribose without adversely affecting the reactivity of the 3' hydroxyl.
**SUMMARY 8.3 Nucleic Acid Chemistry**

- Native DNA undergoes reversible unwinding and separation of strands (melting) on heating or at extremes of pH. DNAs rich in G=C pairs have higher melting points than DNAs rich in A=T pairs.
- Denatured single-stranded DNAs from two species can form a hybrid duplex, the degree of hybridization depending on the extent of sequence similarity. Hybridization is the basis for important techniques used to study and isolate specific genes and RNAs.
- DNA is a relatively stable polymer. Spontaneous reactions such as deamination of certain bases, hydrolysis of base-sugar N-glycosyl bonds, radiation-induced formation of pyrimidine dimers, and oxidative damage occur at very low rates, yet are important because of a cell's very low tolerance for changes in genetic material.
- DNA sequences can be determined and DNA polymers synthesized with simple, automated protocols involving chemical and enzymatic methods.

### 8.4 Other Functions of Nucleotides

In addition to their roles as the subunits of nucleic acids, nucleotides have a variety of other functions in every cell: as energy carriers, components of enzyme cofactors, and chemical messengers.

**Nucleotides Carry Chemical Energy in Cells**

The phosphate group covalently linked at the 5' hydroxyl of a ribonucleotide may have one or two additional phosphates attached. The resulting molecules are referred to as nucleoside mono-, di-, and triphosphates (Fig. 8-36). Starting from the ribose, the three phosphates are generally labeled α, β, and γ. Hydrolysis of nucleoside triphosphates provides the chemical energy to drive many cellular reactions. Adenosine 5'-triphosphate, ATP, is by far the most widely used for this purpose, but UTP, GTP, and CTP are also used in some reactions. Nucleoside triphosphates also serve as the activated precursors of DNA and RNA synthesis, as described in Chapters 25 and 26.

The energy released by hydrolysis of ATP and the other nucleoside triphosphates is accounted for by the structure of the triphosphate group. The bond between the ribose and the α phosphate is an ester linkage. The α, β and γ linkages are phosphoanhydrides (Fig. 8-37). Hydrolysis of the ester linkage yields about 14 kJ/mol under standard conditions, whereas hydrolysis of each anhydride bond yields about 30 kJ/mol. ATP hydrolysis often plays an important thermodynamic role in biosynthesis. When coupled to a reaction with a positive free-energy change, ATP hydrolysis shifts the equilibrium of the overall process to favor product formation.
(recall the relationship between equilibrium constant and free-energy change described by Eqn 6-3 on p. 188).

**Adenine Nucleotides Are Components of Many Enzyme Cofactors**

A variety of enzyme cofactors serving a wide range of chemical functions include adenosine as part of their structure (Fig. 8–38). They are unrelated structurally except for the presence of adenosine. In none of these cofactors does the adenosine portion participate directly in the primary function, but removal of adenosine generally results in a drastic reduction of cofactor activities. For example, removal of the adenine nucleotide (3’-phosphoadenosine diphosphate) from acetoacetyl-CoA, the coenzyme A derivative of acetoacetate, reduces its reactivity as a substrate for β-ketoacyl-CoA transferase (an enzyme of lipid metabolism) by a factor of $10^6$. Although this requirement for adenosine has not been investigated in detail, it must involve the binding energy between enzyme and substrate (or cofactor) that is used both in catalysis and in stabilizing the initial enzyme-substrate complex (Chapter 6). In the case of β-ketoacyl-CoA transferase, the nucleotide moiety of coenzyme A seems to be a binding “handle” that helps to pull the substrate (acetoacetyl-CoA) into the active site. Similar roles may be found for the nucleoside portion of other nucleotide cofactors.

Why is adenosine, rather than some other large molecule, used in these structures? The answer here may involve a form of evolutionary economy. Adenosine is certainly not unique in the amount of potential binding energy it can contribute. The importance of adenosine probably lies not so much in some special chemical

---

**FIGURE 8–38** Some coenzymes containing adenosine. The adenosine portion is shaded in light red. Coenzyme A (CoA) functions in acyl group transfer reactions; the acyl group (such as the acetyl or acetoacetyl group) is attached to the CoA through a thioester linkage to the β-mercaptoethylamine moiety. NAD+ functions in hydride transfers, and FAD, the active form of vitamin B₂ (riboflavin), in electron transfers. Another coenzyme incorporating adenosine is 5’-deoxyadenosylcobalamain, the active form of vitamin B₁₂ (see Box 17–2), which participates in intramolecular group transfers between adjacent carbons.
characteristic as in the evolutionary advantage of using one compound for multiple roles. Once ATP became the universal source of chemical energy, systems developed to synthesize ATP in greater abundance than the other nucleotides; because it is abundant, it becomes the logical choice for incorporation into a wide variety of structures. The economy extends to protein structure. A single protein domain that binds adenosine can be used in different enzymes. Such a domain, called a nucleotide-binding fold, is found in many enzymes that bind ATP and nucleotide cofactors.

Some Nucleotides Are Regulatory Molecules

Cells respond to their environment by taking cues from hormones or other external chemical signals. The interaction of these extracellular chemical signals (“first messengers”) with receptors on the cell surface often leads to the production of second messengers inside the cell, which in turn leads to adaptive changes in the cell interior (Chapter 12). Often, the second messenger is a nucleotide (Fig. 8-39). One of the most common is adenosine 3′,5′-cyclic monophosphate (cyclic AMP, or cAMP), formed from ATP in a reaction catalyzed by adenylyl cyclase, an enzyme associated with the inner face of the plasma membrane. Cyclic AMP serves regulatory functions in virtually every cell outside the plant kingdom. Guanosine 3′,5′-cyclic monophosphate (cGMP) occurs in many cells and also has regulatory functions.

Another regulatory nucleotide, ppGpp (Fig. 8–39), is produced in bacteria in response to a slowdown in protein synthesis during amino acid starvation. This nucleotide inhibits the synthesis of the rRNA and tRNA molecules (see Fig. 28–24) needed for protein synthesis, preventing the unnecessary production of nucleic acids.

**SUMMARY 8.4 Other Functions of Nucleotides**

- ATP is the central carrier of chemical energy in cells. The presence of an adenosine moiety in a variety of enzyme cofactors may be related to binding-energy requirements.
- Cyclic AMP, formed from ATP in a reaction catalyzed by adenylyl cyclase, is a common second messenger produced in response to hormones and other chemical signals.

**Key Terms**

Terms in bold are defined in the glossary.

- gene 271
- ribosomal RNA (rRNA) 271
- messenger RNA (mRNA) 271
- transfer RNA (tRNA) 271
- nucleotide 271
- nucleoside 272
- pyrimidine 272
- purine 272
- deoxyribonucleotide 273
- ribonucleotide 273
- phosphodiester linkage 275
- 5′ end 275
- 3′ end 275
- oligonucleotide 276
- polynucleotide 276
- base pair 277
- major groove 279
- minor groove 279
- B-form DNA 281
- A-form DNA 281
- Z-form DNA 281
- palindrome 281
- hairpin 282
- cruciform 282
- triplex DNA 282
- G tetraplex 282
- transcription 284
- monocistronic mRNA 284
- polycistronic mRNA 284
- mutation 289
- second messenger 298
- adenosine 3′,5′-cyclic monophosphate (cyclic AMP, cAMP) 298

Variations in DNA Structure

Good summary of the structural properties of quadruplexes.

Nucleic Acid Chemistry

Faster and more powerful DNA sequencing technologies are under development.

ATP as Energy Carrier

A relatively short article, full of insights.

Problems

1. Nucleotide Structure Which positions in the purine ring of a purine nucleotide in DNA have the potential to form hydrogen bonds but are not involved in Watson-Crick base pairing?

2. Base Sequence of Complementary DNA Strands One strand of a double-helical DNA has the sequence (5')GCC-GATATTCTCCTCAAAATTTGC(C3'). Write the base sequence of the complementary strand. What is the potential type of sequence contained in this DNA segment? Does the double-stranded DNA have the potential to form any alternative structures?

3. DNA of the Human Body Calculate the weight in grams of a double-helical DNA molecule stretching from the Earth to the moon (~320,000 km). The DNA double helix weighs about $1 \times 10^{-18}$ g per 1,000 nucleotide pairs; each base pair extends 3.4 Å. For an interesting comparison, your body contains about 0.5 g of DNA!

4. DNA Bending Assume that a poly(A) tract five base pairs long produces a 20° bend in a DNA strand. Calculate the total (net) bend produced in a DNA if the center base pairs (the third of five) of two successive (dA)₅ tracts are located (a) 10 base pairs apart; (b) 15 base pairs apart. Assume 10 base pairs per turn in the DNA double helix.

5. Distinction between DNA Structure and RNA Structure Hairpins may form at palindromic sequences in single strands of either RNA or DNA. How is the helical structure of a long and fully base-paired (except at the end) hairpin in RNA different from that of a similar hairpin in DNA?

6. Nucleotide Chemistry The cells of many eukaryotic organisms have highly specialized systems that specifically repair G-T mismatches in DNA. The mismatch is repaired to form a G=C (not A=T) base pair. This G-T mismatch repair mechanism occurs in addition to a more general system that repairs virtually all mismatches. Can you suggest why cells might require a specialized system to repair G-T mismatches?

7. Spontaneous DNA Damage Hydrolysis of the N-glycosyl bond between deoxyribose and a purine in DNA creates an AP site. An AP site generates a thermodynamic destabilization greater than that created by any DNA mismatched base pair. This effect is not completely understood. Examine the structure of an AP site (see Fig. 8-33b) and describe some chemical consequences of base loss.

8. Nucleic Acid Structure Explain why the absorption of UV light by double-stranded DNA increases (the hyperchromic effect) when the DNA is denatured.

9. Determination of Protein Concentration in a Solution Containing Proteins and Nucleic Acids The concentration of protein or nucleic acid in a solution containing both can be estimated by using their different light absorption properties: proteins absorb most strongly at 280 nm and nucleic acids at 260 nm. Estimates of their respective concentrations in a mixture can be made by measuring the absorbance (A) of the solution at 280 and 260 nm and using the table on page 300, which gives $R_{280/260}$, the ratio of absorbances at 280 and 260 nm; the percentage of total mass that is nucleic acid; and a factor, F, that corrects the $A_{280}$ reading and gives a more accurate protein concentration.
The protein concentration (in mg/mL) = \( F \times A_{280} \) (assuming the cuvette is 1 cm wide). Calculate the protein concentration in a solution of \( A_{280} = 0.69 \) and \( A_{280} = 0.94 \).

10. Solubility of the Components of DNA

Draw the following structures and rate their relative solubilities in water (most soluble to least soluble): deoxyribose, guanine, phosphate. How are these solubilities consistent with the three-dimensional structure of double-stranded DNA?

11. Sanger Sequencing Logic

In the Sanger (dideoxy) method for DNA sequencing, a small amount of a dideoxynucleotide triphosphate—say, ddCTP—is added to the sequencing reaction along with a larger amount of the corresponding dCTP. What result would be observed if the dCTP were omitted?

12. DNA Sequencing

The following DNA fragment was sequenced by the Sanger method. The red asterisk indicates a fluorescent label.

\[ \text{5'- ATTACGCAAGGACATTAGAC-3'} \]

A sample of the DNA was reacted with DNA polymerase and each of the nucleotide mixtures (in an appropriate buffer) listed below. Dideoxynucleotides (ddNTPs) were added in relatively small amounts.

1. dATP, dTTP, dCTP, dGTP, ddTTP
2. dATP, dTTP, dCTP, dGTP, ddGTP
3. dATP, dCTP, dGTP, ddTTP
4. dATP, dTTP, dCTP, dGTP

The resulting DNA was separated by electrophoresis on an agarose gel, and the fluorescent bands on the gel were located. The band pattern resulting from nucleotide mixture 1 is shown below. Assuming that all mixtures were run on the same gel, what did the remaining lanes of the gel look like?

13. Snake Venom Phosphodiesterase

An exonuclease is an enzyme that sequentially cleaves nucleotides from the end of a polynucleotide strand. Snake venom phosphodiesterase, which hydrolyzes nucleotides from the 3’ end of any oligonucleotide with a free 3’-hydroxyl group, cleaves between the 3’ hydroxyl of the ribose or deoxyribose and the phosphoryl group of the next nucleotide. It acts on single-stranded DNA or RNA and has no base specificity. This enzyme was used in sequence determination experiments before the development of modern nucleic acid sequencing techniques. What are the products of partial digestion by snake venom phosphodiesterase of an oligonucleotide with the following sequence?

\[ (5') GCGCCAUUGC(3') - OH \]

(b) One factor that prevents potential DNA damage in spores is their greatly decreased water content. How would this affect some types of mutations?

(b) Endospores have a category of proteins called small acid-soluble proteins (SASPs) that bind to their DNA, preventing formation of cyclobutane-type dimers. What causes cyclobutane dimers, and why do bacterial endospores need mechanisms to prevent their formation?
15. Oligonucleotide Synthesis In the scheme of Figure 8–35, each new base to be added to the growing oligonucleotide is modified so that its 3’ hydroxyl is activated and the 5’ hydroxyl has a dimethoxytrityl (DMT) group attached. What is the function of the DMT group on the incoming base?

Biochemistry on the Internet

16. The Structure of DNA Elucidation of the three-dimensional structure of DNA helped researchers understand how this molecule conveys information that can be faithfully replicated from one generation to the next. To see the secondary structure of double-stranded DNA, go to the Protein Data Bank website (www.rcsb.org). Use the PDB identifiers listed below to retrieve the structure summaries for the two forms of DNA. Open the structures using Jmol (linked under the Display Options), and use the controls in the Jmol menu to complete the following exercises. Refer to the Jmol help links as needed.

(a) Obtain the file for 141D, a highly conserved, repeated DNA sequence from the end of the HIV-1 (the virus that causes AIDS) genome. Display the molecule as a ball-and-stick structure (in the control menu, choose Select > All, then Render > Scheme > Ball and Stick). Identify the sugar–phosphate backbone for each strand of the DNA duplex. Locate and identify individual bases. Identify the 5’ end of each strand. Locate the major and minor grooves. Is this a right- or left-handed helix?

(b) Obtain the file for 145D, a DNA with the Z conformation. Display the molecule as a ball-and-stick structure. Identify the sugar–phosphate backbone for each strand of the DNA duplex. Is this a right- or left-handed helix?

(c) To fully appreciate the secondary structure of DNA, view the molecules in stereo. On the control menu, Select > All, then Render > Stereographic > Cross-eyed or Wall-eyed. You will see two images of the DNA molecule. Sit with your nose approximately 10 inches from the monitor and focus on the tip of your nose (cross-eyed) or the opposite edges of the screen (wall-eyed). In the background you should see three images of the DNA helix. Shift your focus to the middle image, which should appear three-dimensional. (Note that only one of the two authors can make this work.)

Data Analysis Problem

17. Chargaff’s Studies of DNA Structure The chapter section “DNA Is a Double Helix that Stores Genetic Information” includes a summary of the main findings of Erwin Chargaff and his coworkers, listed as four conclusions (“Chargaff’s rules”; p. 278). In this problem, you will examine the data Chargaff collected in support of these conclusions.

In one paper, Chargaff (1950) described his analytical methods and some early results. Briefly, he treated DNA samples with acid to remove the bases, separated the bases by paper chromatography, and measured the amount of each base with UV spectroscopy. His results are shown in the three tables below. The molar ratio is the ratio of the number of moles of each base in the sample to the number of moles of phosphate in the sample—this gives the fraction of the total number of bases represented by each particular base. The recovery is the sum of all four bases (the sum of the molar ratios); full recovery of all bases in the DNA would give a recovery of 1.0.

(a) Based on these data, Chargaff concluded that “no differences in composition have so far been found in DNA from different tissues of the same species.” This corresponds to conclusion 2 in this chapter. However, a skeptic looking at the data above might say, “They certainly look different to me!” If you were Chargaff, how would you use the data to convince the skeptic to change her mind?

(b) The base composition of DNA from normal and cancerous liver cells (hepatocarcinoma) was not distinguishably different. Would you expect Chargaff’s technique to be capable of detecting a difference between the DNA of normal and cancerous cells? Explain your reasoning.

As you might expect, Chargaff’s data were not completely convincing. He went on to improve his techniques, as described...
in a later paper (Chargaff, 1951), in which he reported molar ratios of bases in DNA from a variety of organisms:

(c) According to Chargaff, as stated in conclusion 1 in this chapter, "The base composition of DNA generally varies from one species to another." Provide an argument, based on the data presented so far, that supports this conclusion.

(d) According to conclusion 4, "In all cellular DNAs, regardless of the species ... A + G = T + C." Provide an argument, based on the data presented so far, that supports this conclusion.

Part of Chargaff's intent was to disprove the "tetranucleotide hypothesis"; this was the idea that DNA was a monotonous tetranucleotide polymer (AGCT)$_n$ and therefore not capable of containing sequence information. Although the data presented above show that DNA cannot be simply a tetranucleotide—if so, all samples would have molar ratios of 0.25 for each base—it was still possible that the DNA from different organisms was a slightly more complex, but still monotonous, repeating sequence.

To address this issue, Chargaff took DNA from wheat germ and treated it with the enzyme deoxyribonuclease for different time intervals. At each time interval, some of the DNA was converted to small fragments; the remaining, larger fragments he called the "core." In the table below, the "19% core" corresponds to the larger fragments left behind when 81% of the DNA was degraded; the "8% core" corresponds to the larger fragments left after 92% degradation.

<table>

9.1 DNA Cloning: The Basics 304
9.2 From Genes to Genomes 315
9.3 From Genomes to Proteomes 324
9.4 Genome Alterations and New Products of Biotechnology 330

We now turn to a technology that is fundamental to the advance of modern biological sciences, defining present and future biochemical frontiers and illustrating many important principles of biochemistry. Elucidation of the laws governing enzymatic catalysis, macromolecular structure, cellular metabolism, and information pathways allows research to be directed at increasingly complex biochemical processes. Cell division, immunity, embryogenesis, vision, taste, oncogenesis, cognition—all are orchestrated in an elaborate symphony of molecular and macromolecular interactions that we are now beginning to understand with increasing clarity. The real implications of the biochemical journey begun in the nineteenth century are found in the ever-increasing power to analyze and alter living systems.

To understand a complex biological process, a biochemist isolates and studies the individual components in vitro, then pieces together the parts to get a coherent picture of the overall process. A major source of molecular insights is the cell’s own information archive, its DNA. The sheer size of chromosomes, however, presents an enormous challenge: how does one find and study a particular gene among the tens of thousands of genes nested in the billions of base pairs of a mammalian genome? Solutions began to emerge in the 1970s.

Decades of advances by thousands of scientists working in genetics, biochemistry, cell biology, and physical chemistry came together in the laboratories of Paul Berg, Herbert Boyer, and Stanley Cohen to yield techniques for locating, isolating, preparing, and studying small segments of DNA derived from much larger chromosomes. Techniques for DNA cloning paved the way to the modern fields of genomics and proteomics, the study of genes and proteins on the scale of whole cells and organisms. These new methods are transforming basic research, agriculture, medicine, ecology, forensics, and many other fields, while occasionally presenting society with difficult choices and ethical dilemmas.

We begin this chapter with an outline of the fundamental biochemical principles of the now-classic discipline of DNA cloning. Next, we illustrate the range of applications and the potential of a range of newer technologies, with a broad emphasis on modern advances in genomics and proteomics.
9.1 DNA Cloning: The Basics

A clone is an identical copy. This term originally applied to cells of a single type, isolated and allowed to reproduce to create a population of identical cells. DNA cloning involves separating a specific gene or DNA segment from a larger chromosome, attaching it to a small molecule of carrier DNA, and then replicating this modified DNA thousands or millions of times through both an increase in host cell number and the creation of multiple copies of the cloned DNA in each cell. The result is selective amplification of a particular gene or DNA segment. Cloning of DNA from any organism entails five general procedures:

1. Cutting DNA at precise locations. Sequence-specific endonucleases (restriction endonucleases) provide the necessary molecular scissors.

2. Selecting a small molecule of DNA capable of self-replication. These DNAs are called cloning vectors (a vector is a delivery agent). They are typically plasmids or viral DNAs.

3. Joining two DNA fragments covalently. The enzyme DNA ligase links the cloning vector and DNA to be cloned. Composite DNA molecules comprising covalently linked segments from two or more sources are called recombinant DNAs.

4. Moving recombinant DNA from the test tube to a host cell that will provide the enzymatic machinery for DNA replication.

5. Selecting or identifying host cells that contain recombinant DNA.

The methods used to accomplish these and related tasks are collectively referred to as recombinant DNA technology or, more informally, genetic engineering.

Much of our initial discussion will focus on DNA cloning in the bacterium Escherichia coli, the first organism used for recombinant DNA work and still the most common host cell. *E. coli* has many advantages: its DNA metabolism (like many other of its biochemical processes) is well understood; many naturally occurring cloning vectors associated with *E. coli*, such as plasmids and bacteriophages (bacterial viruses; also called phages), are well characterized; and techniques are available for moving DNA expeditiously from one bacterial cell to another. The principles discussed here are broadly applicable to DNA cloning in other organisms, a topic discussed more fully later in the chapter.

Restriction Endonucleases and DNA Ligase Yield Recombinant DNA

Particularly important to recombinant DNA technology is a set of enzymes (Table 9-1) made available through decades of research on nucleic acid metabolism. Two classes of enzymes lie at the heart of the classic approach to generating and propagating a recombinant DNA molecule (Fig. 9-1). First, restriction endonucleases (also called restriction enzymes) recognize and cleave DNA at specific sequences (recognition sequences or restriction sites) to generate a set of smaller fragments. Second, the DNA fragment to be cloned is joined to a suitable cloning vector by using DNA ligases to link the DNA molecules together. The recombinant vector is then introduced into a host cell, which amplifies the fragment in the course of many generations of cell division.

Restriction endonucleases are found in a wide range of bacterial species. Werner Arber discovered in the early 1960s that their biological function is to recognize and cleave foreign DNA (the DNA of an infecting virus,
for example); such DNA is said to be restricted. In the host cell’s DNA, the sequence that would be recognized by its own restriction endonuclease is protected from digestion by methylation of the DNA, catalyzed by a specific DNA methylase. The restriction endonuclease and the corresponding methylase are sometimes referred to as a restriction-modification system.

There are three types of restriction endonucleases, designated I, II, and III. Types I and III are generally large, multisubunit complexes containing both the endonuclease and methylase activities. Type I restriction endonucleases cleave DNA at random sites that can be more than 1,000 base pairs (bp) from the recognition sequence. Type III restriction endonucleases cleave the DNA about 25 bp from the recognition sequence. Both types move along the DNA in a reaction that requires the energy of ATP. Type II restriction endonucleases, first isolated by Hamilton Smith in 1970, are simpler, require no ATP, and cleave the DNA within the recognition sequence itself. The extraordinary utility of this group of restriction endonucleases was demonstrated by Daniel Nathans, who first used them to develop novel methods for mapping and analyzing genes and genomes.

Thousands of restriction endonucleases have been discovered in different bacterial species, and more than 100 different DNA sequences are recognized by one or more of these enzymes. The recognition sequences are usually 4 to 6 bp long and palindromic (see Fig. 8-18). Table 9–2 lists sequences recognized by a few type II restriction endonucleases.

Arrows indicate the phosphodiester bonds cleaved by each restriction endonuclease. Asterisks indicate bases that are methylated by the corresponding methylase (where known). N denotes any base. Note that the name of each enzyme consists of a three-letter abbreviation (in italics) of the bacterial species from which it is derived, sometimes followed by a strain designation and Roman numerals to distinguish different restriction endonucleases isolated from the same bacterial species. Thus *BamHI* is the first (I) restriction endonuclease characterized from *Bacillus amyloliquefaciens*, strain H.
Some restriction endonucleases make staggered cuts on the two DNA strands, leaving two to four nucleotides of one strand unpaired at each resulting end. These unpaired strands are referred to as sticky ends (Fig. 9-2a), because they can base-pair with each other or with complementary sticky ends of other DNA fragments. Other restriction endonucleases cleave both strands of DNA at the opposing phosphodiester bonds, leaving no unpaired bases on the ends, often called blunt ends (Fig. 9-2b).

The average size of the DNA fragments produced by cleaving genomic DNA with a restriction endonuclease depends on the frequency with which a particular restriction site occurs in the DNA molecule; this in turn depends largely on the size of the recognition sequence.

In a DNA molecule with a random sequence in which all four nucleotides were equally abundant, a 6 bp sequence recognized by a restriction endonuclease such as BamHI would occur on average once every $4^6 (4,096)$ bp, assuming the DNA had a 50% G=C content. Enzymes that recognize a 4 bp sequence would produce smaller DNA fragments from a random-sequence DNA molecule; a recognition sequence of this size would be expected to occur about once every $4^4 (256)$ bp. In natural DNA molecules, particular recognition sequences tend to occur less frequently than this because nucleotide sequences in DNA are not random and the four nucleotides are not equally abundant. In laboratory experiments, the average size of the fragments produced by restriction endonuclease cleavage of a large DNA

![Diagram of DNA molecules cleaved by restriction endonucleases.](https://example.com/diagram.png)

**FIGURE 9-2 Cleavage of DNA molecules by restriction endonucleases.**
Restriction endonucleases recognize and cleave only specific sequences, leaving either (a) sticky ends (with protruding single strands) or (b) blunt ends. Fragments can be ligated to other DNAs, such as the cleaved cloning vector (a plasmid) shown here. This reaction is facilitated by the annealing of complementary sticky ends; ligation is less efficient for DNA fragments with blunt ends than for those with complementary sticky ends, and DNA fragments with different (non-complementary) sticky ends generally are not ligated. (c) A synthetic DNA fragment with recognition sequences for several restriction endonucleases can be inserted into a plasmid that has been cleaved by a restriction endonuclease. The insert is called a linker, an insert with multiple restriction sites is called a polylinker. 

---

**Restriction Enzymes**
can be increased by simply terminating the reaction before completion; the result is called a partial digest. Fragment size can also be increased by using a special class of endonucleases called homing endonucleases (see Fig. 26-38). These recognize and cleave much longer DNA sequences (14 to 20 bp).

Fragment size can also be increased by using a special class of endonucleases called homing endonucleases (see Fig. 26-38). These recognize and cleave much longer DNA sequences (14 to 20 bp).

Once a DNA molecule has been cleaved into fragments, a particular fragment of known size can be enriched by agarose or acrylamide gel electrophoresis or by HPLC (pp. 89, 88). For a typical mammalian genome, however, cleavage by a restriction endonuclease usually yields too many different DNA fragments to permit convenient isolation of a particular fragment. A common intermediate step in the cloning of a specific gene or DNA segment is the construction of a DNA library (described in Section 9.2).

After the target DNA fragment is isolated, DNA ligase can be used to join it to a similarly digested cloning vector—that is, a vector digested by the same restriction endonuclease; a fragment generated by EcoRI, for example, generally will not link to a fragment generated by BamHI. As described in more detail in Chapter 25 (see Fig. 25-17), DNA ligase catalyzes the formation of new phosphodiester bonds in a reaction that uses ATP or a similar cofactor. The base pairing of complementary sticky ends greatly facilitates the ligation reaction (Fig. 9-2a). Blunt ends can also be ligated, albeit less efficiently. Researchers can create new DNA sequences by inserting synthetic DNA fragments (called linkers) between the ends that are being ligated. Inserted DNA fragments with multiple recognition sequences for restriction endonucleases (often useful later as points for inserting additional DNA by cleavage and ligation) are called polylinkers (Fig. 9-2c).

The effectiveness of sticky ends in selectively joining two DNA fragments was apparent in the earliest recombinant DNA experiments. Before restriction endonucleases were widely available, some workers found they could generate sticky ends by the combined action of the bacteriophage λ exonuclease and terminal transferase (Table 9-1). The fragments to be joined were given complementary homopolymeric tails. Peter Lobban and Dale Kaiser used this method in 1971 in the first experiments to join naturally occurring DNA fragments. Similar methods were used soon after in the laboratory of Paul Berg to join DNA segments from simian virus 40 (SV40) to DNA derived from bacteriophage λ, thereby creating the first recombinant DNA molecule with DNA segments from different species.

**Cloning Vectors Allow Amplification of Inserted DNA Segments**

The principles that govern the delivery of recombinant DNA in clonable form to a host cell, and its subsequent amplification in the host, are well illustrated by considering three popular cloning vectors commonly used in experiments with *E. coli*—plasmids, bacteriophages, and bacterial artificial chromosomes—and a vector used to clone large DNA segments in yeast.

**Plasmids**  Plasmids are circular DNA molecules that replicate separately from the host chromosome. Naturally occurring bacterial plasmids range in size from 5,000 to 400,000 bp. They can be introduced into bacterial cells by a process called **transformation**. The cells (generally *E. coli*) and plasmid DNA are incubated together at 0 °C in a calcium chloride solution, then subjected to a shock by rapidly shifting the temperature to 37 to 43 °C. For reasons not well understood, some of the cells treated in this way take up the plasmid DNA. Some species of bacteria, such as *Acinetobacter baylyi*, are naturally competent for DNA uptake and do not require the calcium chloride treatment. In an alternative method, cells incubated with the plasmid DNA are subjected to a high-voltage pulse. This approach, called **electroporation**, transiently renders the bacterial membrane permeable to large molecules.

Regardless of the approach, few cells actually take up the plasmid DNA, so a method is needed to select those that do. The usual strategy is to use a plasmid that includes a gene that the host cell requires for growth under specific conditions, such as a gene that confers resistance to an antibiotic. Only cells transformed by the recombinant plasmid can grow in the presence of that antibiotic, making any cell that contains the plasmid "selectable" under those growth conditions. Such a gene is called a selectable marker.

Investigators have developed many different plasmid vectors suitable for cloning by modifying naturally occurring plasmids. The now classic *E. coli* plasmid pBR322 offers a good example of the features useful in a cloning vector (Fig. 9-3).

**FIGURE 9-3** The constructed *E. coli* plasmid pBR322. Note the location of some important restriction sites—for *PstI*, EcoRI, BamHI, *SalI*, and *PvuII*; ampicillin- and tetracycline-resistance genes; and the replication origin (ori). Constructed in 1977, this was one of the early plasmids designed expressly for cloning in *E. coli*.
Important pBR322 features include:

1. An origin of replication, ori, a sequence where replication is initiated by cellular enzymes (Chapter 25). This sequence is required to propagate the plasmid and maintain it at a level of 10 to 20 copies per cell.

2. Two genes that confer resistance to different antibiotics (tetR, ampR), allowing the identification of cells that contain the intact plasmid or a recombinant version of the plasmid (Fig. 9-4).

3. Several unique recognition sequences (PstI, EcoRI, BamHI, Sall, PvuII) that are targets for different restriction endonucleases, providing sites where the plasmid can later be cut to insert foreign DNA.

4. Small size (4,361 bp), which facilitates entry of the plasmid into cells and the biochemical manipulation of the DNA.

Transformation of typical bacterial cells with purified DNA (never a very efficient process) becomes less successful as plasmid size increases, and it is difficult to clone DNA segments longer than about 15,000 bp when plasmids are used as the vector.

**Bacteriophages**  Bacteriophage λ has a very efficient mechanism for delivering its 48,502 bp of DNA into a bacterium, and it can be used as a vector to clone somewhat larger DNA segments (Fig. 9-5). Two key features contribute to its utility:

1. About one-third of the λ genome is nonessential and can be replaced with foreign DNA.

2. DNA is packaged into infectious phage particles only if it is between 40,000 and 53,000 bp long, a constraint that can be used to ensure packaging of recombinant DNA only.

Researchers have developed bacteriophage λ vectors that can be readily cleaved into three pieces, two of which contain essential genes but which together are only about 30,000 bp long. The third piece, “filler” DNA, is discarded when the vector is to be used for cloning, and additional DNA is inserted between the two essential segments to generate ligated DNA molecules long enough to produce viable phage particles. In effect, the packaging mechanism selects for recombinant viral DNAs.

Bacteriophage λ vectors permit the cloning of DNA fragments of up to 23,000 bp. Once the bacteriophage λ fragments are ligated to foreign DNA fragments of suitable size, the resulting recombinant DNAs can be packaged into phage particles by adding them to crude bacterial cell extracts that contain all the proteins needed to assemble a complete phage. This is called **in vitro packaging** (Fig. 9-5). All viable phage particles will contain a foreign DNA fragment. The subsequent transmission of the recombinant DNA into E. coli cells is highly efficient.
Recombinant DNAs

Bacteriophage cloning vectors. Recombinant DNA methods are used to modify the bacteriophage \( \lambda \) genome, removing the genes not needed for phage production and replacing them with "filler" DNA to make the phage DNA large enough for packaging into phage particles. As shown here, the filler is replaced with foreign DNA in cloning experiments. Recombinants are packaged into viable phage particles in vitro only if they include an appropriately sized foreign DNA fragment as well as both of the essential \( \lambda \) DNA end fragments.

Bacterial Artificial Chromosomes (BACs) Bacterial artificial chromosomes are simply plasmids designed for the cloning of very long segments (typically 100,000 to 300,000 bp) of DNA (Fig. 9-6). They generally include selectable markers such as resistance to the antibiotic chloramphenicol (Cm\(^R\)), as well as a very stable origin of replication (ori) that maintains the plasmid at one or two copies per cell. DNA fragments of several hundred thousand base pairs are cloned into the BAC vector. The large circular DNAs are then introduced into host bacteria by electroporation. These procedures use host bacteria with mutations that compromise the structure of their cell wall, permitting the uptake of the large DNA molecules.

Bacterial artificial chromosomes (BACs) as cloning vectors. The vector is a relatively simple plasmid, with a replication origin (ori) that directs replication. The \( \bar{p} \)par genes, derived from a type of plasmid called an F plasmid, assist in the even distribution of plasmids to daughter cells at cell division. This increases the likelihood of each daughter cell carrying one copy of the plasmid, even when few copies are present. The low number of copies is useful in cloning large segments of DNA because it limits the opportunities for unwanted recombination reactions that can unpredictably alter large cloned DNAs over time. The BAC includes selectable markers. A lac\( \bar{Z} \) gene (required for the production of the enzyme \( \beta \)-galactosidase) is situated in the cloning region such that it is inactivated by cloned DNA inserts. Introduction of recombinant BACs into cells by electroporation is promoted by the use of cells with an altered (more porous) cell wall. Recombinant DNAs are screened for resistance to the antibiotic chloramphenicol (Cm\(^R\)). Plates also contain a substrate for \( \beta \)-galactosidase that yields a colored product. Colonies with active \( \beta \)-galactosidase and hence no DNA insert in the BAC vector turn blue; colonies without \( \beta \)-galactosidase activity—and thus with the desired DNA inserts—are white.
**Yeast Artificial Chromosomes (YACs)**  
*E. coli* cells are by no means the only hosts for genetic engineering. Yeasts are particularly convenient eukaryotic organisms for this work. As with *E. coli*, yeast genetics is a well-developed discipline. The genome of the most commonly used yeast, *Saccharomyces cerevisiae*, contains only $14 \times 10^6$ bp (a simple genome by eukaryotic standards, less than four times the size of the *E. coli* chromosome), and its entire sequence is known. Yeast is also very easy to maintain and grow on a large scale in the laboratory. Plasmid vectors have been constructed for yeast, employing the same principles that govern the use of *E. coli* vectors described above. Convenient methods are now available for moving DNA into and out of yeast cells, facilitating the study of many aspects of eukaryotic cell biochemistry. Some recombinant plasmids incorporate multiple replication origins and other elements that allow them to be used in more than one species (for example, yeast or *E. coli*). Plasmids that can be propagated in cells of two or more different species are called **shuttle vectors**.

Research with large genomes and the associated need for high-capacity cloning vectors led to the development of **yeast artificial chromosomes (YACs)**. YAC vectors contain all the elements needed to maintain a eukaryotic chromosome in the yeast nucleus: a yeast origin of replication, two selectable markers, and specialized sequences (derived from the telomeres and centromere, regions of the chromosome discussed in Chapter 24) needed for stability and proper segregation of the chromosomes at cell division. Before being used in cloning, the vector is propagated as a circular bacterial plasmid. Cleavage with a restriction endonuclease (*BamHI* in Fig. 9–7) removes a length of DNA between two telomere sequences (TEL), leaving the telomeres at the ends of the linearized DNA. Cleavage at another internal site (*EcoRI* in Fig. 9–7) divides the vector into two DNA segments, referred to as vector arms, each with a different selectable marker.

The genomic DNA is prepared by partial digestion with restriction endonucleases (*EcoRI* in Fig. 9–7) to obtain a suitable fragment size. Genomic fragments are then separated by **pulsed field gel electrophoresis**, a variation of gel electrophoresis (see Fig. 3–18) that allows the separation of very large DNA segments. The DNA fragments of appropriate size (up to about $2 \times 10^6$ bp) are mixed with the prepared vector arms and ligated. The ligation mixture is then used to transform treated yeast cells with very large DNA molecules. Culture on a medium that requires the presence of both selectable marker genes ensures the growth of only those yeast cells that contain an artificial chromosome with a large insert sandwiched between the two vector arms (Fig. 9–7). The stability of YAC clones increases with size (up to a point). Those with inserts of more than 150,000 bp are nearly as stable as normal cellular chromosomes, whereas those with inserts of less than 100,000 bp are gradually lost during mitosis (so generally there are no yeast cell clones carrying only the two vector ends ligated together or with only short inserts). YACs that lack a telomere at either end are rapidly degraded.

**Specific DNA Sequences Are Detectable by Hybridization**  
DNA hybridization, a process outlined in Chapter 8 (see Fig. 8–29), is the most common sequence-based process for detecting a particular gene or segment of nucleic acid. There are many variations of the basic method, most making use of a labeled (such as radioactive) DNA.
or RNA fragment, known as a **probe**, complementary to the DNA being sought. In one classic approach to detect a particular DNA sequence within a DNA library (a collection of DNA clones), nitrocellulose paper is pressed onto an agar plate containing many individual bacterial colonies from the library, each colony with a different recombinant DNA. Some cells from each colony adhere to the paper, forming a replica of the plate. The paper is treated with alkali to disrupt the cells and denature the DNA within, which remains bound to the region of the paper around the colony from which it came. Added radioactive DNA probe anneals only to its complementary DNA. After any unannealed probe DNA is washed away, the hybridized DNA can be detected by autoradiography (Fig. 9–8).

A common limiting step in detecting and cloning a gene is the generation of a complementary strand of nucleic acid to use as a probe. The origin of a probe depends on what is known about the gene under investigation. Sometimes a homologous gene cloned from another species makes a suitable probe. Or, if the protein product of a gene has been purified, probes can be designed and synthesized by working backward from the amino acid sequence, deducing the DNA sequence that would code for it (Fig. 9–9). Now, researchers typically obtain the necessary DNA sequence information from sequence databases that detail the structure of millions of genes from a wide range of organisms.

**FIGURE 9–8** Use of **hybridization** to identify a clone with a particular DNA **segment**. The radioactive DNA probe hybridizes to complementary DNA and is revealed by autoradiography. Once the labeled colonies have been identified, the corresponding colonies on the original agar plate can be used as a source of cloned DNA for further study.

**FIGURE 9–9** **Probe to detect the gene for a protein of known amino acid sequence.** Because more than one DNA sequence can code for any given amino acid sequence, the genetic code is said to be “degenerate.” (As described in Chapter 27, an amino acid is coded for by a set of three nucleotides called a **codon**. Most amino acids have two or more codons; see Fig. 27–7.) Thus the correct DNA sequence for a known amino acid sequence cannot be known in advance. The probe is designed to be complementary to a region of the gene with minimal degeneracy, that is, a region with the fewest possible codons for the amino acids—two codons at most in the example shown here. Oligonucleotides are synthesized with selectively randomized sequences, so that they contain either of the two possible nucleotides at each position of potential degeneracy (shaded in pink). The oligonucleotide shown here represents a mixture of eight different sequences: one of the eight will complement the gene perfectly, and all eight will match at least 17 of the 20 positions.

Expression of Cloned Genes Produces Large Quantities of Protein

Frequently it is the product of the cloned gene, rather than the gene itself, that is of primary interest—particularly when the protein has commercial, therapeutic, or research value. With an increased understanding of the fundamentals of DNA, RNA, and protein metabolism and their regulation in E. coli, investigators can now manipulate cells to express cloned genes in order to study their protein products.

Most eukaryotic genes lack the DNA sequence elements—such as promoters, sequences that instruct RNA polymerase where to bind—required for their expression in E. coli cells, so bacterial regulatory sequences for transcription and translation must be inserted at appropriate positions relative to the eukaryotic gene in the vector DNA. (Promoters, regulatory sequences, and other aspects of the regulation of gene expression are discussed in Chapter 28.) In some cases cloned genes are so efficiently expressed that their protein product represents 10% or more of the cellular protein; they are said to be overexpressed. At these concentrations some foreign proteins can kill an E. coli cell, so gene expression must be limited to the few hours before the planned harvest of the cells.

Cloning vectors with the transcription and translation signals needed for the regulated expression of a cloned gene are often called expression vectors. These contain the transcription and translation elements-such as promoters, sequences that instruct RNA polymerase where to bind—and sequences required for efficient translation of the mRNA derived from the gene. The selectable marker allows the selection of cells containing the recombinant DNA.

Alterations in Cloned Genes Produce Modified Proteins

Cloning techniques can be used not only to overproduce proteins but to produce protein products subtly altered from their native forms. Specific amino acids may be replaced individually by site-directed mutagenesis. This powerful approach to studying protein structure and function changes the amino acid sequence of a protein by altering the DNA sequence of the cloned gene. If appropriate restriction sites flank the sequence to be altered, researchers can simply remove a DNA segment and replace it with a synthetic one that is identical to the original except for the desired change (Fig. 9-11a). When suitably located restriction sites are not present, an approach called oligonucleotide-directed mutagenesis (Fig. 9-11b) can create a specific DNA sequence change. A short synthetic DNA strand with a specific base change is annealed to a single-stranded copy of the cloned gene within a suitable vector. The mismatch of a single base pair in 15 to 20 bp does not prevent annealing if it is done at an appropriate temperature. The annealed strand serves as a primer for the synthesis of a strand complementary to the plasmid vector. This slightly mismatched duplex recombinant plasmid is then used to transform bacteria, where the mismatch is repaired by cellular DNA repair enzymes (Chapter 25). About half of the repair events will remove and replace the altered base and restore the gene to its original sequence; the other half will remove and replace the normal base, retaining the desired mutation. Transformants are screened (often by sequencing their plasmid DNA) until a bacterial colony containing a plasmid with the altered sequence is found.

Changes can also be introduced that involve more than one base pair. Large parts of a gene can be deleted by cutting out a segment with restriction endonucleases...
DNA ligase

In E. coli cells, about half the plasmids will have gene with desired base-pair change.

(b)

FIGURE 9-11 Two approaches to site-directed mutagenesis. (a) A synthetic DNA segment replaces a DNA fragment that has been removed by cleavage with a restriction endonuclease. (b) A synthetic oligonucleotide with a desired sequence change at one position is hybridized to a single-stranded copy of the gene to be altered. This acts as primer for synthesis of a duplex DNA (with one mismatch), which is then used to transform cells. Cellular DNA repair systems will convert about 50% of the mismatches to reflect the desired sequence change.

and ligating the remaining portions to form a smaller gene. Parts of two different genes can be ligated to create new combinations. The product of such a fused gene is called a fusion protein.

Researchers now have ingenious methods to bring about virtually any genetic alteration in vitro. Reintroduction of the altered DNA into the cell permits investigation of the consequences of the alteration. Site-directed mutagenesis has greatly facilitated research on proteins by allowing investigators to make specific changes in the primary structure of a protein and to examine the effects of these changes on the folding, three-dimensional structure, and activity of the protein.

Terminal Tags Provide Binding Sites for Affinity Purification

Affinity chromatography is one of the most efficient methods available for protein purification (see Fig. 3–17c). Unfortunately, there are many proteins for which there is no known ligand that can be conveniently immobilized on a chromatographic medium. The use of fusion proteins has made it possible to purify almost any protein by affinity chromatography.

First, the gene encoding the target protein is fused to a gene encoding a peptide or protein that binds to a known ligand with high affinity and specificity. The peptide or protein used for this purpose, which may be attached at either the amino or carboxyl terminus, is called a terminal tag or (more often) simply a tag. Some proteins and peptides commonly used as tags are listed in Table 9–3 along with their ligands.

The general procedure is illustrated by the attachment of a tag consisting of glutathione-S-transferase (GST). GST is a small enzyme (M, 26,000) that binds tightly and specifically to the molecule glutathione (Figs 9–12). If the GST gene sequence is fused to a target gene, the fusion protein acquires the capacity to bind glutathione. The fusion protein is expressed in a bacterial or other host organism, and a crude extract is prepared. A column is filled with a porous matrix consisting of the ligand (in this case, glutathione) immobilized to microscopic beads of a stable polymer such as cross-linked agarose. As the crude extract percolates through this column matrix, the fusion protein becomes immobilized by binding to the glutathione. The other

Glutathione-S-transferase (GST)

**(a)** Glutathione (GSH)

**(b)** The use of tagged proteins in protein purification. The use of a GST tag is illustrated. (a) Glutathione-S-transferase (GST) is a small enzyme (depicted here by the purple icon) that binds glutathione (a glutamate residue to which a Cys-Gly dipeptide is attached at the carboxyl carbon of the Glu side chain, hence the abbreviation GSH). (b) The GST tag is fused to the carboxyl terminus of the target protein by genetic engineering. The tagged protein is expressed in host cells, and is present in the crude extract when the cells are lysed. The extract is subjected to chromatography on a column containing a medium with immobilized glutathione. The GST-tagged protein binds to the glutathione, retarding its migration through the column, while the other proteins wash through rapidly. The tagged protein is subsequently eluted from the column with a solution containing elevated salt concentration or free glutathione.

A short tag with widespread application consists of a simple sequence of six or more histidine residues. These histidine tags or His tags, as they are more commonly known, bind tightly and specifically to nickel ions. Chromatography media with immobilized Ni\(^{2+}\) can then be used to efficiently separate His-tagged proteins from others in an extract. Larger tags, such as maltose-binding protein, can enhance solubility and compensate for lack of stability in target proteins, allowing the purification of proteins that cannot be purified by other methods.

Tag technology is powerful and convenient, and has been used successfully in thousands of published studies. However, one must be wary when using tagged proteins in experiments. Terminal tags are not inert. Even very small tags can affect the properties of the proteins to which they are attached and thus affect experimental results. Activity may be affected even when tags are removed by proteases, if one or a few extra amino acid residues remain associated with the target protein. Results obtained from tagged proteins should always be evaluated with the aid of well-designed controls to assess the effect of the tag on protein function.

**SUMMARY 9.1 DNA Cloning: The Basics**

- DNA cloning and genetic engineering involve the cleavage of DNA and assembly of DNA segments in new combinations—recombinant DNA.
- Cloning entails cutting DNA into fragments with enzymes; selecting and possibly modifying a fragment of interest; inserting the DNA fragment into a suitable cloning vector; transferring the vector with the DNA insert into a host cell for replication; and identifying and selecting cells that contain the DNA fragment.
- Key enzymes in gene cloning include restriction endonucleases (especially the type II enzymes) and DNA ligase.

Segment of chromosome from organism X

Using hybridization methods, researchers can order individual clones in a library by identifying clones with overlapping sequences. A set of overlapping clones represents a catalog for a long contiguous segment of a genome, often referred to as a contig (Fig. 9-13). Previously studied sequences or entire genes can be located within the library using hybridization methods to determine which library clones harbor the known sequence. If the sequence has already been mapped on a chromosome, investigators can determine the location (in the genome) of the cloned DNA and any contig of which it is a part. A well-characterized library may contain thousands of long contigs, all assigned to and ordered on particular chromosomes to form a detailed physical map. The known sequences within the library (each called a sequence-tagged site, or STS) can provide landmarks for genomic sequencing projects.

As more and more genome sequences become available, the utility of genomic libraries is diminishing and investigators are constructing more specialized libraries designed to study gene function. An example is a library that includes only those genes that are expressed—that is, are transcribed into RNA—in a given organism or even in certain cells or tissues. Such a library focuses on those portions of a genome relevant to the function of a tissue or cell type. The researcher first extracts mRNA from an organism or from specific cells of an

DNA Libraries Provide Specialized Catalogs of Genetic Information

A DNA library is a collection of DNA clones, gathered together as a source of DNA for sequencing, gene discovery, or gene function studies. The library can take a variety of forms, depending on the source of the DNA. Among the largest types of DNA library is a genomic library, produced when the complete genome of a particular organism is cleaved into thousands of fragments, and all the fragments are cloned by insertion into a cloning vector.

The first step in preparing a genomic library is partial digestion of the DNA by restriction endonucleases, such that any given sequence will appear in fragments of a range of sizes—a range that is compatible with the cloning vector and ensures that virtually all sequences are represented among the clones in the library. Fragments that are too large or too small for cloning are removed by centrifugation or electrophoresis. The cloning vector, such as a BAC or YAC plasmid, is cleaved with the same restriction endonuclease and ligated to the genomic DNA fragments. The ligated DNA mixture is then used to transform bacterial or yeast cells to produce a library of cell types, each type harboring a different recombinant DNA molecule. Ideally, all the DNA in the genome under study will be represented in the library. Each transformed bacterium or yeast cell grows into a colony, or “clone,” of identical cells, each cell bearing the same recombinant plasmid, one of many represented in the overall library.
organism and then prepares complementary DNAs (cDNAs) from the RNA in a multistep reaction catalyzed by the enzyme reverse transcriptase (Fig. 9–14). The resulting double-stranded DNA fragments are then inserted into a suitable vector and cloned, creating a population of clones called a cDNA library. The search for a particular gene is made easier by focusing on a cDNA library generated from the mRNAs of a cell known to express that gene. For example, if we wished to clone globin genes, we could first generate a cDNA library from erythrocyte precursor cells, in which about half the mRNAs code for globins. To aid in the mapping of large genomes, cDNAs in a library can be partially sequenced at random to produce a useful type of STS called an expressed sequence tag (EST). ESTs, ranging in size from a few dozen to several hundred base pairs, can be positioned within the larger genome map, providing markers for expressed genes. Hundreds of thousands of ESTs were included in the detailed physical maps used as a guide to sequencing the human genome.

A cDNA library can be made even more specialized by cloning cDNAs or cDNA fragments into a vector that fuses each cDNA sequence with the sequence for a marker, or reporter gene; the fused genes form a "reporter construct." Two useful markers are the genes for green fluorescent protein and epitope tags. A target gene fused with a gene for green fluorescent protein (GFP) generates a fusion protein that is highly fluorescent—it literally lights up (Fig. 9–15a). GFP, derived from the jellyfish Aequorea victoria, has a β-barrel structure, with a fluorophore in the center of the barrel (see Box 12–3, p. 434). The fluorophore is

![Diagram](https://example.com/DNA.png)

**FIGURE 9–14** Construction of a cDNA library from mRNA. A cell's mRNA includes transcripts from thousands of genes, and the cDNAs generated are correspondingly heterogeneous. The duplex DNA produced by this method is inserted into an appropriate cloning vector. Reverse transcriptase can synthesize DNA on an RNA or a DNA template (see Fig. 26–33).

![Diagram](https://example.com/Reporter Constructs.png)

**FIGURE 9–15** Specialized DNA libraries. (a) Cloning of cDNA next to a gene for green fluorescent protein (GFP) creates a reporter construct. RNA transcription proceeds through the gene of interest (insert DNA) and the reporter gene, and the mRNA transcript is then expressed as a fusion protein. The GFP part of the protein is visible in the fluorescence microscope. The photograph shows a nematode worm containing a GFP fusion protein expressed only in the four "touch" neurons that run the length of its body. Reporter Constructs (b) If the cDNA is cloned next to a gene for an epitope tag, the resulting fusion protein can be precipitated by antibodies to the epitope. Any other proteins that interact with the tagged protein also precipitate, helping to elucidate protein-protein interactions.
derived from a rearrangement and oxidation of several amino acid residues in an autocatalytic reaction that requires only molecular oxygen (see Box 12–3, Fig. 3). Thus the protein is readily cloned in an active form in almost any cell. Just a few molecules of this protein can be observed microscopically, allowing the study of its location and movements in a cell. Careful protein engineering has generated mutant forms of GFP with a range of different colors and other properties (brightness, stability), and related proteins have recently been isolated from other species.

An epitope tag is a short protein sequence that is bound tightly by a well-characterized monoclonal antibody (p. 173). The tagged protein can be specifically precipitated from a crude protein extract by interaction with the antibody (Fig. 9–15b). If any other proteins bind to the tagged protein, those will precipitate as well, providing information about protein-protein interactions in a cell. The diversity and utility of specialized DNA libraries (and tagged proteins) are growing every year.

The Polymerase Chain Reaction Amplifies Specific DNA Sequences

The Human Genome Project, along with the many associated efforts to sequence the genomes of organisms of every type, is providing unprecedented access to gene sequence information. This in turn is simplifying the process of cloning individual genes for more detailed biochemical analysis. If we know the sequence of at least the flanking parts of a DNA segment to be cloned, we can hugely amplify the number of copies of that DNA segment, using the polymerase chain reaction (PCR), a process conceived by Kary Mullis in 1983. The amplified DNA can be cloned directly or used in a variety of analytical procedures.

The PCR procedure has an elegant simplicity. Two synthetic oligonucleotides are prepared, complementary to sequences on opposite strands of the target DNA at positions defining the ends of the segment to be amplified. The oligonucleotides serve as replication primers that can be extended by DNA polymerase. The 3' ends of the hybridized probes are oriented toward each other and positioned to prime DNA synthesis across the desired DNA segment (Fig. 9–16). (DNA polymerases synthesize DNA strands from deoxyribonucleotides, using a DNA template, as described in Chapter 25.) Isolated DNA containing the segment to be amplified is heated briefly to denature it, and then cooled in the presence of a large excess of the synthetic oligonucleotide primers. The four deoxynucleoside triphosphates are then added, and the primed DNA segment is replicated selectively. The cycle of heating, cooling, and replication is repeated 25 or 30 times over a few hours in an automated process, amplifying the DNA segment between the primers until it can be readily analyzed or cloned. PCR uses a heat-stable DNA polymerase, such as the Taq polymerase (derived from a bacterium that lives at 90 °C), which remains active after every heating step and does not have to be replenished. Careful design of the primers used for PCR, such as including restriction endonuclease cleavage sites, can facilitate the subsequent cloning of the amplified DNA (Fig. 9–16b).

This technology is highly sensitive: PCR can detect and amplify as little as one DNA molecule in almost any type of sample. Although DNA degrades over time (p. 289), PCR has allowed successful cloning of DNA from samples more than 40,000 years old. Investigators have used the technique to clone DNA fragments from the mummified remains of humans and extinct animals such as the woolly mammoth, creating the new fields of molecular archaeology and molecular paleontology. DNA from burial sites has been amplified by PCR and used to trace ancient human migrations. Epidemiologists can use PCR-enhanced DNA samples from human remains to trace the evolution of human pathogenic viruses. In addition to its usefulness for cloning DNA, PCR is a potent tool in forensic medicine (Box 9–1). It is also being used for detection of viral infections before they cause symptoms and for prenatal diagnosis of a wide array of genetic diseases.

The PCR method is also important in advancing the goal of whole genome sequencing. For example, the mapping of expressed sequence tags to particular chromosomes often involves amplification of the EST by PCR, followed by hybridization of the amplified DNA to clones in an ordered library. Investigators found many other applications of PCR in the Human Genome Project, to which we now turn.

Genome Sequences Provide the Ultimate Genetic Libraries

The genome is the ultimate source of information about an organism, and there is no genome we are more interested in than our own. Less than 10 years after the development of practical DNA sequencing methods, serious discussions began about the prospects for sequencing the entire 3 billion base pairs of the human genome. The international Human Genome Project got underway with substantial funding in the late 1980s. The effort eventually included significant contributions from 20 sequencing centers distributed among six nations: the United States, Great Britain, Japan, France, China, and Germany. General coordination was provided by the Office of Genome Research at the National Institutes of Health, led first by James Watson and after 1992 by Francis Collins. At the outset, the task of sequencing a $3 \times 10^9$ bp genome seemed to be a titanic job, but it gradually yielded to advances in technology. The completed sequence of the human genome was published in April 2003, several years ahead of schedule.
FIGURE 9-16 Amplification of a DNA segment by the polymerase chain reaction. (a) The PCR procedure has three steps. DNA strands are (1) separated by heating, then (2) annealed to an excess of short synthetic DNA primers (blue) that flank the region to be amplified; (3) new DNA is synthesized by polymerization. The three steps are repeated for 25 or 30 cycles. The thermostable DNA polymerase Taq (from Thermus aquaticus, a bacterial species that grows in hot springs) is not denatured by the heating steps. (b) DNA amplified by PCR can be cloned. The primers can include noncomplementary ends that have a site for cleavage by a restriction endonuclease. Although these parts of the primers do not anneal to the target DNA, the PCR process incorporates them into the DNA that is amplified. Cleavage of the amplified fragments at these sites creates sticky ends, used in ligation of the amplified DNA to a cloning vector. (a) Polymerase Chain Reaction

Region of target DNA to be amplified

1. Heat to separate strands.
2. Add synthetic oligonucleotide primers; cool.

3. Add thermostable DNA polymerase to catalyze 5'→3' DNA synthesis.

Repeat steps 1 and 2.

DNA synthesis (step 3) is catalyzed by the thermostable DNA polymerase (still present).

Repeat steps 1 through 3.

After 25 cycles, the target sequence has been amplified about 10^6-fold.

(a)

EcoRI endonuclease
Traditionally, one of the most accurate methods for placing an individual at the scene of a crime has been a fingerprint. With the advent of recombinant DNA technology, a more powerful tool is now available: DNA fingerprinting (also called DNA typing or DNA profiling). The method was first described by English geneticist Alec Jeffreys in 1985.

DNA fingerprinting is based on sequence polymorphisms, slight sequence differences between individuals, 1 bp in every 1,000 bp, on average. Each difference from the prototype human genome sequence (the first one obtained) occurs in some fraction of the human population; every individual has some differences. Some of the sequence changes affect recognition sites for restriction enzymes, resulting in variation in the size of DNA fragments produced by digestion with a particular restriction enzyme. These variations are restriction fragment length polymorphisms (RFLPs).

Another type of sequence variation, and the one now most commonly in DNA typing, involves short tandem repeats (STRs).

The detection of RFLPs relies on a specialized hybridization procedure called Southern blotting (Fig. 1). DNA fragments from digestion of genomic DNA by restriction endonucleases are separated by size electrophoretically, denatured by soaking the agarose gel in alkali, and then blotted onto a nylon membrane to reproduce the distribution of fragments in the gel. The membrane is immersed in a solution containing a radioactively labeled DNA probe. A probe for a sequence that is repeated several times in the human genome generally identifies a few of the thousands of DNA fragments generated when the human genome is digested with a restriction endonuclease. Autoradiography reveals the fragments to which the probe hybridizes, as in Figure 1. The method is very accurate (continued on next page)

![Diagram of DNA fingerprinting process](image-url)

**FIGURE 1** The Southern blot procedure, as applied to RFLP DNA fingerprinting. Southern blotting (used for many purposes in molecular biology) was named after Jeremy Southern, who developed the technique. In this example of a forensic application, the DNA from a semen sample obtained from a rape and murder victim was compared with DNA samples from the victim and two suspects. Each sample was cleaved into fragments and separated by gel electrophoresis.
and was first used in court cases in the late 1980s. However, it requires a large sample of undegraded DNA (>25 ng). That amount of DNA is often not available at a crime scene or disaster site.

The requirement for more-sensitive DNA typing methods led to a focus on the polymerase chain reaction (PCR; see Fig. 9–16), and on STRs. An STR locus is a short DNA sequence, repeated many times in tandem at a particular location in a chromosome; most commonly, the repeated sequences are 4 bp long. The STR loci that are most useful for DNA typing are quite short, from 4 to 50 repeats long (16 to 200 total base pairs for tetranucleotide repeats), and have multiple length variants in the human population. More than 20,000 tetranucleotide STR loci have been characterized in the human genome. More than a million STRs of all types may be present in the human genome, accounting for about 3% of all human DNA.

The polymerase chain reaction is readily applied to STR analysis, and the focus of forensic scientists changed from RFLPs to STRs as the promise of increased sensitivity became apparent in the early 1990s. The DNA sequences flanking STRs are unique to each type of STR and identical (except for very rare mutations) in all humans. PCR primers are targeted to this flanking DNA, and designed to amplify the DNA across the STR (Fig. 2a). The length of the PCR product then reflects the length of the STR in that sample. Since each human inherits one chromosome from each parent, the STR lengths on the two chromosomes are often different, generating two signals from one individual. If multiple STR loci are analyzed, a profile can be generated that is essentially unique to a particular individual. PCR amplification allows investigators to obtain DNA fingerprints from less than 1 ng of partially degraded DNA, an amount that can be obtained from a single hair follicle, a drop of blood, a small semen sample on a bed sheet, or samples that might be months or even many years old.

Successful forensic use of STR analysis required standardization. The first forensic STR standard was established in the United Kingdom in 1995. The U.S. standard, called the COMbined DNA Index System (CODIS), was established in 1998. The CODIS system is based on 13 well-studied STR loci (Table 1), which must be present in any DNA typing experiment carried out in the United States. The amelogenin gene is also used as a marker. This gene, present on the human sex chromosomes, has slightly different flanking DNA on the X and Y chromosomes. PCR amplification across the amelogenin gene thus generates different-size products that can reveal the sex of the DNA donor.

*Repeat lengths observed in the human population. Partial or imperfect repeats can be included in some alleles.

†Number of different alleles observed to date in the human population. Careful analysis of a locus in many individuals is a prerequisite to its use in forensic DNA typing.
The CODIS database contained 2.8 million samples prior to 2006, and is linked to all 50 United States. As of mid-2005, it had assisted more than 25,000 forensic investigations.

Convenient kits have been developed commercially that allow the amplification of 16 or more STR loci in one test tube. These "multiplex" STR kits (Fig. 2b) have PCR primers unique to each locus. Each primer is carefully designed to avoid hybridization to any other primer in the kit and to generate PCR products of different sizes so as to spread out the signals from the different loci during electrophoresis. The primers are linked to colored dyes to help distinguish the different PCR products. The most widely used kits now include the 13 CODIS loci, amelogenin, and two additional loci used by law enforcement agencies elsewhere in the world (16 total). The kits are very precise in establishing human identity. When good DNA profiles are obtained, the chance of an accidental match between two individuals in the human population is less than 1 in $10^{18}$ (quintillion).

DNA typing has been used to both convict and acquit suspects and, in other cases, to establish paternity with an extraordinary degree of certainty. The impact of these procedures on court cases will continue to grow as standards are improved and as international DNA typing databases grow. Even very old mysteries can be solved: in 1996, DNA fingerprinting helped to confirm the identification of the bones of the last Russian czar and his family, who were assassinated in 1918.
This advance was the product of a carefully planned international effort spanning 14 years. Research teams first generated a detailed physical map of the human genome, with clones derived from each chromosome organized into a series of long contigs (Fig. 9-17). Each contig contained landmarks in the form of STSs at a distance of every 100,000 bp or less. The genome thus mapped could be divided up between the international sequencing centers, each center sequencing the mapped BAC or YAC clones corresponding to its particular segments of the genome. Because many of the clones were more than 100,000 bp long, and modern sequencing techniques can resolve only 600 to 750 bp of sequence at a time, each clone had to be sequenced in pieces. The sequencing strategy used a shotgun approach, in which researchers used powerful new automated sequencers to sequence random segments of a given clone, then assembled the sequence of the entire clone by computerized identification of overlaps. The number of clone pieces sequenced was determined statistically so that the entire length of the clone was sequenced four to six times on average. The sequenced DNA was then made available in a database covering the entire genome. Construction of the physical map was a time-consuming task, and its progress was followed in annual reports in major journals throughout the 1990s—by the end of which the map was largely in place. Completion of the entire sequencing project was initially projected for the year 2005, but circumstances and technology intervened to accelerate the process.

A competing commercial effort to sequence the human genome was initiated by the newly established Celera Corporation in 1997. Led by J. Craig Venter, the Celera group made use of a different strategy called "whole genome shotgun sequencing," which eliminates the step of assembling a physical map of the genome. Instead, teams sequenced DNA segments from throughout the genome at random. The sequenced segments were ordered by the computerized identification of sequence overlaps (with some reference to the public project's detailed physical map). At the outset of the Human Genome Project, shotgun sequencing on this scale had been deemed impractical. However, advances in computer software and sequencing automation had made the approach feasible by 1997. The ensuing race between the private and public sequencing efforts substantially advanced the timeline for completion of the project. Publication of the draft human genome sequence in 2001 was followed by two years of follow-up work to eliminate nearly a thousand discontinuities and to provide high-quality sequence data that are contiguous throughout the genome.

The Human Genome Project marks the culmination of twentieth-century biology and promises a vastly changed scientific landscape for the new century. The human genome is only part of the story, as the genomes of many other species are also being (or have been) sequenced, including the yeasts Saccharomyces cerevisiae (completed in 1996) and Schizosaccharomyces pombe (2002), the nematode Caenorhabditis elegans (1998), the fruit fly Drosophila melanogaster (2000), the plant Arabidopsis thaliana (2000), the mouse Mus musculus (2002), and hundreds of bacterial and archaeal species (Fig. 9-18). Most of the early efforts were focused on species commonly used in laboratories. However, the technology continues to improve, and the complete genomic sequences of over 1,200 organisms of all types will be available by the time this book is published. Broad efforts to map genes, attempts to identify new proteins and disease genes, and many other initiatives are underway.
FIGURE 9–18 Genomic sequencing timeline. Discussions in the mid-1980s led to initiation of the Human Genome Project in 1990. Preparatory work, including extensive mapping to provide genome landmarks, occupied much of the 1990s. Separate projects were launched to sequence the genomes of other organisms important to research. The sequencing efforts completed to date include many bacterial species (such as *Haemophilus influenzae*), yeast (*S. cerevisiae*), nematode worms (e.g., *C. elegans*), insects (*D. melanogaster* and *A. mellifera*), plants (*A. thaliana* and *Oryza sativa* L.), rodents (*M. musculus* and *Rattus norvegicus*), primates (*H. sapiens* and *Pan troglodytes*), and some nasty human pathogens (e.g., *Trichomonas vaginalis*). Each genome project has a website that serves as a central repository for the latest data.

The result is a database with the potential not only to fuel rapid advances in biology but to change the way that humans think about themselves. Early insights provided by the human genome sequence are that we are not as complicated as we thought. Decades-old estimates that humans possessed about 100,000 genes within the approximately $3.2 \times 10^6$ bp in the human genome have been supplanted by the discovery that we have only 25,000 to 30,000 genes. This is perhaps three times more genes than a fruit fly (with 20,000) and twice as many as a nematode worm (23,000). Although humans evolved relatively recently, the human genome is very old. Of 1,278 protein families identified in one early screen, only 94 were unique to vertebrates. However, while we share many protein domain types with plants, worms, and flies, we use these domains in more complex arrangements. Alternative modes of gene expression (Chapter 26) allow the production of more than one protein from a single gene—a process that humans and other vertebrates engage in more than do bacteria, worms, or any other forms of life. This allows for greater complexity in the proteins generated from our gene complement.

We now know that only 1.1% to 1.4% of our DNA actually encodes proteins. More than 50% of our genome consists of short, repeated sequences, the vast majority of which—about 45% of our genome in all—come from transposons, short movable DNA sequences that are molecular parasites (Chapter 25). Many of the transposons have been there a long time, now altered so that they can no longer move to new genomic locations. Others are still actively moving at low frequencies, helping to make the genome an ever-dynamic and evolving entity. At least a few transposons have been co-opted by their host and appear to serve useful cellular functions.

What does all this information tell us about how much one human differs from another? Within the human population are millions of single-base differences, called single nucleotide polymorphisms, or SNPs (pronounced “snips”). Each human differs from the next by about 1 bp in every 1,000 bp. From these small genetic differences arises the human variety we are all aware of—differences in hair color, eyesight, allergies to medication, foot size, and even (to some unknown degree) behavior. Some of the SNPs are linked to particular human populations and can provide important information about human migrations that occurred thousands of years ago and about our more distant evolutionary past.

What does this information tell us about what makes us human? The sequence of our closest biological relative, the chimpanzee, might offer some clues. The human and chimpanzee genomes differ by only 1.2% at the level of base pairs, and the differences are less than that in genes encoding proteins. This value sounds small, but in these large genomes it translates into 35 million base pair changes, another 5 million short insertions or deletions, and a substantial number
of larger genomic rearrangements. Sorting out which of
these genomic distinctions are relevant to features that
are uniquely human is a daunting task. The analysis of
primate genomes with an eye to understanding human
biochemistry and evolution has much potential, but the
task remains in its infancy.

As spectacular as these advances are, genome se-
quencing itself is easy compared with what comes next—
the effort to understand all the information in each
genome. The genome sequences being added monthly to
international databases are roadmaps, parts of which are
written in a language we do not yet understand. However,
they have great utility in catalyzing the discovery of new
proteins and processes affecting every aspect of bio-
chemistry, as will become apparent in chapters to come.

**SUMMARY 9.2 From Genes to Genomes**

- The science of genomics broadly encompasses the
  study of genomes and their gene content.
- Genomic DNA segments can be organized in
  libraries—such as genomic libraries and cDNA
  libraries—with a wide range of designs and
  purposes.
- The polymerase chain reaction (PCR) can be used
  to amplify selected DNA segments from a DNA
  library or an entire genome.
- In international cooperative research efforts, the
  genomes of many organisms, including that of
  humans, have been sequenced in their entirety and
  are now available in public databases.

**9.3 From Genomes to Proteomes**

A gene is not simply a DNA sequence; it is information
that is converted to a useful product—a protein or func-
tional RNA molecule—when and if needed by the cell.
The first and most obvious step in exploring a large se-
quenced genome is to catalog the products of the genes
within that genome. Genes that encode RNA as their fi-
nal product are somewhat harder to identify than are
protein-encoding genes, and even the latter can be very
difficult to spot in a vertebrate genome. The explosion of
DNA sequence information has also revealed a sobering
truth. Despite many years of biochemical advances,
there are still thousands of proteins in every eukaryotic
cell (and quite a few in bacteria and archaea) that we
know nothing about. These proteins may have functions
in processes not yet discovered, or may contribute in
unexpected ways to processes we think we understand.
In addition, the genomic sequences tell us nothing about
the three-dimensional structure of proteins or how pro-
teins are modified after they are synthesized. The pro-
teins, with their myriad critical functions in every cell,
are now becoming the focus of new strategies for whole
cell biochemistry.

The complement of proteins expressed by a genome
is called its **proteome**, a term that first appeared in
the research literature in 1995. This concept rapidly
evolved into a separate field of investigation, called pro-
teomics. The problem addressed by proteomics research
is straightforward, although the solution is not. Each
genome presents us with thousands of genes encoding
proteins, and ideally we want to know the structure and
function of all those proteins. Given that many proteins
offer surprises even after years of study, the investigation
of an entire proteome is a daunting enterprise. Simply
discovering the function of new proteins requires inten-
sive work. Biochemists can now apply shortcuts in the
form of a broad array of new and updated technologies.

Protein function can be described on three levels. A
**Phenotypic function** describes the effects of a protein on
the entire organism. For example, the loss of the protein
may lead to slower growth of the organism, an altered de-
velopment pattern, or even death. **Cellular function** is a
description of the network of interactions engaged in by a
protein at the cellular level. Interactions with other pro-
teins in the cell can help define the kinds of metabolic
processes in which the protein participates. Finally, a
**molecular function** refers to the precise biochemical activity
of a protein, including details such as the reactions an en-
zyme catalyzes or the ligands a receptor binds.

For several genomes, such as those of the yeast
*Saccharomyces cerevisiae* and the plant *Arabidopsis
thaliana*, a massive effort is underway to inactivate
each gene by genetic engineering and to investigate the
effect on the organism. If the growth patterns or other
properties of the organism change (or if it does not grow
at all), this provides information on the phenotypic
function of the protein product of the gene.

There are three other main paths to investigating
protein function: (1) sequence and structural compar-
isons with genes and proteins of known function, (2) de-
termination of when and where a gene is expressed, and
(3) investigation of the interactions of the protein with
other proteins. We discuss each of these approaches
in turn.

Many of the same technologies that help elucidate
the function of one protein can be applied to many pro-
teins at once. The developing field of **systems biology**
uses the multitude of biochemical changes in a cell,
including the changes in the cellular protein population,
as a function of environmental or genetic stresses. We
identify approaches applicable to systems biology as
they are discussed.

**Sequence or Structural Relationships Provide
Information on Protein Function**

The rapid accumulation of genome sequence informa-
tion has greatly advanced our understanding of evolution (see
Section 3.4, p. 102). Another important reason to sequence
many genomes is to provide a database that can be used to
Assign gene functions by genome comparisons, an enterprise referred to as comparative genomics. Sometimes a newly discovered gene is related by sequence homologies to a gene previously studied in another or the same species, and its function can be entirely or partly defined by that relationship. Genes that occur in different species but possess a clear sequence and functional relationship to each other are called orthologs. Genes similarly related to each other within a single species are called paralogs (see p. 34). If the function of a gene has been characterized for one species, this information can be used to at least tentatively assign gene function to the ortholog found in the second species. The correlation is easiest to make when comparing genomes from relatively closely related species, such as mouse and human, although many clearly orthologous genes have been identified in species as distant as bacteria and humans. Sometimes even the order of genes on a chromosome is conserved over large segments of the genomes of closely related species (Fig. 9-20). Conserved gene order, called synteny, provides additional evidence for an orthologous relationship between genes at identical locations within the related segments.

Alternatively, certain sequences associated with particular structural motifs (Chapter 4) may be identified within a protein. The presence of a structural motif may suggest that it, say, catalyzes ATP hydrolysis, binds to DNA, or forms a complex with zinc ions, helping to define molecular function. These relationships are determined with the aid of increasingly sophisticated computer programs, limited only by the current information on gene and protein structure and our capacity to associate sequences with particular structural motifs.

To further the assignment of function based on structural relationships, a large-scale structural proteomics project has been initiated. The goal is to crystallize and determine the structure of as many proteins and protein domains as possible, in many cases with little or no existing information about protein function. The project has been assisted by the automation of some of the tedious steps of protein crystallization (see Box 4-5). As these structures are revealed, they will be made available in the structural databases described in Chapter 4. The effort should help define the extent of variation in structural motifs. When a newly discovered protein is found to have structural folds that are clearly related to motifs with known functions in the databases, this information can suggest a molecular function for the protein.

**Cellular Expression Patterns Can Reveal the Cellular Function of a Gene**

In every newly sequenced genome, researchers find genes that encode proteins with no evident structural relationships to known genes or proteins. In these cases, other approaches must be used to generate information about gene function. Determining which tissues a gene is expressed in, or what circumstances trigger the appearance of the gene product, can provide valuable clues. Many different approaches have been developed to study these patterns.

**Two-Dimensional Gel Electrophoresis** As shown in Figure 3-21, two-dimensional gel electrophoresis allows the separation and display of up to 1,000 different proteins on a single gel. Mass spectrometry (see Box 3-2) can then be used to partially sequence individual protein spots and assign each to a gene. The appearance and nonappearance (or disappearance) of particular protein spots in samples from different tissues, from similar tissues at different stages of development, or from tissues treated in ways that simulate a variety of biological conditions can help define cellular function.

Because many proteins are displayed at once in these gels, the technique is also applicable to systems biology. For example, a bacterial pathogen may evolve so as to become resistant to one or more antibiotics. The pattern of protein expression in that bacterial strain is likely to change, and multiple proteins may be affected.

**DNA Microarrays** Major refinements of the technology underlying DNA libraries, PCR, and hybridization have come together in the development of DNA microarrays (sometimes called DNA chips), which allow the rapid and simultaneous screening of many thousands of genes. DNA segments from known genes, a few dozen to hundreds of nucleotides long, are amplified by PCR and placed on a solid surface, using robotic devices that accurately deposit nanoliter quantities of DNA solution. Up to a million such spots are deposited in a predesigned array on a surface area of just a few square centimeters. An alternative strategy is to synthesize...
DNA directly on the solid surface, using photolithography (Fig. 9–21). Once the chip is constructed, it can be probed with mRNAs or cDNAs from a particular cell type or cell culture to identify the genes being expressed in those cells.

A microarray can answer such questions as which genes are expressed at a given stage in the development of an organism. The total complement of mRNA is isolated from cells at two different stages of development and converted to cDNA, using reverse transcriptase and fluorescently labeled deoxynucleotides. The fluorescent cDNAs are then mixed and used as probes, each hybridizing to complementary sequences on the microarray. In Figure 9–22, for example, the labeled nucleotides used to make the cDNA for each sample fluoresce in two different colors. The cDNA from the two samples is mixed and used to probe the microarray. Spots that fluoresce green represent mRNAs more abundant at the single-cell stage; those that fluoresce red represent sequences more abundant later in development. The mRNAs that are equally abundant at both stages of development fluoresce yellow. By using a mixture of two samples to measure relative rather than absolute abundance of sequences, the method corrects for variations in the amounts of DNA originally deposited in each spot on the grid and other possible inconsistencies among spots in the microarray. The spots that fluoresce provide a snapshot of all the genes being expressed in the cells at the moment they were harvested—gene expression examined on a genome-wide scale. For a gene

**FIGURE 9–21 Photolithography.** This technique for preparing a DNA microarray makes use of nucleotide precursors that are activated by light, joining one nucleotide to the next in a photoreaction (as opposed to the chemical process illustrated in Fig. 8–35). A computer is programmed with the oligonucleotide sequences to be synthesized at each point on a solid surface. The reactive groups on that surface are initially rendered inactive because of attached photoinactive blocking groups (●). A screen covering the surface is opened over the areas programmed to receive a particular nucleotide. A flash of light eliminates the blocking group in the uncovered spots, and then a solution with a particular nucleotide (e.g., *A●), activated to react at its 3'-hydroxyl group (●), is washed over the surface. A blocking group on the 5'-hydroxyl group of the nucleotide prevents unwanted reactions, and the nucleotide becomes linked to the surface in the illuminated spots via its 3'-hydroxyl group. The screen is then replaced with another screen that selectively illuminates only spots programmed to receive a G; light removes the 5' blocking groups of previously bound nucleotides, and *G● is then added to link G to those spots. The surface is washed successively with solutions containing each remaining type of activated nucleotide (*C●, *T●), using selective screening and light to ensure that the correct nucleotides are added at each spot in the correct sequence. This continues until the required sequences are built up on each spot on the surface. Many polymers with the same sequence are generated on each spot, not just the single polymer shown. The surface itself has thousands of spots, each with different sequences (see Fig. 9–22); this array shows just four spots, to illustrate the strategy.
Add the cDNAs to a microarray; fluorescent cDNAs anneal to complementary sequences on the microarray. Each fluorescent spot represents a gene expressed in the cells.

**FIGURE 9-22 DNA microarray.** A microarray can be prepared from any known DNA sequence, from any source, generated by chemical synthesis or by PCR. The DNA is positioned on a solid surface (usually specially treated glass slides) with the aid of a robotic device capable of depositing very small (nanoliter) drops in precise patterns. UV light cross-links the DNA to the glass slides. Once the DNA is attached to the surface, the microarray can be probed with other fluorescently labeled nucleic acids. Here, mRNA samples are collected from cells at two different stages in the development of a frog. The cDNA probes are made with nucleotides that fluoresce in different colors for each sample, a mixture of the cDNAs is used to probe the microarray. Green spots represent mRNAs more abundant at the single-cell stage; red spots, sequences more abundant later in development. The yellow spots indicate approximately equal abundance at both stages.

Microarrays are an invaluable tool of systems biology, allowing researchers to examine changes in gene expression on a cellular scale. The research focus may be one gene, or the entire genome. The same technology is also used to examine changes in DNA, such as genetic changes induced by natural selection or simple variation in a population. If a bacterial population has a new phenotype that signals the presence of one or more mutations, the mutations can often be identified quickly using microarrays. A microarray containing the wild-type sequence information is probed with DNA from the mutant cells. Hybridization will be reduced of unknown function, the time and circumstances of its expression can provide important clues about its role in the cell.

An example of this technique is illustrated in **Figure 9-23**, showing the dramatic results this technique can produce. Segments from each of the more than 6,000 genes in the completely sequenced yeast genome were separately amplified by PCR, and each segment was deposited in a defined pattern to create the illustrated microarray. In a sense, this array provides a snapshot of the entire yeast genome.

wherever the mutant cell DNA and the wild-type DNA do not match, producing a signal at the relevant spots. More detailed sequencing can then reveal the exact changes at each genomic region affected. This approach is providing new tools with which to track issues of medical interest, such as the development of new viral strains and the evolution of antibiotic resistance in bacterial pathogens.

The medical applications of microarrays already have an important role in cancer treatment. There are many different types of human cancer, and tumors—even within a particular tissue—can vary greatly in their growth rate, tendency to metastasize, and response to various therapies. It is often impossible to differentiate tumor types based solely on appearance. However, the cells making up a tumor exhibit characteristic patterns of gene expression, called a transcriptional profile, which often differ greatly from one tumor to the next. These can provide a kind of tumor fingerprint. Recent progress in the diagnosis and treatment of breast cancer provides a vivid example. Broad clinical studies over the past decade have used microarrays to develop transcriptional profiles of many thousands of breast cancers. Treatment protocols have been tracked, and successes and failures carefully documented. Particular genes and groups of genes are gradually being identified that, when expressed at higher levels, and in certain combinations, serve as prognostic predictors. The result is a growing database of correlations that allows the use of transcriptional profiles to develop prognoses and select the most beneficial therapies. These tools are becoming widespread in oncology clinics, and their value to oncologists and patients will only increase with time and experience.

**Protein Chips** Proteins, too, can be immobilized on a solid surface and used to help define the presence or absence of other proteins in a sample. For example, researchers prepare an array of antibodies to particular proteins by immobilizing them as individual spots on a solid surface. A sample of proteins is added, and if the protein that binds any of the antibodies is present in the sample, it can be detected by a solid-state form of the ELISA assay (see Fig. 5–26b). Many other types and applications of protein chips are being developed. This is another technology that can be applied to one protein, or all of the proteins within a biological system.

**Detection of Protein-Protein Interactions Helps to Define Cellular and Molecular Function**

A key to defining the function of a particular protein is to determine what it binds to. In the case of protein-protein interactions, the association of a protein of unknown function with one whose function is known can provide a useful and compelling "guilt by association." The techniques used in this effort are quite varied.

**Comparisons of Genome Composition** Although not evidence of direct association, the mere presence of combinations of genes in particular genomes can hint at protein function. We can simply search the genomic databases for particular genes, then determine what other genes are present in the same genomes (Fig. 9–24). When two genes always appear together in a genome, it suggests that the proteins they encode may be functionally related. Such correlations are most useful if the function of at least one of the proteins is known.

**Purification of Protein Complexes** With the construction of cDNA libraries in which each gene is contiguous with (fused to) an epitope tag, workers can immunoprecipitate the protein product of a gene by using the antibody that binds to the epitope (Fig. 9–15b). If the tagged protein is expressed in cells, other proteins that bind to it may also be precipitated with it. Identification of the associated proteins reveals some of the protein-protein interactions of the tagged protein. There are many variations of this process. For example, a crude extract of cells that express a similarly tagged protein is added to a column containing immobilized antibody. The tagged protein binds to the antibody, and proteins that interact with the tagged protein are sometimes also retained on the column. The connection between the protein and the tag is cleaved with a specific protease, and the protein complexes are eluted from the column and analyzed. Researchers can use these methods to define complex networks of interactions within a cell. Many of the terminal tags listed in Table 9–3 can be used in similar chromatographic protocols, employing the affinity of a tag for a particular ligand to identify proteins that bind to a particular tagged protein.
Yeast Two-Hybrid Analysis A sophisticated genetic approach to defining protein-protein interactions is based on the properties of the Gal4 protein (Gal4p), which activates transcription of certain genes in yeast (see Fig. 28–31). Gal4p has two domains, one that binds to a specific DNA sequence and another that activates the RNA polymerase that synthesizes mRNA from an adjacent reporter gene. The domains are stable when separated, but activation of the RNA polymerase requires interaction with the activation domain, which in turn requires positioning by the DNA-binding domain. Hence, the domains must be brought together to function correctly (Fig. 9–25a).

In this method, the protein-coding regions of genes to be analyzed are fused to the coding sequences of either the DNA-binding domain or the activation domain of Gal4p, and the resulting genes express a series of fusion proteins. If a protein fused to the DNA-binding domain interacts with a protein fused to the activation domain, transcription is activated. The reporter gene transcribed by this activation is generally one that yields a protein required for growth, or is an enzyme that catalyzes a reaction with a colored product. Thus, when grown on the proper medium, cells that contain a pair of interacting proteins are easily distinguished from those that do not. Typically, many genes are fused to the Gal4p DNA-binding domain gene in one yeast strain, and many other genes are fused to the Gal4p activation domain gene in another yeast strain, then the yeast strains are mated and individual diploid cells grown into colonies (Fig. 9–25b). This allows for large-scale screening for proteins that interact in the cell.

All these techniques provide important clues to protein function. However, they do not replace classical biochemistry. They simply provide researchers with an expedited entrance into important new biological problems. In the end, a detailed functional understanding of any new protein requires traditional biochemical analyses—such as were used for the many well-studied proteins described in this text. When paired with the simultaneously evolving tools of biochemistry and molecular biology, genomics and proteomics are speeding the discovery not only of new proteins but of new biological processes and mechanisms.

SUMMARY 9.3 From Genomes to Proteomes

- A proteome is the complement of proteins produced by a cell's genome. The new field of proteomics encompasses an effort to catalog and determine the functions of all the proteins in a cell. Integrated research to investigate multiple proteins or other macromolecules in a cell is sometimes called systems biology.
- One of the most effective ways to determine the function of a new gene is by comparative genomics, the search of databases for genes with similar
sequences. Paralogs and orthologs are proteins (and their genes) with clear functional and sequence relationships in the same or in different species. In some cases, the presence of a gene in combination with certain other genes, observed as a pattern in several genomes, can point toward a possible function.

- Cellular proteomes can be displayed by two-dimensional gel electrophoresis and explored with the aid of mass spectrometry.
- The cellular function of a protein can sometimes be inferred by determining when and where its gene is expressed. Researchers use DNA microarrays (chips) and protein chips to explore gene expression at the cellular level.
- Several new techniques, including comparative genomics, immunoprecipitation, and yeast two-hybrid analysis, can identify protein-protein interactions. These interactions provide important clues to protein function.

9.4 Genome Alterations and New Products of Biotechnology

We don’t need to look far to find practical applications for the new biotechnologies or to find new opportunities for breakthroughs in basic research. Herein lie both the promise and the challenge of genomics. We not only can understand genomes, we can change them. This is perhaps the ultimate manifestation of the new technologies. We will enhance our capacity to engineer organisms and produce new pharmaceutical agents and, as a consequence, will improve human nutrition and health. This promise can be realized only if practical safeguards are in place to ensure responsible application of these techniques.

A Bacterial Plant Parasite Aids Cloning in Plants

The introduction of recombinant DNA into plants has enormous implications for agriculture, making possible the alteration of the nutritional profile or yield of crops or their resistance to environmental stresses, such as insect pests, diseases, cold, salinity, and drought. Fertile plants of some species may be generated from a single transformed cell, so that an introduced gene passes to progeny through the seeds.

As yet, researchers have not found any naturally occurring plant cell plasmids to facilitate cloning in plants, so the biggest technical challenge is getting DNA into plant cells. An important and adaptable ally in this effort is the soil bacterium Agrobacterium tumefaciens. This bacterium can invade plants at the site of a wound, transform nearby cells, and induce them to form a tumor called a crown gall. Agrobacterium contains the large (200,000 bp) Ti plasmid (Fig. 9-26a). When the bacterium is in contact with a damaged plant cell, a 23,000 bp segment of the Ti plasmid called T DNA is transferred from the plasmid and integrated at a random position in one of the plant cell chromosomes (Fig. 9-26b). The transfer of T DNA from Agrobacterium to the plant cell chromosome depends on two 25 bp repeats that flank the T DNA and on the products of the virulence (vir) genes on the Ti plasmid (Fig. 9-26a).

The T DNA encodes enzymes that convert plant metabolites to two classes of compounds that benefit the bacterium (Fig. 9-27). The first group consists of plant growth hormones (auxins and cytokinins) that stimulate growth of the transformed plant cells to form the crown gall tumor. The second constitutes a series of unusual
FIGURE 9–27 Metabolites produced in *Agrobacterium*-infected plant cells. Auxins and cytokinins are plant growth hormones. The most common auxin, indoleacetate, is derived from tryptophan. Cytokinins are amino acids called opines, which serve as a food source for the bacterium. The opines are produced in high concentrations in the tumor cells and secreted to the surroundings, where they can be metabolized only by *Agrobacterium*, using enzymes encoded elsewhere on the Ti plasmid. The bacterium thereby diverts plant resources by converting them to a form that benefits only itself.

This rare example of DNA transfer from a bacterium to a eukaryotic cell is a natural genetic engineering process—one that researchers can harness to transfer recombinant DNA (instead of T DNA) to the plant genome. A common cloning strategy employs an *Agrobacterium* with two different recombinant plasmids. The first is a Ti plasmid from which the T DNA segment has been removed in the laboratory (Fig. 9–28a).

FIGURE 9–28 A two-plasmid strategy to create a recombinant plant. (a) One plasmid is a modified Ti plasmid that contains the vir genes but lacks T DNA. (b) The other plasmid contains a segment of DNA that bears both a foreign gene (the gene of interest, e.g., the gene for the insecticidal protein described in Fig. 9–30) and an antibiotic-resistance element (here, kanamycin resistance), flanked by the two 25 bp repeats of T DNA that are required for transfer of the plasmid genes to the plant chromosome. This plasmid also contains the replication origin needed for propagation in *Agrobacterium*.

When bacteria invade at the site of a wound (the edge of the cut leaf), the vir genes on the first plasmid mediate transfer into the plant genome of the segment of the second plasmid that is flanked by the 25 bp repeats. Leaf segments are placed on an agar dish that contains both kanamycin and appropriate levels of plant growth hormones, and new plants are generated from segments with the transformed cells. Non-transformed cells are killed by the kanamycin. The foreign gene and the antibiotic-resistance element are normally transferred together, so plant cells that grow in this medium generally contain the foreign gene.
The second is an *Agrobacterium*-E. coli shuttle vector in which the 25 bp repeats of the T DNA flank a foreign gene that the researcher wants to introduce into the plant cell, along with a selectable marker such as resistance to the antibiotic kanamycin (Fig. 9-28b). The engineered *Agrobacterium* is used to infect a leaf, but crown galls are not formed because the T DNA genes for the auxin, cytokinin, and opine biosynthetic enzymes are absent from both plasmids. Instead, the *vir* gene products from the altered Ti plasmid direct the transformation of the plant cells by the foreign gene—the gene flanked by the T DNA 25 bp repeats in the second plasmid. The transformed plant cells can be selected by growth on agar plates that contain kanamycin, and addition of growth hormones induces the formation of new plants that contain the foreign gene in every cell.

The successful transfer of recombinant DNA into plants was vividly illustrated by an experiment in which the luciferase gene from fireflies was introduced into the cells of a tobacco plant (Fig. 9-29)—a favorite plant for transformation experiments because its cells are particularly easy to transform with *Agrobacterium*. The potential of this technology is not limited to the production of glow-in-the-dark plants, of course. The same approach has been used to produce crop plants that are resistant to herbicides, plant viruses, and insect pests (Fig. 9-30). Potential benefits include increased yields and less need for environmentally harmful agricultural chemicals.

Biotechnology can introduce new traits into a plant much faster than traditional methods of plant breeding. A prominent example is the development of soybeans that are resistant to the general herbicide glyphosate (the active ingredient in the product RoundUp). Glyphosate breaks down in the environment more rapidly than many other herbicides (glyphosate-sensitive plants can be planted in a treated area after as little as 48 hours), and its use on fields does not generally lead to contamination of groundwater or carryover from one year to the next. A field of glyphosate-resistant soybeans can be treated once with glyphosate during a summer growing season to eliminate essentially all weeds in the field, while leaving the soybeans unaffected (Fig. 9-31). Potential pitfalls of the technology, such as the evolution of glyphosate-resistant weeds or the escape of difficult-to-control recombinant plants, remain a concern of researchers and the public.

**Figure 9-30** Tomato plants engineered to be resistant to insect larvae. Two tomato plants were exposed to equal numbers of moth larvae. The plant on the left has not been genetically altered. The plant on the right expresses a gene for a protein toxin derived from the bacterium Bacillus thuringiensis. This protein, introduced by a protocol similar to that depicted in Figure 9-28, is toxic to the larvae of some moth species while being harmless to humans and other organisms. Insect resistance has also been genetically engineered in cotton and other plants.

**Manipulation of Animal Cell Genomes Provides Information on Chromosome Structure and Gene Expression**

The transformation of animal cells by foreign genetic material offers an important mechanism for expanding our knowledge of the structure and function of animal genomes, as well as for the generation of animals with new traits. This potential has stimulated intensive research into more-sophisticated means of cloning animals. Most work of this kind requires a source of cells into which DNA can be introduced. Although intact tissues are often difficult to maintain and manipulate in vitro, many types of animal cells can be isolated and grown in the laboratory if their growth requirements are carefully met. Cells derived from a particular animal tissue and grown under appropriate tissue culture conditions can maintain their differentiated properties (for example, a hepatocyte (liver cell) remains a hepatocyte) for weeks or even months.
electroporation, techniques roughly comparable to the common methods used to transform bacteria. They are inefficient in animal cells, however, transforming only 1 in 100 to 10,000 cells. Microinjection—the injection of DNA directly into a nucleus, using a very fine needle—has a high success rate for skilled practitioners, but the total number of cells that can be treated is small, because each must be injected individually.

The most efficient and widely used methods for transforming animal cells rely on liposomes or viral vectors. Liposomes are small vesicles consisting of a lipid bilayer that encloses an aqueous compartment (see Fig. 11-4). Liposomes that enclose a recombinant DNA molecule can be fused with the membranes of target cells to deliver DNA into the cell. The DNA sometimes reaches the nucleus, where it can integrate into a chromosome (mostly at random locations). Viral vectors are even more efficient at delivering DNA. Animal viruses have effective mechanisms for introducing their nucleic acids into cells, and several types also have mechanisms to integrate their DNA into a host-cell chromosome. Some of these, such as retroviruses (see Fig. 26-33) and adenoviruses, have been modified to serve as viral vectors to introduce foreign DNA into mammalian cells.

The work on retroviral vectors illustrates some of the strategies being used (Fig. 9-32). When an engineered retrovirus enters a cell, its RNA genome is transcribed to DNA by reverse transcriptase and then integrated into the host genome by the enzyme viral integrase. Special regions of DNA are required for this procedure: long terminal repeat (LTR) sequences to integrate retroviral DNA into the host chromosome and the psi (ψ) sequence to package the viral RNA in viral particles (see Fig. 26-34).

The gag, pol, and env genes of the retroviral genome, required for retroviral replication and assembly of viral particles, can be replaced with foreign DNA. To assemble viruses that contain the recombinant genetic information, researchers must introduce the DNA into cultured cells that are simultaneously infected with a “helper virus” that has the genes to produce viral particles but lacks the ψ sequence required for packaging. Thus the recombinant DNA can be transcribed and its RNA packaged into viral particles. These particles can act as vectors to introduce the recombinant RNA into target cells. Viral reverse transcriptase and integrase enzymes (produced by the helper virus) are also packaged in the viral particle and introduced into the target cells. Once the engineered viral genome is inside a cell, these enzymes create a DNA copy of the recombinant viral RNA genome and integrate it into a host chromosome. The integrated recombinant DNA then becomes a permanent part of the target cell’s chromosome and is replicated with the chromosome at every cell division. The cell itself is not endangered by the integrated viral DNA, because the recombinant virus lacks the genes needed to produce RNA copies of its genome and package them into new viral particles. The use of recombinant retroviruses is often the best method for introducing DNA into large numbers of mammalian cells.

Retroviral RNA genome with foreign gene

Recombinant virus particles infect a target cell.

Retroviral genome with foreign gene is integrated into the target cell chromosome.

**FIGURE 9-32** Use of retroviral vectors in mammalian cell cloning. A typical retroviral genome (somewhat simplified here), engineered to carry a foreign gene (pink), is added to a host-cell tissue culture. The helper virus (not shown) lacks the packaging sequence, φ, so its RNA transcripts cannot be packaged into viral particles, but it provides the gag, pol, and env gene products needed to package the engineered retrovirus into functional viral particles. This enables the foreign gene in the recombinant retroviral genome to be introduced efficiently into the target cells.

Each type of virus has different attributes, so several classes of animal viruses are being engineered as vectors to transform mammalian cells. Adenoviruses, for example, lack a mechanism for integrating DNA into a chromosome. Recombinant DNA introduced via an adenoviral vector is therefore expressed for only a short time and then destroyed. This can be useful if the objective is transient expression of a gene.

Transformation of animal cells by any of the above techniques has its problems. Introduced DNA is generally integrated into chromosomes at random locations. Even when the foreign DNA contains a sequence similar to a sequence in a host chromosome, allowing targeting to that position, nonhomologous integrants still outnumber the targeted ones by several orders of magnitude. If these integration events disrupt essential genes, they can sometimes alter cellular functions (most animal cells are diploid or polyploid, however, so an integration usually leaves at least one unaffected copy of any given gene). A particularly poor outcome would involve an integration event that inadvertently activated a gene that stimulated cell division, potentially creating a cancer cell. Although such an event was once thought to be rare, recent trials suggest it is a significant hazard (Box 9–2). Finally, the site of an integration can determine the level of expression of the integrated gene, because integrants are not transcribed equally well everywhere in the genome.

Despite these challenges, the transformation of animal cells has been used extensively to study chromosome structure and the function, regulation, and expression of genes. The successful introduction of recombinant DNA into an animal can be illustrated by an experiment that permanently altered an easily observable inheritable physical trait. Microinjection of DNA into the nuclei of fertilized mouse eggs can produce efficient transformation (chromosomal integration). When the injected eggs are introduced into a female mouse and allowed to develop, the new gene is often expressed in some of the newborn mice. Those in which the germ line has been altered can be identified by testing their offspring. By careful breeding of these mice, researchers can establish a transgenic mouse line in which all the mice are homozygous for the new gene or genes. Transgenic mice have now been produced with a wide range of genetic variations, including many relevant to human diseases and their control, pointing the way to human gene therapy (Box 9–2). A very similar approach is used to generate mice in which a particular gene has been inactivated ("knockout mice"), a way of establishing the function of the inactivated gene. This technology was used to introduce into mice defects in genes that help to control obesity (see Fig. 23–34).

**Creating a Transgenic Mouse**

The capacity to transform the genomes of animals is not limited to mice. The zebrafish, a common tropical aquarium fish, is also an important model organism for researchers. New strains of zebrafish, with their genomes altered so that they express one of the variants of the green fluorescent protein that fluoresce in the different parts of the light spectrum (see Fig. 9–15), may be found in a pet store near you (Fig. 9–33).
fluorescent Drotein have been introduced into different strains of zebrafish, making each of them literally glow in the dark. Each variant expressing it glow in a particular color (red, green, or yellow).

As biotechnology gained momentum in the 1980s, a rational approach to the treatment of genetic diseases became increasingly attractive. In principle, DNA can be introduced into human cells to correct inherited genetic deficiencies. Genetic correction may even be targeted to a specific tissue by inoculating an individual with a genetically engineered, tissue-specific virus carrying a payload of DNA to be incorporated into deficient cells. The goal is entrancing, but the research path is strewn with impediments.

Alterting chromosomal DNA entails substantial risk—a risk that cannot be quantified in the early stages of discovery. Consequently, early efforts at human gene therapy were directed at only a small subset of genetic diseases. Panels of scientists and ethicists developed a list of several conditions that should be satisfied to justify the risk involved, including the following. (1) The genetic defect must be a well-characterized, single-gene disorder. (2) Both the mutant and the normal gene must be cloned and sequenced. (3) In the absence of a technique for eliminating the existing mutant gene, the functional gene must function well in the presence of the mutant gene. (4) Finally, and most important, the risks inherent in a new technology must be outweighed by the seriousness of the disease. Protocols for human clinical trials were submitted by scientists in several nations and reviewed for scientific rigor and ethical compliance by carefully selected advisory panels in each country; then human trials commenced.

Early targets of gene therapy included cancer and genetic diseases affecting the immune system. Immunity is mediated by leukocytes (white blood cells) of several different types, all arising from undifferentiated stem cells in the bone marrow. These cells divide quickly and have special metabolic requirements. Differentiation can become blocked in several ways, resulting in a condition called severe combined immune deficiency (SCID). One form of SCID results from genetically inherited defects in the gene encoding adenosine deaminase (ADA), an enzyme involved in nucleotide biosynthesis (discussed in Chapter 22). Another form of SCID arises from a defect in a cell-surface receptor protein that binds chemical signals called cytokines, which trigger differentiation. In both cases, the progenitor stem cells cannot differentiate into the mature immune system cells, such as T and B lymphocytes (see p. 170). Children with these rare human diseases are highly susceptible to bacterial and viral infections, and often suffer from a range of related physiological and neurological problems. In the absence of an effective therapy, the children must be confined in a sterile environment. About 20% of these children have a human leukocyte antigen (HLA)–identical sibling who can serve as a bone marrow transplant donor, a procedure that can cure the disease. The remaining children need a different approach.

The first human gene therapy trial was carried out at the National Institutes of Health in Bethesda, Maryland, in 1990. The patient was a four-year-old girl crippled by ADA deficiency. Bone marrow cells from the child were transformed with an engineered retrovirus containing a functional ADA gene; when the alteration of cells is done in this way—in the laboratory rather than in the living patient—the procedure is said to be done ex vivo. The treated cells were reintroduced into the patient’s marrow. Four years later, the child was leading a normal life, going to school, and even testifying about her experiences before Congress. However, her recovery cannot be uniquely attributed to gene therapy. Before the gene therapy clinical trials began, researchers had developed a new treatment for ADA deficiency, in which synthetic ADA was administered in a complex with polyethylene (continued on next page)
glycol (PEG). For many ADA-SCID patients, injection of the ADA-PEG complex allowed some immune system development, with weight gain and reduced infection, although not full immune reconstitution. The new gene therapy was risky, and withdrawing the inoculation treatment from patients in the gene therapy trial was judged unethical. So trial participants received both treatments at once, making it unclear which treatment was primarily responsible for the positive clinical outcome. Nevertheless, the clinical trial provided important information: it was feasible to transfer genes ex vivo to large numbers of leukocytes, and cells bearing the transferred gene were still detectable years after treatment, suggesting that long-term correction was possible. In addition, the risk associated with use of the retroviral vectors appeared to be low.

Through the 1990s, hundreds of human gene therapy clinical trials were carried out, targeting a variety of genetic diseases, but the results in most cases were discouraging. One major impediment proved to be the inefficiency of introducing new genes into cells. Transformation failed in many cells, and the number of transformed cells often proved insufficient to reverse the disorder. In the ADA trials, achieving a sufficient population of transformed cells was particularly difficult, because of the ongoing ADA-PEG therapy. Normally, stem cells with the correct ADA gene would have a growth advantage over the untreated cells, expanding their population and gradually predominating in the bone marrow. However, the injections of ADA-PEG in the same patients allowed the untransformed (ADA-deficient) cells to live and develop, and the transformed cells did not have the needed growth advantage to expand their population at the expense of the others.

A gene therapy trial initiated in 1999 was successful in correcting a form of SCID caused by defective cytokine receptors (in particular a subunit called \( \gamma_c \)), as reported in 2000 by physician researchers in France, Italy, and Britain. These researchers introduced the corrected gene for the \( \gamma_c \) cytokine–receptor subunit into CD34\(^+\) cells. (The stem cells that give rise to immune system cells have a protein called CD34 on their surface; these cells can be separated from other bone marrow cells by antibodies to CD34.) The transformed cells were placed back into the patients’ bone marrow. In this trial, introduction of the corrected gene clearly conferred a growth advantage over the untreated cells. A functioning immune system was detected in nine of eleven patients within 6 to 12 weeks, and levels of mature immune system T lymphocytes reached the levels found in age-matched control subjects (who did not have SCID) within 6 to 8 months. Immune system function was restored, and nearly 4 years later (mid-2003) most of the children were leading normal lives. This provided dramatic confirmation that human gene therapy could cure a serious genetic disease.

In 2003 came a setback. Two of the patients who had received cells with the correct cytokine receptor gene developed a severe form of leukemia. During the gene therapy treatment in both cases, one of the introduced retroviruses had by chance inserted itself into a chromosome of one CD34\(^+\) cell, resulting in abnormally high expression of a gene called LMO-2. The affected cell differentiated into an immune system T cell, and the elevated expression of LMO-2 led to uncontrolled growth of the cell, giving rise to the leukemia. Both patients were successfully treated with chemotherapy, and no other patients developed problems. However, the incident shows that early worries about the risk associated with retroviral vectors were well founded. After a review of the gene therapy trial protocols, including consultations with ethicists and parents of children affected by these diseases, further gene therapy trials are still planned for children who are not candidates for bone marrow transplants. The reason is simple enough. The potential benefit to the children with these debilitating conditions has been judged to outweigh the demonstrated risk. Development of new viral vectors appears to be the most important prerequisite to more effective therapies.

Human gene therapy is not limited to genetic diseases. Cancer cells are being targeted by delivering genes for proteins that might destroy the cell or restore the normal control of cell division. Immune system cells associated with tumors, called tumor-infiltrating lymphocytes, can be genetically modified to produce tumor necrosis factor (TNF; see Fig. 12–51). When these lymphocytes are taken from a cancer patient, modified, and reintroduced, the engineered cells target the tumor, and the TNF they produce causes tumor shrinkage. AIDS may also be treatable with gene therapy; DNA that encodes an RNA molecule complementary to a viral HIV mRNA could be introduced into immune system cells (the targets of HIV). The RNA transcribed from the introduced DNA would pair with the HIV mRNA, preventing its translation and interfering with the virus’s life cycle. Alternatively, a gene could be introduced that encodes an inactive form of one subunit of a multisubunit HIV enzyme; with one nonfunctional subunit, the entire enzyme might be inactivated.

Our growing understanding of the human genome and the genetic basis for some diseases brings the promise of early diagnosis and constructive intervention. As the early results demonstrate, however, the road to effective therapies will be a long one, with many detours. We need to learn more about cellular metabolism, more about how genes interact, and more about how to manage the dangers. The prospect of vanquishing life-destroying genetic defects and other debilitating diseases provides the motivation to press on.
in some other organisms. The vasoconstriction it induces can cause or exacerbate hypertension, congestive heart failure, and coronary artery disease. Some of the methods described in Section 9.3 for elucidating protein-protein interactions have been used to demonstrate that urotensin II is bound by a G protein–coupled receptor called GPR14. As we shall see in Chapter 12, G proteins play an important role in many signaling pathways. However, GPR14 was an “orphan” receptor, in that human genome sequencing had identified it as a G protein–coupled receptor, but with no known function. The association of urotensin II with GPR14 now makes the latter protein a key target for drug therapies aimed at interfering with the action of urotensin II.

Urotensin II

Another objective of medical research is to identify new agents that can treat the diseases caused by human pathogens. This now means identifying enzymatic targets in microbial pathogens that can be inactivated with a new drug. The ideal microbial target enzyme should be (1) essential to the pathogen cell's survival, (2) well-conserved among a wide range of pathogens, and (3) absent or significantly different in humans. The task of identifying metabolic processes that are critical to microorganisms but absent in humans is made much easier by comparative genomics, augmented by the functional information available from genomics and proteomics.

### Recombinant DNA Technology Yields New Products and Challenges

The products of recombinant DNA technology range from proteins to engineered organisms. The technology can produce large amounts of commercially useful proteins, can design microorganisms for special tasks, and can engineer plants or animals with traits that are useful in agriculture or medicine. Some products of this technology have been approved for consumer or professional use, and many more are in development. Genetic engineering has been transformed over a few years from a promising new technology to a multibillion-dollar industry, with much of the growth occurring in the pharmaceutical industry. Some major classes of products are listed in Table 9-4.

**Erythropoietin** is typical of recent breakthrough products. This protein hormone (MW, 51,000) stimulates erythrocyte production. People with diseases that compromise kidney function often have a deficiency of this protein, resulting in anemia. Erythropoietin produced by recombinant DNA technology can be used to treat these individuals, reducing the need for repeated blood transfusions.

Other applications of this technology continue to emerge. Enzymes produced by recombinant DNA technology are already used in the production of detergents, sugars, and cheese. Engineered proteins are being used as

food additives to supplement nutrition, flavor, and fragrance. Microorganisms are being engineered with altered or entirely novel metabolic pathways to extract oil and minerals from ground deposits, to digest oil spills, to detoxify hazardous waste dumps and sewage, or to produce ethanol as fuel. Engineered plants with improved resistance to drought, frost, pests, and disease are increasing crop yields and reducing the need for agricultural chemicals. Complete animals can be cloned by moving an entire nucleus and all of its genetic material to a prepared egg from which the nucleus has been removed.

The extraordinary promise of modern biotechnology does not come without controversy. The cloning of mammals challenges societal mores and may be accompanied by serious deficiencies in the health and longevity of the cloned animal. If useful pharmaceutical agents can be produced, so can toxins suitable for biological warfare. The potential for hazards posed by the release of engineered plants and other organisms into the biosphere continues to be monitored carefully. The full range of the long-term consequences of this technology for our species and for the global environment is impossible to foresee, but will certainly demand our increasing understanding of both cellular metabolism and ecology.

**SUMMARY 9.4 Genome Alterations and New Products of Biotechnology**

- Advances in whole genome sequencing and genetic engineering methods are enhancing our ability to modify genomes in all species.
- Cloning in plants, which makes use of the Ti plasmid vector from *Agrobacterium*, allows the introduction of new plant traits.
- In animal cloning, researchers introduce foreign DNA primarily with the use of viral vectors or microinjection. These techniques can produce transgenic animals and provide new methods for human gene therapy.
- The use of genomics and proteomics in basic and pharmaceutical research is greatly advancing the discovery of new drugs. Biotechnology is also generating an ever-expanding range of other products and technologies.

**Further Reading**

**General**

- The first recombinant DNA experiment linking DNA from two species.
- Report of the first recombinant DNA experiment.
- Although supplanted by more recent manuals, this three-volume set includes much useful background information on the biological, chemical, and physical principles underlying both classic and current techniques.

**Gene Cloning**

- Successes and pitfalls in the retrieval of DNA from very old samples.
- Good description of how nucleic acid chemistry affects the retrieval of DNA in archaeology.
Problems

1. Cloning When joining two or more DNA fragments, a researcher can adjust the sequence at the junction in a variety of subtle ways, as seen in the following exercises.

(a) Draw the structure of each end of a linear DNA fragment produced by an EcoRI restriction digest (include those sequences remaining from the EcoRI recognition sequence).

(b) Draw the structure resulting from the reaction of this end sequence with DNA polymerase I and the four deoxynucleoside triphosphates (see Fig. 8-33).

(c) Draw the sequence produced at the junction that arises if two ends with the structure derived in (b) are ligated (see Fig. 25-17).

(d) Draw the structure produced if the structure derived in (a) is treated with a nuclease that degrades only single-stranded DNA.

(e) Draw the sequence of the junction produced if an end with structure (b) is ligated to an end with structure (d).

(f) Draw the structure of the end of a linear DNA fragment that was produced by a PstI restriction digest (include those sequences remaining from the PstI recognition sequence).

(g) Draw the sequence of the junction produced if an end with structure (b) is ligated to an end with structure (f).

(h) Suppose you can synthesize a short duplex DNA fragment with any sequence you desire. With this synthetic fragment and the procedures described in (a) through (g), design a protocol that would remove an EcoRI restriction site from a DNA molecule and incorporate a new BamHI restriction site at approximately the same location. (See Fig. 9-2.)

(i) Design four different short synthetic double-stranded DNA fragments that would permit ligation of structure (a) with a DNA fragment produced by a PstI restriction digest. In one of these fragments, design the sequence so that the final junction contains the recognition sequences for both EcoRI and PstI. In the second and third fragments, design the sequence so that the junction contains only the EcoRI and only the PstI sequence appears in the junction.

2. Selecting for Recombinant Plasmids When cloning a foreign DNA fragment into a plasmid, it is often useful to insert the fragment at a site that interrupts a selectable marker (such as the tetracycline-resistance gene of pBR322). The loss of function...
of the interrupted gene can be used to identify clones containing recombinant plasmids with foreign DNA. With a bacteriophage λ vector it is not necessary to do this, yet one can easily distinguish vectors that incorporate large foreign DNA fragments from those that do not. How are these recombinant vectors identified?

3. DNA Cloning The plasmid cloning vector pBR322 (see Fig. 9-3) is cleaved with the restriction endonuclease PstI. An isolated DNA fragment from a eukaryotic genome (also produced by PstI cleavage) is added to the prepared vector and ligated. The mixture of ligated DNAs is then used to transform bacteria, and plasmid-containing bacteria are selected by growth in the presence of tetracycline.

(a) In addition to the desired recombinant plasmid, what other types of plasmids might be found among the transformed bacteria that are tetracycline resistant? How can the types be distinguished?

(b) The cloned DNA fragment is 1,000 bp long and has an EcoRI site 250 bp from one end. Three different recombinant plasmids are cleaved with EcoRI and analyzed by gel electrophoresis, giving the patterns shown. What does each pattern say about the cloned DNA? Note that in pBR322, the PstI and EcoRI restriction sites are about 750 bp apart. The entire plasmid with no cloned insert is 4,361 bp. Size markers in lane 4 have the number of nucleotides noted.

4. Identifying the Gene for a Protein with a Known Amino Acid Sequence Using Figure 27-7 to translate the genetic code, design a DNA probe that would allow you to identify the gene for a protein with the following amino-terminal amino acid sequence. The probe should be 18 to 20 nucleotides long, a size that provides adequate specificity if there is sufficient homology between the probe and the gene.

\[ \text{H}_3\text{N}^+\text{--Ala--Pro--Met--Thr--Trp--Tyr--Cys--Met--Asp--Trp--Ile--Ala--Gly--Pro--Trp--Phe--Arg--Lys--Asn--Thr--Lys--} \]

5. Designing a Diagnostic Test for a Genetic Disease Huntington's disease (HD) is an inherited neurodegenerative disorder, characterized by the gradual, irreversible impairment of psychological, motor, and cognitive functions. Symptoms typically appear in middle age, but onset can occur at almost any age. The course of the disease can last 15 to 20 years. The molecular basis of the disease is becoming better understood. The genetic mutation underlying HD has been traced to a gene encoding a protein (\( M_r 350,000 \)) of unknown function. In individuals who will not develop HD, a region of the gene that encodes the amino terminus of the protein has a sequence of CAG codons (for glutamine) that is repeated 6 to 39 times in succession. In individuals with adult-onset HD, this codon is typically repeated 40 to 55 times. In individuals with childhood-onset HD, this codon is repeated more than 70 times. The length of this simple trinucleotide repeat indicates whether an individual will develop HD, and at approximately what age the first symptoms will occur.

A small portion of the amino-terminal coding sequence of the 3,143-codon HD gene is given below. The nucleotide sequence of the DNA is shown in black, the amino acid sequence corresponding to the gene is shown in blue, and the CAG repeat is shaded. Using Figure 27-7 to translate the genetic code, outline a PCR-based test for HD that could be carried out using a blood sample. Assume the PCR primer must be 25 nucleotides long. By convention, unless otherwise specified a DNA sequence encoding a protein is displayed with the coding strand (the sequence identical to the mRNA transcribed from the gene) on top such that it is read 5' to 3', left to right.

6. Using PCR to Detect Circular DNA Molecules In a species of ciliated protist, a segment of genomic DNA is sometimes deleted. The deletion is a genetically programmed reaction associated with cellular mating. A researcher proposes that the DNA is deleted in a type of recombination called site-specific recombination, with the DNA on either end of the segment joined together and the deleted DNA ending up as a circular DNA reaction product.

Suggest how the researcher might use the polymerase chain reaction (PCR) to detect the presence of the circular form of the deleted DNA in an extract of the protist.

7. Glowing Plants When grown in ordinary garden soil and watered normally, a plant engineered to express green fluorescent protein (see Fig. 9-15a) will glow in the dark, whereas a plant engineered to express firefly luciferase (see Fig. 9-29) will not. Explain these observations.
8. RFLP Analysis for Paternity Testing  DNA fingerprinting and RFLP analysis are often used to test for paternity. A child inherits chromosomes from both mother and father, so DNA from a child displays restriction fragments derived from each parent. In the gel shown here, which child, if any, can be excluded as being the biological offspring of the putative father? Explain your reasoning. Lane M is the sample from the mother, F from the putative father, and C1, C2, and C3 from the children.

9. Mapping a Chromosome Segment  A group of overlapping clones, designated A through F, is isolated from one region of a chromosome. Each of the clones is separately cleaved by a restriction enzyme and the pieces resolved by agarose gel electrophoresis, with the results shown in the figure below. There are nine different restriction fragments in this chromosomal region, with a subset appearing in each clone. Using this information, deduce the order of the restriction fragments in the chromosome.

10. Cloning in Plants  The strategy outlined in Figure 9-28 employs Agrobacterium cells that contain two separate plasmids. Suggest why the sequences on the two plasmids are not combined on one plasmid.

11. DNA Fingerprinting and RFLP Analysis  DNA is extracted from the blood cells of two different humans, individuals 1 and 2. In separate experiments, the DNA from each individual is cleaved by restriction endonucleases A, B, and C, and the fragments separated by electrophoresis. A hypothetical map of a 10,000 bp segment of a human chromosome is shown (1 kbp = 1,000 bp). Individual 2 has point mutations that eliminate restriction recognition sites B* and C*. You probe the gel with a radioactive oligonucleotide complementary to the indicated sequence and expose a piece of x-ray film to the gel. Indicate where you would expect to see bands on the film. The lanes of the gel are marked in the accompanying diagram.

12. Use of Photolithography to Make a DNA Microarray  Figure 9-21 shows the first steps in the process of making a DNA microarray, or DNA chip, using photolithography. Describe the remaining steps needed to obtain the desired sequences (a different four-nucleotide sequence on each of the four spots) shown in the first panel of the figure. After each step, give the resulting nucleotide sequence attached at each spot.

13. Cloning in Mammals  The retroviral vectors described in Figure 9-32 make possible the efficient integration of foreign DNA into a mammalian genome. Explain how these vectors, which lack genes for replication and viral packaging (gag, pol, env), are assembled into infectious viral particles. Suggest why it is important that these vectors lack the replication and packaging genes.

Data Analysis Problem

14. HincII: The First Restriction Endonuclease  Discovery of the first restriction endonuclease to be of practical use was reported in two papers published in 1970. In the first paper, Smith and Wilcox described the isolation of an enzyme that cleaved double-stranded DNA. They initially demonstrated the enzyme’s nuclease activity by measuring the decrease in viscosity of DNA samples treated with the enzyme.
(a) Why does treatment with a nuclease decrease the viscosity of a solution of DNA?

The authors determined whether the enzyme was an endo- or an exonuclease by treating $\text{P}^{32}$-labeled DNA with the enzyme, then adding trichloroacetic acid (TCA). Under the conditions used in their experiment, single nucleotides would be TCA-soluble and oligonucleotides would precipitate.

(b) No TCA-soluble $\text{P}^{32}$-labeled material formed on treatment of $\text{P}^{32}$-labeled DNA with the nuclease. Based on this finding, is the enzyme an endo- or exonuclease? Explain your reasoning.

When a polynucleotide is cleaved, the phosphate usually is not removed but remains attached to the 5' or 3' end of the resulting DNA fragment. Smith and Wilcox determined the location of the phosphate on the fragment formed by the nuclease in the following steps:

1. Treat unlabeled DNA with the nuclease.
2. Treat a sample (A) of the product with y-$\text{P}^{32}$-labeled ATP and polynucleotide kinase (which can attach the y-phosphate of ATP to a 5' OH but not to a 5' phosphate or to a 3' OH or 3' phosphate). Measure the amount of $\text{P}^{32}$ incorporated into the DNA.
3. Treat another sample (B) of the product of step 1 with alkaline phosphatase (which removes phosphate groups from free 5' and 3' ends), followed by polynucleotide kinase and y-$\text{P}^{32}$-labeled ATP. Measure the amount of $\text{P}^{32}$ incorporated into the DNA.

(c) Smith and Wilcox found that sample A had 136 counts/min of $\text{P}^{32}$; sample B had 3,740 counts/min. Did the nuclease cleavage leave the phosphate on the 5' or the 3' end of the DNA fragments? Explain your reasoning.

(d) Treatment of bacteriophage T7 DNA with the nuclease gave approximately 40 specific fragments of various lengths. How is this result consistent with the enzyme's recognizing a specific sequence in the DNA as opposed to making random double-strand breaks?

At this point, there were two possibilities for the site-specific cleavage: the cleavage occurred either (1) at the site of recognition or (2) near the site of recognition but not within the sequence recognized. To address this issue, Kelly and Smith determined the sequence of the 5' ends of the DNA fragments generated by the nuclease, in the following steps:

1. Treat phage T7 DNA with the enzyme.
2. Treat the resulting fragments with alkaline phosphatase to remove the 5' phosphates.
3. Treat the dephosphorylated fragments with polynucleotide kinase and y-$\text{P}^{32}$-labeled ATP to label the 5' ends.
4. Treat the labeled molecules with DNases to break them into a mixture of mono-, di-, and trinucleotides.
5. Determine the sequence of the labeled mono-, di-, and trinucleotides by comparing them with oligonucleotides of known sequence on thin-layer chromatography.

The labeled products were identified as follows: mononucleotides: A and G; dinucleotides: 5'-pApA-3' and 5'-pGpA-3'; trinucleotides: 5'-pApApC-3' and 5'-pGpApC-3'.

(e) Which model of cleavage is consistent with these results? Explain your reasoning.

Kelly and Smith went on to determine the sequence of the 3' ends of the fragments. They found a mixture of 5'-pTpC-3' and 5'-pTpT-3'. They did not determine the sequence of any trinucleotides at the 3' end.

(f) Based on these data, what is the recognition sequence for the nuclease and where in the sequence is the DNA backbone cleaved? Use Table 9-2 as a model for your answer.

10.2 Structural Lipids in Membranes 349
10.3 Lipids as Signals, Cofactors, and Pigments 357
10.4 Working with Lipids 363

Biological lipids are a chemically diverse group of compounds, the common and defining feature of which is their insolubility in water. The biological functions of the lipids are as diverse as their chemistry. Fats and oils are the principal stored forms of energy in many organisms. Phospholipids and sterols are major structural elements of biological membranes. Other lipids, although present in relatively small quantities, play crucial roles as enzyme cofactors, electron carriers, light-absorbing pigments, hydrophobic anchors for proteins, "chaperones" to help membrane proteins fold, emulsifying agents in the digestive tract, hormones, and intracellular messengers. This chapter introduces representative lipids of each type, organized according to their functional roles, with emphasis on their chemical structure and physical properties. Although we follow a functional organization for our discussion, the literally thousands of different lipids can also be organized into eight general categories of chemical structure (see Table 10–3). We discuss the energy-yielding oxidation of lipids in Chapter 17 and their synthesis in Chapter 21.

10.1 Storage Lipids

The fats and oils used almost universally as stored forms of energy in living organisms are derivatives of fatty acids. The fatty acids are hydrocarbon derivatives, at about the same low oxidation state (that is, as highly reduced) as the hydrocarbons in fossil fuels. The cellular oxidation of fatty acids (to CO₂ and H₂O), like the controlled, rapid burning of fossil fuels in internal combustion engines, is highly exergonic.

We introduce here the structures and nomenclature of the fatty acids most commonly found in living organisms. Two types of fatty acid–containing compounds, triacylglycerols and waxes, are described to illustrate the diversity of structure and physical properties in this family of compounds.

Fatty Acids Are Hydrocarbon Derivatives

Fatty acids are carboxylic acids with hydrocarbon chains ranging from 4 to 36 carbons long (C₄ to C₃₆). In some fatty acids, this chain is unbranched and fully saturated (contains no double bonds); in others the chain contains one or more double bonds (Table 10–1). A few contain three-carbon rings, hydroxyl groups, or methyl-group branches.

KEY CONVENTION: A simplified nomenclature for unbranched fatty acids specifies the chain length and number of double bonds, separated by a colon (Fig. 10–1a);

![Figure 10-1](image-url)

(a) 18:1(Δ⁹) cis-9-Octadecenoic acid
(b) 20:5(Δ⁵,8,11,14,17) Eicosapentaenoic acid (EPA), an omega-3 fatty acid

FIGURE 10–1 Two conventions for naming fatty acids. (a) Standard nomenclature assigns the number 1 to the carboxyl carbon (C₁), and α to the carbon next to it. The position of any double bond(s) is indicated by Δ followed by a superscript number indicating the lower-numbered carbon in the double bond. (b) For polyunsaturated fatty acids (PUFAs), an alternative convention numbers the carbons in the opposite direction, assigning the number 1 to the methyl carbon at the other end of the chain; this carbon is also designated ω (omega; the last letter in the Greek alphabet). The positions of the double bonds are indicated relative to the ω carbon.

*All acids are shown in their nonionized form. At pH 7, all free fatty acids have an ionized carboxylate. Note that numbering of carbon atoms begins at the carboxyl carbon.

The prefix n- indicates the "normal" unbranched structure. For instance, "dodecanoic" simply indicates 12 carbon atoms, which could be arranged in a variety of branched forms; "n-dodecanoic" specifies the linear, unbranched form. For unsaturated fatty acids, the configuration of each double bond is indicated; in biological fatty acids the configuration is almost always cis.

for example, the 16-carbon saturated palmitic acid is abbreviated 16:0, and the 18-carbon oleic acid, with one double bond, is 18:1. The positions of any double bonds are specified relative to the carboxyl carbon, numbered 1, by superscript numbers following Δ (delta); a 20-carbon fatty acid with one double bond between C-9 and C-10 (C-1 being the carboxyl carbon) and another between C-12 and C-13 is designated 20:2(Δ⁹,12).

There is also a common pattern in the location of double bonds; in most monounsaturated fatty acids the double bond is between C-9 and C-10 (Δ⁹), and the other double bonds of polyunsaturated fatty acids are generally Δ₁₂ and Δ₁₅. (Arachidonic acid is an exception to this generalization.) The double bonds of polyunsaturated fatty acids are almost never conjugated (alternating single and double bonds, as in —CH=CH—CH=CH—), but are separated by a methylene group: —CH=CH—CH₂—CH=CH— (Fig. 10-1b). In nearly all naturally occurring unsaturated fatty acids, the double bonds are in the cis configuration. Trans fatty acids are produced by fermentation in the rumen of dairy animals and are obtained from dairy products and meat.

The most commonly occurring fatty acids have even numbers of carbon atoms in an unbranched chain of 12 to 24 carbons (Table 10-1). As we shall see in Chapter 21, the even number of carbons results from the mode of synthesis of these compounds, which involves successive condensations of two-carbon (acetate) units.

**KEY CONVENTION:** The family of polyunsaturated fatty acids (PUFAs) with a double bond between the third and fourth carbon from the methyl end of the chain are of special importance in human nutrition. Because the physiological role of PUFAs is related more to the position of the first double bond near the methyl end of the chain than to the carboxyl end, an alternative nomenclature is sometimes used for these fatty acids. The carbon of the methyl group—that is, the carbon most distant from the carboxyl group—is called the omega (omega) carbon and is given the number 1 (Fig. 10-1b). In this convention, PUFAs with a double bond between C-3 and C-4 are called omega-3 (ω-3) fatty acids, and those with a double bond between C-6 and C-7 are omega-6 (ω-6) fatty acids.

Humans require but do not have the enzymatic capacity to synthesize the omega-3 PUFAs α-linolenic acid (ALA; 18:3(Δ[^6,12,15]), in the standard convention), and must therefore obtain it in the diet. From ALA, humans can synthesize two other omega-3 PUFAs important in cellular function: eicosapentaenoic acid (EPA; 20:5(Δ[^6,8,11,13,15]), shown in Fig. 10-1b) and docosahexaenoic acid (DHA; 22:6(Δ[^4,7,10,13,16,19])). An imbalance of omega-6 and omega-3 PUFAs in the diet is associated with an increased risk of cardiovascular disease. The optimal dietary ratio of omega-6 to omega-3 PUFAs is between 1:1 and 4:1, but the ratio in the diets of most North Americans is closer to 10:1 to 30:1, leading to an increased frequency of heart disease and stroke. The "Mediterranean diet," which has been associated with lowered cardiovascular risk, is richer in omega-3 PUFAs, obtained in leafy vegetables (salads) and fish oils. The latter oils are especially rich in EPA and DHA, and fish oil supplements are often prescribed for individuals with a history of cardiovascular disease.

The physical properties of the fatty acids, and of compounds that contain them, are largely determined by the length and degree of unsaturation of the hydrocarbon chain. The nonpolar hydrocarbon chain accounts for the poor solubility of fatty acids in water. Lauric acid (12:0, M, 200), for example, has a solubility in water of 0.063 mg/g—much less than that of glucose (M, 180), which is 1,100 mg/g. The longer the fatty acyl chain and the fewer the double bonds, the lower is the solubility in water. The carboxylic acid group is polar (and ionized at neutral pH) and accounts for the slight solubility of short-chain fatty acids in water.

Melting points are also strongly influenced by the length and degree of unsaturation of the hydrocarbon chain. At room temperature (25°C), the saturated fatty acids from 12:0 to 24:0 have a waxy consistency, whereas unsaturated fatty acids of these lengths are oily liquids. This difference in melting points is due to different degrees of packing of the fatty acid molecules (Fig. 10-2). In the fully saturated compounds, free rotation around each carbon–carbon bond gives the hydrocarbon chain great flexibility; the most stable conformation is the fully extended form, in which the steric hindrance of neighboring atoms is minimized. These molecules can pack together tightly in nearly crystalline arrays, with atoms all along their lengths in van der Waals contact with the atoms of neighboring molecules. In unsaturated fatty acids, a cis double bond forces a kink in the hydrocarbon chain. Fatty acids with one or several such kinks cannot pack together as tightly as fully saturated fatty acids, and their interactions with each other are therefore weaker. Because less thermal energy is needed to disorder these poorly ordered arrays of unsaturated fatty acids, they have markedly lower melting points than saturated fatty acids of the same chain length (Table 10-1).

In vertebrates, free fatty acids (unesterified fatty acids, with a free carboxylate group) circulate in the blood bound noncovalently to a protein carrier, serum albumin. However, fatty acids are present in blood plasma mostly as carboxylic acid derivatives such as esters or amides. Lacking the charged carboxylate group, these fatty acid derivatives are generally even less soluble in water than are the free fatty acids.
Triacylglycerols Are Fatty Acid Esters of Glycerol

The simplest lipids constructed from fatty acids are the **triacylglycerols**, also referred to as triglycerides, fats, or neutral fats. Triacylglycerols are composed of three fatty acids each in ester linkage with a single glycerol (Fig. 10-3). Those containing the same kind of fatty acid in all three positions are called simple triacylglycerols and are named after the fatty acid they contain. Simple triacylglycerols of 16:0, 18:0, and 18:1, for example, are tripalmitin, tristearin, and triolein, respectively. Most naturally occurring triacylglycerols are mixed; they contain two or three different fatty acids. To name these compounds unambiguously, the name and position of each fatty acid must be specified.

Because the polar hydroxyls of glycerol and the polar carboxylates of the fatty acids are bound in ester linkages, triacylglycerols are nonpolar, hydrophobic molecules, essentially insoluble in water. Lipids have lower specific gravities than water, which explains why mixtures of oil and water (oil-and-vinegar salad dressing, for example) have two phases: oil, with the lower specific gravity, floats on the aqueous phase.

**Triacylglycerols Provide Stored Energy and Insulation**

In most eukaryotic cells, triacylglycerols form a separate phase of microscopic, oily droplets in the aqueous cytosol, serving as depots of metabolic fuel. In vertebrates, specialized cells called adipocytes, or fat cells, store large amounts of triacylglycerols as fat droplets that nearly fill the cell (Fig. 10-4a). Triacylglycerols are also stored as oils in the seeds of many types of plants, providing energy and biosynthetic precursors during seed germination (Fig. 10-4b). Adipocytes and germinating seeds contain **lipases**, enzymes that catalyze the hydrolysis of stored triacylglycerols, releasing fatty acids for export to sites where they are required as fuel.

**FIGURE 10–4 Fat stores in cells.** (a) Cross section of four guinea pig adipocytes, showing huge fat droplets that virtually fill the cells. Also visible are several capillaries in cross section. (b) Cross section of a cotyledon cell from a seed of the plant Arabidopsis. The large dark structures are protein bodies, which are surrounded by stored oils in the light-colored oil bodies.
There are two significant advantages to using triacylglycerols as stored fuels, rather than polysaccharides such as glycogen and starch. First, the carbon atoms of fatty acids are more reduced than those of sugars, and oxidation of triacylglycerols yields more than twice as much energy, gram for gram, as the oxidation of carbohydrates. Second, because triacylglycerols are hydrophobic and therefore unhydrated, the organism that carries fat as fuel does not have to carry the extra weight of water of hydration that is associated with stored polysaccharides (2 g per gram of polysaccharide). Humans have fat tissue (composed primarily of adipocytes) under the skin, in the abdominal cavity, and in the mammary glands. Moderately obese people with 15 to 20 kg of triacylglycerols deposited in their adipocytes could meet their energy needs for months by drawing on their fat stores. In contrast, the human body can store less than a day's energy supply in the form of glycogen. Carbohydrates such as glucose and glycogen do offer certain advantages as quick sources of metabolic energy, one of which is their ready solubility in water.

In some animals, triacylglycerols stored under the skin serve not only as energy stores but as insulation against low temperatures. Seals, walruses, penguins, and other warm-blooded polar animals are amply padded with triacylglycerols. In hibernating animals (bears, for example), the huge fat reserves accumulated before hibernation serve the dual purposes of insulation and energy storage (see Box 17-1). The low density of triacylglycerols is the basis for another remarkable function of these compounds. In sperm whales, a store of triacylglycerols and waxes allows the animals to match the buoyancy of their bodies to that of their surroundings during deep dives in cold water (Box 10-1).

Partial Hydrogenation of Cooking Oils Produces Trans Fatty Acids

Most natural fats, such as those in vegetable oils, dairy products, and animal fat, are complex mixtures of simple and mixed triacylglycerols. These contain a variety of fatty acids differing in chain length and temperature of the oil is lowered several degrees during a deep dive, it congeals or crystallizes and becomes denser. Thus the buoyancy of the whale changes to match the density of seawater. Various physiological mechanisms promote rapid cooling of the oil during a dive. As the whale returns to the surface, the congealed spermaceti oil warms and melts, decreasing its density to match that of the surface water. Thus we see in the sperm whale a remarkable anatomical and biochemical adaptation. The triacylglycerols and waxes synthesized by the whale contain fatty acids of the necessary chain length and degree of unsaturation to give the spermaceti oil the proper melting point for the animal's diving habits.

Unfortunately for the sperm whale population, spermaceti oil was at one time considered the finest lamp oil and continues to be commercially valuable as a lubricant. Several centuries of intensive hunting of these mammals have driven sperm whales onto the endangered species list.
and degree of saturation (Fig. 10–5). Vegetable oils such as corn (maize) and olive oil are composed largely of triacylglycerols with unsaturated fatty acids and thus are liquids at room temperature. Triacylglycerols containing only saturated fatty acids, such as tristearin, the major component of beef fat, are white, greasy solids at room temperature.

When lipid-rich foods are exposed too long to the oxygen in air, they may spoil and become rancid. The unpleasant taste and smell associated with rancidity result from the oxidative cleavage of double bonds in unsaturated fatty acids, which produces aldehydes and carboxylic acids of shorter chain length and therefore higher volatility. To improve the shelf life of vegetable oils used in cooking, and to increase their stability at the high temperatures used in deep-frying, commercial vegetable oils are subjected to partial hydrogenation. This process converts many of the cis double bonds in the fatty acids to single bonds and increases the melting temperature of the oils so that they are more nearly solid at room temperature (margarine is produced from vegetable oil in this way). Partial hydrogenation has another, undesirable, effect: some cis double bonds are converted to trans double bonds. There is now strong evidence that dietary intake of trans fatty acids (often referred to simply as “trans fats”) leads to a higher incidence of cardiovascular disease, and that avoiding these fats in the diet substantially reduces the risk of coronary heart disease. Dietary trans fatty acids raise the level of triacylglycerols and of LDL (“bad”) cholesterol in the blood, and lower the level of HDL (“good”) cholesterol, and these changes alone are enough to increase the risk of coronary heart disease. But trans fatty acids may have further adverse effects. They seem, for example, to increase the body’s inflammatory response, which is another risk factor for heart disease. (See Chapter 21 for a description of LDL and HDL—low-density and high-density lipoprotein—cholesterol and their health effects.)

Many fast foods are deep-fried in partially hydrogenated vegetable oils and therefore contain high levels of trans fatty acids (Table 10–2). In view of the detrimental effects of these fats, some countries (Denmark, for example) and some cities (New York City and Philadelphia) severely restrict the use of partially hydrogenated oils in restaurants. French fries prepared in a chain fast-food restaurant in Denmark now contain almost no detectable trans fatty acids, whereas the same product prepared in the United States contains 5 to 10 g of trans fatty acids per serving (Table 10–2). The deleterious effects of trans fats occur at intakes of 2 to 7 g/day (20 to 60 kcal in a daily caloric intake of 2000 kcal; note that a nutritional Calorie is the equivalent of the kilocalorie used by chemists and biochemists, so a 2000 Calorie diet is the equivalent of a 2000 kcal diet). A single serving of french fries in a U.S. restaurant may contain this amount of trans fatty acid! Many other prepared foods, baked goods, and snacks on the shelves of supermarkets have comparably high levels of trans fats.

Waxes Serve as Energy Stores and Water Repellents

Biological waxes are esters of long-chain (C_{14} to C_{36}) saturated and unsaturated fatty acids with long-chain (C_{16} to C_{36}) alcohols (Fig. 10-6). Their melting points (60 to 100 °C) are generally higher than those of triacylglycerols. In plankton, the free-floating microorganisms at the bottom of the food chain for marine animals, waxes are the chief storage form of metabolic fuel.

Waxes also serve a diversity of other functions related to their water-repellent properties and their firm consistency. Certain skin glands of vertebrates secrete waxes to protect hair and skin and keep it pliable, lubricated, and waterproof. Birds, particularly waterfowl, secrete waxes from their preen glands to keep their feathers water-repellent. The shiny leaves of holly, rhododendrons, poison ivy, and many tropical plants are coated with a thick layer of waxes, which prevents excessive evaporation of water and protects against parasites.

Biological waxes find a variety of applications in the pharmaceutical, cosmetic, and other industries. Lanolin (from lamb’s wool), beeswax (Fig. 10-6), carnauba wax (from a Brazilian palm tree), and wax extracted from spermaceti oil (from whales; see Box 10-1) are widely used in the manufacture of lotions, ointments, and polishes.

**FIGURE 10-6** Biological wax. (a) Triacontanoylpalmitate, the major component of beeswax, is an ester of palmitic acid with the alcohol triacontanol. (b) A honeycomb, constructed of beeswax, is firm at 25 °C and completely impervious to water. The term “wax” originates in the Old English weax, meaning “the material of the honeycomb.”

**SUMMARY 10.1 Storage Lipids**

- Lipids are water-insoluble cellular components, of diverse structure, that can be extracted by nonpolar solvents.
- Almost all fatty acids, the hydrocarbon components of many lipids, have an even number of carbon atoms (usually 12 to 24); they are either saturated or unsaturated, with double bonds almost always in the cis configuration.
- Triacylglycerols contain three fatty acid molecules esterified to the three hydroxyl groups of glycerol. Simple triacylglycerols contain only one type of fatty acid; mixed triacylglycerols, two or three types. Triacylglycerols are primarily storage fats; they are present in many foods.
- Partial hydrogenation of vegetable oils in the food industry converts some cis double bonds to the trans configuration. Trans fatty acids in the diet are an important risk factor for coronary heart disease.

### 10.2 Structural Lipids in Membranes

The central architectural feature of biological membranes is a double layer of lipids, which acts as a barrier to the passage of polar molecules and ions. Membrane lipids are amphipathic: one end of the molecule is hydrophobic, the other hydrophilic. Their hydrophobic interactions with each other and their hydrophilic interactions with water direct their packing into sheets called membrane bilayers. In this section we describe five general types of membrane lipids: glycerophospholipids, in which the hydrophobic regions are composed of two fatty acids joined to glycerol; galactolipids and sulfolipids, which also contain two fatty acids esterified to glycerol, but lack the characteristic phosphate of phospholipids; archaeal tetraether lipids, in which two very long alkyl chains are ether-linked to glycerol at both ends; sphingolipids, in which a single fatty acid is joined to a fatty amine, sphingosine; and sterols, compounds characterized by a rigid system of four fused hydrocarbon rings.

The hydrophilic moieties in these amphipathic compounds may be as simple as a single —OH group at one end of the sterol ring system, or they may be much more complex. In glycerophospholipids and some sphingolipids, a polar head group is joined to the hydrophobic moiety by a phosphodiester linkage; these are the phospholipids. Other sphingolipids lack phosphate but have a simple sugar or complex oligosaccharide at their polar ends; these are the glycolipids (Fig. 10-7). Within these groups of membrane lipids, enormous diversity results from various combinations of fatty acid “tails” and polar “heads.” The arrangement of these lipids in membranes, and their structural and functional roles therein, are considered in the next chapter.
FIGURE 10–7 Some common types of storage and membrane lipids. All the lipid types shown here have either glycerol or sphingosine as the backbone (pink screen), to which are attached one or more long-chain alkyl groups (yellow) and a polar head group (blue). In triacylglycerols, glycerophospholipids, galactolipids, and sulfolipids, the alkyl groups are fatty acids in ester linkage. Sphingolipids contain a single fatty acid, in amide linkage to the sphingosine backbone. The membrane lipids of archaea are variable; that shown here has two very long, branched alkyl chains, each end in ether linkage. In phospholipids the polar head group is joined through a phosphodiester, whereas glycolipids have a direct glycosidic linkage between the head-group sugar and the backbone glycerol.

Glycerophospholipids Are Derivatives of Phosphatidic Acid

Glycerophospholipids, also called phosphoglycerides, are membrane lipids in which two fatty acids are attached in ester linkage to the first and second carbons of glycerol, and a highly polar or charged group is attached through a phosphodiester linkage to the third carbon. Glycerol is prochiral; it has no asymmetric carbons, but attachment of phosphate at one end converts it into a chiral compound, which can be correctly named either L-glycerol 3-phosphate, D-glycerol 1-phosphate, or sn-glycerol 3-phosphate (Fig. 10–8). Glycerophospholipids are named as derivatives of the parent compound, phosphatidic acid (Fig. 10–9), according to the polar alcohol in the head group. Phosphatidylcholine and phosphatidylethanolamine have choline and ethanolamine as their polar head groups, for example. In all these compounds, the head group is joined to glycerol through a phosphodiester bond, in which the phosphate group bears a negative charge at neutral pH. The polar alcohol may be negatively charged (as in phosphatidylinositol 4,5-bisphosphate), neutral (phosphatidylserine), or positively charged (phosphatidylcholine, phosphatidylethanolamine). As we shall see in Chapter 11, these charges contribute greatly to the surface properties of membranes.

The fatty acids in glycerophospholipids can be any of a wide variety, so a given phospholipid (phosphatidylcholine, for example) may consist of several molecular species, each with its unique complement of fatty acids. The distribution of molecular species is specific for different organisms, different tissues of the same organism, and different glycerophospholipids in the same cell or tissue. In general, glycerophospholipids contain a C\textsubscript{16} or C\textsubscript{18} saturated fatty acid at C-1 and a C\textsubscript{16} or C\textsubscript{20} unsaturated fatty acid at C-2. With few exceptions, the biological significance of the variation in fatty acids and head groups is not yet understood.

Some Glycerophospholipids Have Ether-Linked Fatty Acids

Some animal tissues and some unicellular organisms are rich in ether lipids, in which one of the two acyl chains is attached to glycerol in ether, rather than ester linkage. The ether-linked chain may be saturated, as in the alkyl ether lipids, or may contain a double bond between C-1 and C-2, as in plasmalogens (Fig. 10–10). Vertebrate heart tissue is uniquely enriched in ether lipids; about half of the heart phospholipids are plasmalogens. The membranes of halophilic bacteria, ciliated protists, and certain invertebrates also contain high proportions of ether lipids. The functional significance of ether lipids in these membranes is unknown; perhaps their resistance to the phospholipases that cleave ester-linked fatty acids from membrane lipids is important in some roles.

At least one ether lipid, platelet-activating factor, is a potent molecular signal. It is released from leukocytes called basophils and stimulates platelet aggregation and the release of serotonin (a vasoconstrictor).

**FIGURE 10-9 Glycerophospholipids.** The common glycerophospholipids are diacylglycerols linked to head-group alcohols through a phosphodiester bond. Phosphatidic acid, a phosphomonoester, is the parent compound. Each derivative is named for the head-group alcohol (X), with the prefix "phosphatidyl-". In cardiolipin, two phosphatidic acids share a single glycerol (R¹ and R² are fatty acyl groups).

**FIGURE 10-10 Ether lipids.** Plasmalogens have an ether-linked alkyl chain where most glycerophospholipids have an ester-linked fatty acid (compare Fig. 10-9). Platelet-activating factor has a long ether-linked alkyl chain at C-1 of glycerol, but C-2 is ester-linked to acetic acid, which makes the compound much more water-soluble than most glycerophospholipids and plasmalogens. The head-group alcohol is ethanolamine in plasmalogens and choline in platelet-activating factor.
Chloroplasts Contain Galactolipids and Sulfolipids

The second group of membrane lipids are those that predominate in plant cells: the **galactolipids**, in which one or two galactose residues are connected by a glycosidic linkage to C-3 of a 1,2-diacylglycerol (Fig. 10–11; see also Fig. 10–7). Galactolipids are localized in the thylakoid membranes (internal membranes) of chloroplasts; they make up 70% to 80% of the total membrane lipids of a vascular plant. They are probably the most abundant membrane lipids in the biosphere. Phosphate is often the limiting plant nutrient in soil, and perhaps the evolutionary pressure to conserve phosphate for more critical roles favored plants that made phosphate-free lipids. Plant membranes also contain sulfolipids, in which a sulfonated glucose residue is joined to a diacylglycerol in glycosidic linkage. In sulfolipids, the sulfonate on the head group bears a negative charge like that of the phosphate group in phospholipids (Fig. 10–11).

**Archaea Contain Unique Membrane Lipids**

The archaea, most of which live in ecological niches with extreme conditions—high temperatures (boiling water), low pH, high ionic strength, for example—have membrane lipids containing long-chain (32 carbons) branched hydrocarbons linked at each end to glycerol (Fig. 10–12). These linkages are through ether bonds, which are much more stable to hydrolysis at low pH and high temperature than are the ester bonds found in the lipids of bacteria and eukaryotes. In their fully extended form, these archaeal lipids are twice the length of phospholipids and sphingolipids, and can span the full width of the surface membrane. At each end of the extended molecule is a polar head consisting of glycerol linked to either phosphate or sugar residues. The general name for these compounds, glycerol dialkyl glycerol tetraethers (GDGTs), reflects their unique structure. The glycerol moiety of the archaeal lipids is not the same stereoisomer as that in the lipids of Bacteria and Eukarya; the central carbon is in the R configuration in Archaea, in the S configuration in the other domains (Fig. 10–8).

**Sphingolipids Are Derivatives of Sphingosine**

Sphingolipids, the fourth large class of membrane lipids, also have a polar head group and two nonpolar tails, but unlike glycerophospholipids and galactolipids they contain no glycerol. Sphingolipids are composed of one molecule of the long-chain amino alcohol sphingosine (also called 4-sphingenine) or one of its derivatives, one molecule of a long-chain fatty acid, and a polar head group that is joined by a glycosidic linkage in some cases and a phosphodiester in others (Fig. 10–13).

**FIGURE 10–11 Three glycolipids of chloroplast thylakoid membranes.** In monogalactosyldiacylglycerols (MGDGs) and digalactosyldiacylglycerols (DGDGs), almost all the acyl groups are derived from linoleic acid, 18:2(Δ9,12), and the head groups are uncharged. In the sulfolipid 6-sulfo-6-deoxy-α-D-glucopyranosylglycerol, the sulfonate carries a fixed negative charge.
10.2 Structural Lipids in Membranes

**FIGURE 10–12** A typical membrane lipid of archaea. In this diphytanyl tetraether lipid, the diphytanyl moieties (yellow) are long hydrocarbons composed of eight five-carbon isoprene groups condensed end-to-end (on the condensation of isoprene units, see Fig. 21–36; also, compare the diphytanyl groups with the 20-carbon phytol side chain of chlorophylls in Fig. 19–47a). In this extended form, the diphytanyl groups are about twice the length of a 16-carbon fatty acid typically found in the membrane lipids of bacteria and eukaryotes. The glycerol moieties in the archaeal lipids are in the R configuration, in contrast to those of bacteria and eukaryotes, which have the S configuration. Archaeal lipids differ in the substituents on the glycerols. In the molecule shown here, one glycerol is linked to the disaccharide α-glucopyranosyl-(1→2)-β-galactofuranose; the other glycerol is linked to a glycerol phosphate head group.

**FIGURE 10–13** Sphingolipids. The first three carbons at the polar end of sphingosine are analogous to the three carbons of glycerol in glycerophospholipids. The amino group at C-2 bears a fatty acid in amide linkage. The fatty acid is usually saturated or monounsaturated, with 16, 18, 22, or 24 carbon atoms. Ceramide is the parent compound for this group. Other sphingolipids differ in the polar head group (X) attached at C-1. Gangliosides have very complex oligosaccharide head groups. Standard symbols for sugars are used in this figure, as shown in Table 7–1.
Carbons C-1, C-2, and C-3 of the sphingosine molecule are structurally analogous to the three carbons of glycerol in glycerophospholipids. When a fatty acid is attached in amide linkage to the —NH2 on C-2, the resulting compound is a ceramide, which is structurally similar to a diacylglycerol. Ceramide is the structural parent of all sphingolipids.

There are three subclasses of sphingolipids, all derivatives of ceramide but differing in their head groups: sphingomyelins, neutral (uncharged) glycolipids, and gangliosides. Sphingomyelins contain phosphocholine or phosphoethanolamine as their polar head group and are therefore classified along with glycerophospholipids as phospholipids (Fig. 10–7). Indeed, sphingomyelins resemble phosphatidylycerolines in their general properties and three-dimensional structure, and in having no net charge on their head groups (Fig. 10–14). Sphingomyelins are present in the plasma membranes of animal cells and are especially prominent in myelin, a membranous sheath that surrounds and insulates the axons of some neurons—thus the name “sphingomyelins.”

Glycosphingolipids, which occur largely in the outer face of plasma membranes, have head groups with one or more sugars connected directly to the —OH at C-1 of the ceramide moiety; they do not contain phosphate. Ceramides have a single sugar linked to ceramide; those with galactose are characteristically found in the plasma membranes of cells in neural tissue, and those with glucose in the plasma membranes of cells in nonneural tissues. Globosides are glycosphingolipids with two or more sugars, usually D-glucose, D-galactose, or N-acetyl-D-galactosamine. Ceramides and globosides are sometimes called neutral glycolipids, as they have no charge at pH 7.

Gangliosides, the most complex sphingolipids, have oligosaccharides as their polar head groups and one or more residues of N-acetylenuraminic acid (Neu5Ac), a sialic acid (often simply called “sialic acid”), at the termini. Sialic acid gives gangliosides the negative charge at pH 7 that distinguishes them from globosides. Gangliosides with one sialic acid residue are in the GM (M for mono-) series, those with two are in the GD (D for di-) series, and so on (GT, three sialic acid residues; GQ, four).

Sphingolipids at Cell Surfaces Are Sites of Biological Recognition

When sphingolipids were discovered more than a century ago by the physician-chemist Johann Thudichum, their biological role seemed as enigmatic as the Sphinx, for which he therefore named them. In humans, at least 60 different sphingolipids have been identified in cellular membranes. Many of these are especially prominent in the plasma membranes of neurons, and some are clearly recognition sites on the cell surface, but a specific function for only a few sphingolipids has been discovered thus far. The carbohydrate moieties of certain sphingolipids define the human blood groups and therefore determine the type of blood that individuals can safely receive in blood transfusions (Fig. 10–15).

Gangliosides are concentrated in the outer face of cells, where they present points of recognition for extracellular molecules or surfaces of neighboring cells. The kinds and amounts of gangliosides in the plasma membrane change dramatically during embryonic development. Tumor formation induces the synthesis of a
new complement of gangliosides, and very low concentrations of a specific ganglioside have been found to induce differentiation of cultured neuronal tumor cells. Investigation of the biological roles of diverse gangliosides remains fertile ground for future research.

**Phospholipids and Sphingolipids Are Degraded in Lysosomes**

Most cells continually degrade and replace their membrane lipids. For each hydrolyzable bond in a glycerophospholipid, there is a specific hydrolytic enzyme in the lysosome (Fig. 10–16). Phospholipases of the A type remove one of the two fatty acids, producing a lysophospholipid. (These esterases do not attack the ether link of plasmalogens.) Lysophospholipases remove the remaining fatty acid.

Gangliosides are degraded by a set of lysosomal enzymes that catalyze the stepwise removal of sugar units, finally yielding a ceramide. A genetic defect in any of these hydrolytic enzymes leads to the accumulation of gangliosides in the cell, with severe medical consequences (Box 10–2).

**Sterols Have Four Fused Carbon Rings**

**Sterols** are structural lipids present in the membranes of most eukaryotic cells. The characteristic structure of this fifth group of membrane lipids is the steroid nucleus, consisting of four fused rings, three with six carbons and one with five (Fig. 10–17). The steroid nucleus is almost planar and is relatively rigid; the fused rings do not allow rotation about C—C bonds. **Cholesterol**, the major sterol

**Figure 10–15** Glycosphingolipids as determinants of blood groups. The human blood groups (O, A, B) are determined in part by the oligosaccharide head groups of these glycosphingolipids. The same three oligosaccharides are also found attached to certain blood proteins of individuals of blood types O, A, and B, respectively. Standard symbols for sugars are used here (see Table 7–1).

**Figure 10–16** The specificities of phospholipases. Phospholipases A1 and A2 hydrolyze the ester bonds of intact glycerophospholipids at C-1 and C-2 of glycerol, respectively. When one of the fatty acids has been removed by a type A phospholipase, the second fatty acid is removed by a lysophospholipase (not shown). Phospholipases C and D each split one of the phosphodiester bonds in the head group. Some phospholipases act on only one type of glycerophospholipid, such as phosphatidylinositol 4,5-bisphosphate (shown here) or phosphatidylcholine; others are less specific.

**Figure 10–17** Cholesterol. The stick structure of cholesterol is visible through a transparent surface contour model of the molecule. In the chemical structure, the rings are labeled A through D to simplify reference to derivatives of the steroid nucleus; the carbon atoms are numbered in blue. The C-3 hydroxyl group (pink in both representations) is the polar head group. For storage and transport of the sterol, this hydroxyl group condenses with a fatty acid to form a sterol ester.
The polar lipids of membranes undergo constant metabolic turnover, the rate of their synthesis normally counterbalanced by the rate of breakdown. The breakdown of lipids is promoted by hydrolytic enzymes in lysosomes, each enzyme capable of hydrolyzing a specific bond. When sphingolipid degradation is impaired by a defect in one of these enzymes (Fig. 1), partial breakdown products accumulate in the tissues, causing serious disease.

For example, Niemann-Pick disease is caused by a rare genetic defect in the enzyme sphingomyelinase, which cleaves phosphocholine from sphingomyelin. Sphingomyelin accumulates in the brain, spleen, and liver. The disease becomes evident in infants and causes mental retardation and early death. More common is Tay-Sachs disease, in which ganglioside GM2 accumulates in the brain and spleen (Fig. 2) owing to lack of the enzyme hexosaminidase A. The symptoms of Tay-Sachs disease are progressive developmental retardation, paralysis, blindness, and death by the age of 3 or 4 years.

Genetic counseling can predict and avert many inheritable diseases. Tests on prospective parents can detect abnormal enzymes, then DNA testing can determine the exact nature of the defect and the risk it poses for offspring. Once a pregnancy occurs, fetal cells obtained by sampling a part of the placenta (chorionic villus sampling) or the fluid surrounding the fetus (amniocentesis) can be tested in the same way.

**FIGURE 1** Pathways for the breakdown of GM1, globoside, and sphingomyelin to ceramide. A defect in the enzyme hydrolyzing a particular step is indicated by $\otimes$; the disease that results from accumulation of the partial breakdown product is noted.

**FIGURE 2** Electron micrograph of a portion of a brain cell from an infant with Tay-Sachs disease, obtained post mortem, showing abnormal ganglioside deposits in the lysosomes.
are the fat-soluble vitamins, quinones, and dolichols described in Section 10.3.

In addition to their roles as membrane constituents, the sterols serve as precursors for a variety of products with specific biological activities. Steroid hormones, for example, are potent biological signals that regulate gene expression. **Bile acids** are polar derivatives of cholesterol that act as detergents in the intestine, emulsifying dietary fats to make them more readily accessible to digestive lipases.

**Summary 10.2 Structural Lipids in Membranes**

- The polar lipids, with polar heads and nonpolar tails, are major components of membranes. The most abundant are the glycerophospholipids, which contain fatty acids esterified to two of the hydroxyl groups of glycerol, and a second alcohol, the head group, esterified to the third hydroxyl of glycerol via a phosphodiester bond. Other polar lipids are the sterols.
- Glycerophospholipids differ in the structure of their head group; common glycerophospholipids are phosphatidylethanolamine and phosphatidylcholine. The polar heads of the glycerophospholipids are charged at pH near 7.
- Chloroplast membranes are rich in galactolipids, composed of a diacylglycerol with one or two linked galactose residues, and sulfolipids, diacylglycerols with a linked sulfonated sugar residue and thus a negatively charged head group.
- Archaea have unique membrane lipids, with long-chain alkyl groups ether-linked to glycerol at both ends and with sugar residues and/or phosphate joined to the glycerol to provide a polar or charged head group. These lipids are stable under the harsh conditions in which archaea live.
- The sphingolipids contain sphingosine, a long-chain aliphatic amino alcohol, but no glycerol. Sphingomyelin has, in addition to phosphoric acid and choline, two long hydrocarbon chains, one contributed by a fatty acid and the other by sphingosine. Three other classes of sphingolipids are cerebrosides, globosides, and gangliosides, which contain sugar components.
- Sterols have four fused rings and a hydroxyl group. Cholesterol, the major sterol in animals, is both a structural component of membranes and precursor to a wide variety of steroids.

### 10.3 Lipids as Signals, Cofactors, and Pigments

The two functional classes of lipids considered thus far (storage lipids and structural lipids) are major cellular components; membrane lipids make up 5% to 10% of the dry mass of most cells, and storage lipids more than 80% of the mass of an adipocyte. With some important exceptions, these lipids play a passive role in the cell; lipid fuels are stored until oxidized by enzymes, and membrane lipids form impermeable barriers around cells and cellular compartments. Another group of lipids, present in much smaller amounts, have active roles in the metabolic traffic as metabolites and messengers. Some serve as potent signals—as hormones, carried in the blood from one tissue to another, or as intracellular messengers generated in response to an extracellular signal (hormone or growth factor). Others function as enzyme cofactors in electron-transfer reactions in chloroplasts and mitochondria, or in the transfer of sugar moieties in a variety of glycosylation reactions. A third group consists of lipids with a system of conjugated double bonds; pigment molecules that absorb visible light. Some of these act as light-capturing pigments in vision and photosynthesis; others produce natural colorations, such as the orange of pumpkins and carrots and the yellow of canary feathers. Finally, a very large group of volatile lipids produced in plants serve as signals that pass through the air, allowing plants to communicate with each other, and to invite animal friends and deter foes. We describe in this section a few representatives of these biologically active lipids. In later chapters, their synthesis and biological roles are considered in more detail.

**Phosphatidylinositols and Sphingosine Derivatives Act as Intracellular Signals**

Phosphatidylinositol and its phosphorylated derivatives act at several levels to regulate cell structure and metabolism. Phosphatidylinositol 4,5-bisphosphate (Fig. 10–9) in the cytoplasmic (inner) face of plasma membranes serves as a reservoir of messenger molecules that are released inside the cell in response to extracellular signals interacting with specific surface receptors. Extracellular signals such as the hormone vasopressin activate a specific phospholipase C in the membrane, which hydrolyzes phosphatidylinositol 4,5-bisphosphate to release two products that act as intracellular messengers: inositol 1,4,5-trisphosphate (IP₃),...
which is water-soluble, and diacylglycerol, which remains associated with the plasma membrane. IP$_3$ triggers release of Ca$^{2+}$ from the endoplasmic reticulum, and the combination of diacylglycerol and elevated cytosolic Ca$^{2+}$ activates the enzyme protein kinase C. By phosphorylating specific proteins, this enzyme brings about the cell's response to the extracellular signal. This signaling mechanism is described more fully in Chapter 12 (see Fig. 12-10).

Inositol phospholipids also serve as points of nucleation for supramolecular complexes involved in signaling or in exocytosis. Certain signaling proteins bind specifically to phosphatidylinositol 3,4,5-trisphosphate in the plasma membrane, initiating the formation of multienzyme complexes at the membrane's cytosolic surface. Formation of phosphatidylinositol 3,4,5-trisphosphate in response to extracellular signals therefore brings the proteins together in signaling complexes at the surface of the plasma membrane (see Fig. 12-16).

Membrane sphingolipids also can serve as sources of intracellular messengers. Both ceramide and sphingomyelin (Fig. 10-13) are potent regulators of protein kinases, and ceramide or its derivatives are involved in the regulation of cell division, differentiation, migration, and programmed cell death (also called apoptosis; see Chapter 12).

**Eicosanoids Carry Messages to Nearby Cells**

Eicosanoids are paracrine hormones, substances that act only on cells near the point of hormone synthesis instead of being transported in the blood to act on cells in other tissues or organs. These fatty acid derivatives have a variety of dramatic effects on vertebrate tissues. They are involved in reproductive function; in the inflammation, fever, and pain associated with injury or disease; in the formation of blood clots and the regulation of blood pressure; in gastric acid secretion; and in various other processes important in human health or disease.

All eicosanoids are derived from arachidonic acid (20:4(Δ$^5$,8,11,14)) (Fig. 10–18), the 20-carbon polyunsaturated fatty acid from which they take their general name (Greek *eikos*′, “twenty”). There are three classes of eicosanoids: prostaglandins, thromboxanes, and leukotrienes.

**Prostaglandins (PG)** contain a five-carbon ring originating from the chain of arachidonic acid. Their name derives from the prostate gland, the tissue from which they were first isolated by Bengt Samuelsson and Sune Bergström. Two groups of prostaglandins were originally defined: PGE (ether-soluble) and PGF (fosfat (Swedish for phosphate) buffer-soluble). Each group contains numerous subtypes, named PGE$_1$, PGE$_2$, PGF$_1$, and so forth. Prostaglandins have an array of functions. Some stimulate contraction of the smooth muscle of the uterus during menstruation and labor. Others affect blood flow to specific organs, the wake-sleep cycle, and the responsiveness of certain tissues to hormones such as epinephrine and glucagon. Prostaglandins in a third group elevate body temperature (producing fever) and cause inflammation and pain.

The **thromboxanes** have a six-membered ring containing an ether. They are produced by platelets (also called thrombocytes) and act in the formation of blood clots and the reduction of blood flow to the site of a clot. As shown by John Vane, the nonsteroidal antiinflammatory drugs (NSAIDs)—aspirin, ibuprofen, and meclofenamate, for example—inhibit the enzyme prostaglandin

---

**FIGURE 10–18 Arachidonic acid and some eicosanoid derivatives.** Arachidonic acid (arachidonate at pH 7) is the precursor of eicosanoids, including the prostaglandins, thromboxanes, and leukotrienes. In prostaglandin E$_1$, C-8 and C-12 of arachidonate are joined to form the characteristic five-membered ring. In thromboxane A$_2$, the C-8 and C-12 are joined and an oxygen atom is added to form the six-membered ring. Leukotriene A$_4$ has a series of three conjugated double bonds. Nonsteroidal antiinflammatory drugs (NSAIDs) such as aspirin and ibuprofen block the formation of prostaglandins and thromboxanes from arachidionate by inhibiting the enzyme cyclooxygenase (prostaglandin H$_2$ synthase).
Lipids as Signals, Cofactors, and Pigments

H₂ synthase (also called cyclooxygenase, or COX), which catalyzes an early step in the pathway from arachidonate to prostaglandins and thromboxanes (Fig. 10–18; see also Fig. 21–15).

Leukotrienes, first found in leukocytes, contain three conjugated double bonds. They are powerful biological signals. For example, leukotriene D₄, derived from leukotriene A₄, induces contraction of the smooth muscle lining the airways to the lung. Overproduction of leukotrienes causes asthmatic attacks, and leukotriene synthesis is one target of antiasthmatic drugs such as prednisone. The strong contraction of the smooth muscle of the lungs that occurs during anaphylactic shock is part of the potentially fatal allergic reaction in individuals hypersensitive to bee stings, penicillin, or other agents.

Steroid Hormones Carry Messages between Tissues

Steroids are oxidized derivatives of sterols; they have the sterol nucleus but lack the alkyl chain attached to ring D of cholesterol, and they are more polar than cholesterol. Steroid hormones move through the bloodstream (on protein carriers) from their site of production to target tissues, where they enter cells, bind to highly specific receptor proteins in the nucleus, and trigger changes in gene expression and thus metabolism. Because hormones have very high affinity for their receptors, very low concentrations of hormones (nanomolar or less) are sufficient to produce responses in target tissues. The major groups of steroid hormones are the male and female sex hormones and the hormones produced by the adrenal cortex, cortisol and aldosterone (Fig. 10–19). Prednisone and prednisolone are steroid drugs with potent antiinflammatory activities, mediated in part by the inhibition of arachidonate release by phospholipase A₂ (Fig. 10–18) and consequent inhibition of the synthesis of leukotrienes, prostaglandins, and thromboxanes. These drugs have a variety of medical applications, including the treatment of asthma and rheumatoid arthritis.

Vascular plants contain the steroidlike brassinolide (Fig. 10–19), a potent growth regulator that increases the rate of stem elongation and affects the orientation of cellulose microfibrils in the cell wall during growth.

Vascular Plants Produce Thousands of Volatile Signals

Plants produce literally thousands of different lipophilic compounds, volatile substances that are used to attract pollinators, to repel herbivores, to attract organisms that defend the plant against herbivores, and to communicate with other plants. Jasmonate, for example (see Fig. 12–32), derived from the fatty acid 18:3(Δ⁹,12,15) in membrane lipids, triggers the plant’s defenses in response to insect-inflicted damage. The methyl ester of jasmonate gives the characteristic fragrance of jasmine oil, which is widely used in the perfume industry. Many of the plant volatiles are derived from fatty acids, or

FIGURE 10–19 Steroids derived from cholesterol. Testosterone, the male sex hormone, is produced in the testes. Estradiol, one of the female sex hormones, is produced in the ovaries and placenta. Cortisol and aldosterone are hormones synthesized in the cortex of the adrenal gland; they regulate glucose metabolism and salt excretion, respectively. Prednisolone and prednisone are synthetic steroids used as antiinflammatory agents. Brassinolide is a growth regulator found in vascular plants.
Vitamins A and D Are Hormone Precursors

During the first third of the twentieth century, a major focus of research in physiological chemistry was the identification of vitamins, compounds that are essential to the health of humans and other vertebrates but cannot be synthesized by these animals and must therefore be obtained in the diet. Early nutritional studies identified two general classes of such compounds: those soluble in nonpolar organic solvents (fat-soluble vitamins) and those that could be extracted from foods with aqueous solvents (water-soluble vitamins). Eventually the fat-soluble group was resolved into the four vitamin groups A, D, E, and K, all of which are isoprenoid compounds synthesized by the condensation of multiple isoprene units. Two of these (D and A) serve as hormone precursors.

Vitamin D₃, also called cholecalciferol, is normally formed in the skin from 7-dehydrocholesterol in a photochemical reaction driven by the UV component of sunlight (Fig. 10–20a). Vitamin D₃ is not itself biologically active, but it is converted by enzymes in the liver and kidney to 1,25-dihydroxycholecalciferol, a hormone that regulates calcium uptake in the intestine and calcium levels in kidney and bone. Deficiency of vitamin D leads to defective bone formation and the disease rickets, for which administration of vitamin D produces a dramatic cure (Fig. 10–20b). Vitamin D₂ (ergocalciferol) is a commercial product formed by UV irradiation of the ergosterol of yeast. Vitamin D₂ is structurally similar to D₃, with slight modification to the side chain attached to the sterol D ring. Both have the same biological effects, and D₂ is commonly added to milk and butter as a dietary supplement. Like steroid hormones, the product of vitamin D metabolism, 1,25-dihydroxycholecalciferol, regulates gene expression by interacting with specific nuclear receptor proteins (see p. 1143).

Vitamin A (retinol), in its various forms, functions as a hormone and as the visual pigment of the vertebrate eye (Fig. 10–21). Acting through receptor proteins in the cell nucleus, the vitamin A derivative retinoic acid regulates gene expression in the development of epithelial tissue, including skin. Retinoic acid is the active ingredient in the drug tretinoin (Retin-A), used in the treatment of severe acne and wrinkled skin. Retinal, another vitamin A derivative, is the pigment that initiates the response of rod and cone cells of the retina to light, producing a neuronal signal to the brain. This role of retinal is described in detail in Chapter 12.

Vitamin A was first isolated from fish liver oils; liver, eggs, whole milk, and butter are also good dietary sources. In vertebrates, β-carotene, the pigment that gives carrots, sweet potatoes, and other yellow vegetables their characteristic color, can be enzymatically converted to vitamin A. Deficiency of vitamin A leads to a variety of symptoms in humans, including dryness of the skin, eyes, and mucous membranes; retarded development and growth; and night blindness, an early symptom commonly used in diagnosing vitamin A deficiency.
Vitamins E and K and the Lipid Quinones Are Oxidation-Reduction Cofactors

**Vitamin E** is the collective name for a group of closely related lipids called tocopherols, all of which contain a substituted aromatic ring and a long isoprenoid side chain (Fig. 10-22a). Because they are hydrophobic, tocopherols associate with cell membranes, lipid deposits, and lipoproteins in the blood. Tocopherols are biological antioxidants. The aromatic ring reacts with and destroys the most reactive forms of oxygen radicals and other free radicals, protecting unsaturated fatty acids from oxidation and preventing oxidative damage to membrane lipids, which can cause cell fragility. Tocopherols are found in eggs and vegetable oils and are especially abundant in wheat germ. Laboratory animals fed diets depleted of vitamin E develop scaly skin, muscular weakness and wasting, and sterility. Vitamin E deficiency in humans is very rare; the principal symptom is fragile erythrocytes.

The aromatic ring of **vitamin K** (Fig. 10-22b) undergoes a cycle of oxidation and reduction during the formation of active prothrombin, a blood plasma protein essential in blood clotting. Prothrombin is a proteolytic enzyme that splits peptide bonds in the blood protein fibrinogen to convert it to fibrin, the insoluble fibrous protein that holds blood clots together. Henrik Dam and Edward A. Doisy independently discovered that vitamin K deficiency slows blood clotting, which can be fatal. Vitamin K deficiency is very uncommon in humans, aside from a small percentage of infants who suffer from hemorrhagic disease of the newborn, a potentially fatal disorder. In the United States, newborns are routinely given a 1 mg injection of vitamin K. Vitamin K₁ (phylloquinone) is found in green plant leaves; a related form, vitamin K₂ (menaquinone), is formed by bacteria living in the vertebrate intestine.

\((n = 4 \text{ to } 8)\)

Plastoquinone: a chloroplast electron carrier  
\((n = 4 \text{ to } 8)\)

Dolichol: a sugar carrier  
\((n = 9 \text{ to } 22)\)

**FIGURE 10-22** Some other biologically active isoprenoid compounds or derivatives. Units derived from isoprene are set off by dashed red lines. In most mammalian tissues, ubiquinone (also called coenzyme Q) has 10 isoprene units. Dolichols of animals have 17 to 21 isoprene units (85 to 105 carbon atoms), bacterial dolichols have 11, and those of plants and fungi have 14 to 24.

Warfarin (Fig. 10–22c) is a synthetic compound that inhibits the formation of active prothrombin. It is particularly poisonous to rats, causing death by internal bleeding. Ironically, this potent rodenticide is also an invaluable anticoagulant drug for treating humans at risk for excessive blood clotting, such as surgical patients and those with coronary thrombosis.

Ubiquinone (also called coenzyme Q) and plastoquinone (Fig. 10–22d, e) are isoprenoids that function as lipophilic electron carriers in the oxidation-reduction reactions that drive ATP synthesis in mitochondria and chloroplasts, respectively. Both ubiquinone and plastoquinone can accept either one or two electrons and either one or two protons (see Fig. 19–2).

**Dolichols Activate Sugar Precursors for Biosynthesis**

During assembly of the complex carbohydrates of bacterial cell walls, and during the addition of polysaccharide units to certain proteins (glycoproteins) and lipids (glycolipids) in eukaryotes, the sugar units to be added are chemically activated by attachment to isoprenoid alcohols called dolichols (Fig. 10–22f). These compounds have strong hydrophobic interactions with membrane lipids, anchoring the attached sugars to the membrane, where they participate in sugar-transfer reactions.

**Many Natural Pigments Are Lipidic Conjugated Dienes**

Conjugated dienes have carbon chains with alternating single and double bonds. Because this structural arrangement allows the delocalization of electrons, the compounds can be excited by low-energy electromagnetic radiation (visible light), giving them colors visible to humans and other animals. Carotene (Fig. 10–21) is yellow-orange; similar compounds give bird feathers their striking reds, oranges, and yellows (Fig. 10–23). Like sterols, steroids, dolichols, vitamins A, E, D, and K,
Canthaxanthin (bright red)

Zeaxanthin (bright yellow)

Figure 10-23 Lipids as pigments in plants and bird feathers. Compounds with long conjugated systems absorb light in the visible region of the spectrum. Subtle differences in the chemistry of these compounds produce pigments of strikingly different colors. Birds acquire the pigments that color their feathers red or yellow by eating plant materials that contain carotenoid pigments, such as canthaxanthin and zeaxanthin. The differences in pigmentation between male and female birds are the result of differences in intestinal uptake and processing of carotenoids.

SUMMARY 10.3 Lipids as Signals, Cofactors, and Pigments

- Some types of lipids, although present in relatively small quantities, play critical roles as cofactors or signals.
- Phosphatidylinositol bisphosphate is hydrolyzed to yield two intracellular messengers, diacylglycerol and inositol 1,4,5-trisphosphate. Phosphatidylinositol 3,4,5-trisphosphate is a nucleation point for supramolecular protein complexes involved in biological signaling.
- Prostaglandins, thromboxanes, and leukotrienes (the eicosanoids), derived from arachidonate, are extremely potent hormones.
- Steroid hormones, derived from sterols, serve as powerful biological signals, such as the sex hormones.
- Vitamins D, A, E, and K are fat-soluble compounds made up of isoprene units. All play essential roles in the metabolism or physiology of animals. Vitamin D is precursor to a hormone that regulates calcium metabolism. Vitamin A furnishes the visual pigment of the vertebrate eye and is a regulator of gene expression during epithelial cell growth. Vitamin E functions in the protection of membrane lipids from oxidative damage, and vitamin K is essential in the blood-clotting process.
- Ubiquinones and plastoquinones, also isoprenoid derivatives, are electron carriers in mitochondria and chloroplasts, respectively.
- Dolichols activate and anchor sugars to cellular membranes; the sugar groups are then used in the synthesis of complex carbohydrates, glycolipids, and glycoproteins.
- Lipidic conjugated dienes serve as pigments in flowers and fruits and give bird feathers their striking colors.

10.4 Working with Lipids

Because lipids are insoluble in water, their extraction and subsequent fractionation require the use of organic solvents and some techniques not commonly used in the purification of water-soluble molecules such as proteins and carbohydrates. In general, complex mixtures of lipids are separated by differences in polarity or solubility in nonpolar solvents. Lipids that contain ester- or amide-linked fatty acids can be hydrolyzed by treatment with acid or alkali or with specific hydrolytic enzymes (phospholipases, glycosidases) to yield their components for analysis. Some methods commonly used in lipid analysis are shown in Figure 10-24 and discussed below.

Lipid Extraction Requires Organic Solvents

Neutral lipids (triacylglycerols, waxes, pigments, and so forth) are readily extracted from tissues with ethyl ether, chloroform, or benzene, solvents that do not permit lipid clustering driven by hydrophobic interactions. Membrane lipids are more effectively extracted by more polar organic solvents, such as ethanol or methanol, which reduce the hydrophobic interactions among lipid molecules while also weakening the hydrogen bonds and electrostatic interactions that bind membrane lipids to membrane proteins. A commonly used extractant is a
FIGURE 10–24 Common procedures in the extraction, separation, and identification of cellular lipids. (a) Tissue is homogenized in a chloroform/methanol/water mixture, which on addition of water and removal of unextractable sediment by centrifugation yields two phases. Different types of extracted lipids in the chloroform phase may be separated by (b) adsorption chromatography on a column of silica gel, through which solvents of increasing polarity are passed, or (c) thin-layer chromatography (TLC), in which lipids are carried up a silica gel-coated plate by a rising solvent front, less polar lipids traveling farther than more polar or charged lipids. TLC with appropriate solvents can also be used to separate closely related lipid species; for example, the charged lipids phosphatidylserine, phosphatidylglycerol, and phosphatidylinositol are easily separated by TLC.

For the determination of fatty acid composition, a lipid fraction containing ester-linked fatty acids is transesterified in a warm aqueous solution of NaOH and methanol (d), producing a mixture of fatty acyl methyl esters. These methyl esters are then separated on the basis of chain length and degree of saturation by (e) gas-liquid chromatography (GLC) or (f) high-performance liquid chromatography (HPLC). Precise determination of molecular mass by mass spectrometry allows unambiguous identification of individual lipids.

mixture of chloroform, methanol, and water, initially in volume proportions (1:2:0.8) that are miscible, producing a single phase. After tissue is homogenized in this solvent to extract all lipids, more water is added to the resulting extract and the mixture separates into two phases, methanol/water (top phase) and chloroform (bottom phase). The lipids remain in the chloroform layer, and the more polar molecules such as proteins and sugars partition into the methanol/water layer.

Adsorption Chromatography Separates Lipids of Different Polarity

Complex mixtures of tissue lipids can be fractionated by chromatographic procedures based on the different polarities of each class of lipid. In adsorption chromatography (Fig. 10–24b), an insoluble, polar material such as silica gel (a form of silicic acid, Si(OH)$_4$) is packed into a glass column, and the lipid mixture (in chloroform solution) is applied to the top of the column. (In high-performance liquid chromatography, the column is of smaller diameter and solvents are forced through the column under high pressure.) The polar lipids bind tightly to the polar silicic acid, but the neutral lipids pass directly through the column and emerge in the first chloroform wash. The polar lipids are then eluted, in order of increasing polarity, by washing the column with solvents of progressively higher polarity. Uncharged but polar lipids (cerebrosides, for example) are eluted with acetone, and very polar or charged lipids (such as glycerophospholipids) are eluted with methanol.

Thin-layer chromatography on silicic acid employs the same principle (Fig. 10–24c). A thin layer of silica gel is spread onto a glass plate, to which it adheres. A small sample of lipids dissolved in chloroform is applied near
vapor. As the solvent rises on the plate by capillary action, the entire farthest edge of the plate, which is dipped in a shallow container of an organic solvent or solvent mixture; the entire farthest, as they have lesser tendency to bind to the silicic acid. The separated lipids can be detected by spraying the plate with a dye (rhodamine) that fluoresces when associated with lipids, or by exposing the plate to iodine fumes. Iodine reacts reversibly with the double bonds in fatty acids, such that lipids containing unsaturated fatty acids develop a yellow or brown color. Several other spray reagents are also useful in detecting specific lipids. For subsequent analysis, regions containing separated lipids can be scraped from the plate and the lipids recovered by extraction with an organic solvent.

**Gas-Liquid Chromatography Resolves Mixtures of Volatile Lipid Derivatives**

Gas-liquid chromatography separates volatile components of a mixture according to their relative tendencies to dissolve in the inert material packed in the chromatography column or to volatilize and move through the column, carried by a current of an inert gas such as helium. Some lipids are naturally volatile, but most must first be derivatized to increase their volatility (that is, lower their boiling point). For an analysis of the fatty acids in a sample of phospholipids, the lipids are first transesterified: heated in a methanol/HCl or methanol/NaOH mixture to convert fatty acids esterified to glycerol into their methyl esters (Fig. 10-24d). These fatty acyl methyl esters are then loaded onto the gas-liquid chromatography column, and the column is heated to volatilize the compounds. Those fatty acyl esters most soluble in the column material partition into (dissolve in) that material; the less soluble lipids are carried by the stream of inert gas and emerge first from the column. The order of elution depends on the nature of the solid adsorbant in the column and on the boiling point of the components of the lipid mixture. Using these techniques, mixtures of fatty acids of various chain lengths and various degrees of unsaturation can be completely resolved (Fig. 10-24e).

**Specific Hydrolysis Aids in Determination of Lipid Structure**

Certain classes of lipids are susceptible to degradation under specific conditions. For example, all ester-linked fatty acids in triacylglycerols, phospholipids, and sterol esters are released by mild acid or alkaline treatment, and somewhat harsher hydrolysis conditions release amide-bound fatty acids from sphingolipids. Enzymes that specifically hydrolyze certain lipids are also useful in the determination of lipid structure. Phospholipases A, C, and D (Fig. 10-16) each split particular bonds in phospholipids and yield products with characteristic solubilities and chromatographic behaviors. Phospholipase C, for example, releases a water-soluble phosphoryl alcohol (such as phosphocholine from phosphatidylcholine) and a chloroform-soluble diacylglycerol, each of which can be characterized separately to determine the structure of the intact phospholipid. The combination of specific hydrolysis with characterization of the products by thin-layer, gas-liquid, or high-performance liquid chromatography often allows determination of a lipid structure.

**Mass Spectrometry Reveals Complete Lipid Structure**

To establish unambiguously the length of a hydrocarbon chain or the position of double bonds, mass spectrometric analysis of lipids or their volatile derivatives is invaluable. The chemical properties of similar lipids (for example, two fatty acids of similar length unsaturated at different positions, or two isoprenoids with different numbers of isoprene units) are very much alike, and their order of elution from the various chromatographic procedures often does not distinguish between them. When the eluate from a chromatography column is sampled by mass spectrometry, however, the components of a lipid mixture can be simultaneously separated and identified by their unique pattern of fragmentation (Fig. 10-25).

**Lipidomics Seeks to Catalog All Lipids and Their Functions**

In exploring the biological role of lipids in cells and tissues, it is important to know which lipids are present and in what proportions, and to know how this lipid composition changes with embryonic development, disease, or drug treatment. As lipid biochemists have become aware of the thousands of different naturally occurring lipids, they have proposed a new nomenclature system, with the aim of making it easier to compile and search databases of lipid composition. The system places each lipid in one of eight chemical groups (Table 10-3) designated by two letters. Within these groups, finer distinctions are indicated by numbered classes and subclasses. For example, all glycerophosphocholines are GP01; the subgroup of glycerophosphocholines with two fatty acids in ester linkage is designated GP0101; with one fatty acid ether-linked at position 1 and one in ester linkage at position 2, this becomes GP0102. Specific fatty acids are designated by numbers that give every lipid its own unique identifier, so that each individual lipid, including lipid types not yet discovered, can be unambiguously described in terms of a 12-character identifier. One factor used in this classification is the nature of the biosynthetic precursor. For example, prenol lipids (dolichols and vitamins E and K, for example) are formed from isoprenyl precursors. Polyketides, which we have not discussed in this chapter, include some natural products, many toxic, with biosynthetic pathways related to those for fatty acids. The eight chemical categories in Table 10-3 do not coincide perfectly with the divisions according to biological function that we have
FIGURE 10–25 Determination of fatty acid structure by mass spectrometry. The fatty acid is first converted to a derivative that minimizes migration of the double bonds when the molecule is fragmented by electron bombardment. The derivative shown here is a picolinyl ester of linoleic acid—18:2(Δ⁶,1₂) (M, 371)—in which the alcohol is picolinol (red). When bombarded with a stream of electrons, this molecule is volatilized and converted to a parent ion (M⁺; M, 371), in which the N atom bears the positive charge, and a series of smaller fragments produced by breakage of C—C bonds in the fatty acid. The mass spectrometer separates these charged fragments according to their mass/charge ratio (m/z). (To review the principles of mass spectrometry, see Box 3–2.)

The prominent ions at m/z = 92, 108, 151, and 164 contain the pyridine ring of the picolinol and various fragments of the carboxyl group, showing that the compound is indeed a picolinyl ester. The molecular ion, M⁺ (m/z = 371), confirms the presence of a C₁₈ fatty acid with two double bonds. The uniform series of ions 14 atomic mass units (u) apart represents loss of each successive methyl and methylene group from the methyl end of the acyl chain (beginning at C-18; the right end of the molecule as shown here), until the ion at m/z = 300 is reached. This is followed by a gap of 26 u for the carbons of the terminal double bond, at m/z = 274; a further gap of 14 u for the C-11 methylene group, at m/z = 260; and so forth. By this means the entire structure is determined, although these data alone do not reveal the configuration (cis or trans) of the double bonds.

used in this chapter. For example, the structural lipids of membranes include both glycerophospholipids and sphingolipids, separate categories in Table 10–3. Each method of categorization has its advantages.

The application of mass spectrometric techniques with high throughput and high resolution can provide quantitative catalogs of all the lipids present in a specific cell type—the lipidome—under particular conditions, and of the ways in which the lipidome changes with differentiation, disease such as cancer, or drug treatment. An animal cell contains about a thousand different lipid species, each presumably having a specific function. These functions are known for a growing number of lipids, but the still largely unexplored lipidome offers a rich source of new problems for the next generation of biochemists and cell biologists to solve.

SUMMARY 10.4 Working with Lipids

- In the determination of lipid composition, the lipids are first extracted from tissues with organic solvents and separated by thin-layer, gas-liquid, or high-performance liquid chromatography.

Lipids as Nutrients

A succinct statement of the findings that omega-3 fatty acids reduce the risk of cardiovascular disease.

A summary of the evidence that dietary trans fatty acids predispose to coronary heart disease.

Structural Lipids in Membranes

A minireview of the role of membrane lipids in the folding of membrane proteins.

This article is one of many in a four-volume set that contains definitive descriptions of the clinical, biochemical, and genetic aspects of hundreds of human metabolic diseases—an authoritative source and fascinating reading.

Further Reading

General

A new system of nomenclature for biological lipids, separating them into eight major categories. The definitive reference on lipid classification.

A good general resource on lipid structure and metabolism, at the intermediate level.

An excellent collection of reviews on various aspects of lipid structure, biosynthesis, and function.

Lipids as Signals, Cofactors, and Pigments

Problems

1. **Operational Definition of Lipids** How is the definition of “lipid” different from the types of definitions used for other biomolecules that we have considered, such as amino acids, nucleic acids, and proteins?

2. **Melting Points of Lipids** The melting points of a series of 18-carbon fatty acids are: stearic acid, 69.6 °C; oleic acid, 13.4 °C; linoleic acid, −5 °C; and linolenic acid, −11 °C.

(a) What structural aspect of these 18-carbon fatty acids can be correlated with the melting point?

(b) Draw all the possible triacylglycerols that can be constructed from glycerol, palmitic acid, and oleic acid. Rank them in order of increasing melting point.

(c) Branched-chain fatty acids are found in some bacterial membrane lipids. Would their presence increase or decrease the fluidity of the membranes (that is, give them a lower or higher melting point)? Why?

3. **Preparation of Béarnaise Sauce** During the preparation of béarnaise sauce, egg yolks are incorporated into melted butter to stabilize the sauce and avoid separation. The stabilizing agent in the egg yolks is lecithin (phosphatidylcholine). Suggest why this works.

4. **Isoprene Units in Isoprenoids** Geraniol, farnesol, and squalene are called isoprenoids, because they are synthesized from five-carbon isoprene units. In each compound, circle the five-carbon units representing isoprene units (see Fig. 10–22).

![Geraniol](image1)

![Farnesol](image2)

![Squalene](image3)

5. **Naming Lipid Stereoisomers** The two compounds below are stereoisomers of carvone with quite different properties; the one on the left smells like spearmint, and that on the right, like caraway. Name the compounds using the RS system.

![Spearmint](image4)

![Caraway](image5)
6. RS Designations for Alanine and Lactate  Draw (using wedge-bond notation) and label the (R) and (S) isomers of 2-aminopropanoic acid (alanine) and 2-hydroxypropanoic acid (lactic acid).

7. Hydrophobic and Hydrophilic Components of Membrane Lipids A common structural feature of membrane lipids is their amphipathic nature. For example, in phosphatidylcholine, the two fatty acid chains are hydrophobic and the phosphocholine head group is hydrophilic. For each of the following membrane lipids, name the components that serve as the hydrophobic and hydrophilic units: (a) phosphatidylethanolamine; (b) sphingomyelin; (c) galactosylcerebroside; (d) ganglioside; (e) cholesterol.

8. Structure of Omega-6 Fatty Acid  Draw the structure of the omega-6 fatty acid 16:1.

9. Catalytic Hydrogenation of Vegetable Oils  Catalytic hydrogenation, used in the food industry, converts double bonds in the fatty acids of the oil triacylglycerols to \(-\text{CH}_2-\text{CH}_2-\). How does this affect the physical properties of the oils?

10. Alkali Lability of Triacylglycerols  A common procedure for cleaning the grease trap in a sink is to add a product that contains sodium hydroxide. Explain why this works.

11. Deducing Lipid Structure from Composition  Compositional analysis of a certain lipid shows that it has exactly one mole of fatty acid per mole of inorganic phosphate. Could this be a glycerophospholipid? A ganglioside? A sphingomyelin?

12. Deducing Lipid Structure from Molar Ratio of Components  Complete hydrolysis of a glycerophospholipid yields glycerol, two fatty acids (16:1(\(\Delta^6\)) and 16:0), phosphoric acid, and serine in the molar ratio 1:1:1:1. Name this lipid and draw its structure.

13. Impermeability of Waxes  What property of the waxy cuticles that cover plant leaves makes the cuticles impermeable to water?

14. The Action of Phospholipases  The venom of the Eastern diamondback rattler and the Indian cobra contains phospholipase A\(_2\), which catalyzes the hydrolysis of fatty acids at the C-2 position of glycerophospholipids. The phospholipid breakdown product of this reaction is lysollecithin (lecithin is phosphatidylcholine). At high concentrations, this and other lysophospholipids act as detergents, dissolving the membranes of erythrocytes and lysing the cells. Extensive hemolysis may be life-threatening.

(a) All detergents are amphipathic. What are the hydrophilic and hydrophobic portions of lysollecithin?
(b) The pain and inflammation caused by a snake bite can be treated with certain steroids. What is the basis of this treatment?
(c) Though the high levels of phospholipase A\(_2\) in venom can be deadly, this enzyme is necessary for a variety of normal metabolic processes. What are these processes?

15. Lipids in Blood Group Determination  We refer to the structure of glycosphingolipids determines the blood groups A, B, and O in humans. It is also true that glycoproteins determine blood groups. How can both statements be true?

16. Intracellular Messengers from Phosphatidylinositol  When the hormone vasopressin stimulates cleavage of phosphatidylinositol 4,5-bisphosphate by hormone-sensitive phospholipase C, two products are formed. What are they? Compare their properties and their solubilities in water, and predict whether either would diffuse readily through the cytosol.

17. Storage of Fat-Soluble Vitamins  In contrast to water-soluble vitamins, which must be part of our daily diet, fat-soluble vitamins can be stored in the body in amounts sufficient for many months. Suggest an explanation for this difference.

18. Hydrolysis of Lipids  Name the products of mild hydrolysis with dilute NaOH of (a) 1-stearoyl-2,3-dipalmitoylglycerol; (b) 1-palmitoyl-2-oleoylphosphatidylcholine.

19. Effect of Polarity on Solubility  Rank the following in order of increasing solubility in water: a triacylglycerol, a dicarboxylic acid, and a monoacylglycerol, all containing only palmitic acid.

20. Chromatographic Separation of Lipids  A mixture of lipids is applied to a silica gel column, and the column is then washed with increasingly polar solvents. The mixture consists of phosphatidylserine, phosphatidylethanolamine, phosphatidylcholine, cholesterol, and palmitate (a sterol ester), sphingomyelin, palmitate, \(n\)-tetradecanol, triacylglycerol, and cholesterol. In what order will the lipids elute from the column? Explain your reasoning.

21. Identification of Unknown Lipids  Johann Thudichum, who practiced medicine in London about 100 years ago, also dabbled in lipid chemistry in his spare time. He isolated a variety of lipids from neural tissue, and characterized and named many of them. His carefully sealed and labeled vials of isolated lipids were rediscovered many years later.

(a) How would you confirm, using techniques not available to Thudichum, that the vials labeled "sphingomyelin" and "cerebroside" actually contain these compounds?
(b) How would you distinguish sphingomyelin from phosphatidylcholine by chemical, physical, or enzymatic tests?

22. Ninhydrin to Detect Lipids on TLC Plates  Ninhydrin reacts specifically with primary amines to form a purplish-blue product. A thin-layer chromatogram of rat liver phospholipids
is sprayed with ninhydrin, and the color is allowed to develop. Which phospholipids can be detected in this way?

**Data Analysis Problem**

### 23. Determining the Structure of the Abnormal Lipid in Tay-Sachs Disease

Box 10-2, Figure 1, shows the pathway of breakdown of gangliosides in healthy (normal) individuals and individuals with certain genetic diseases. Some of the data on which the figure is based were presented in a paper by Lars Svennerholm (1962). Note that the sugar Neu5Ac, N-acetylneuraminic acid, represented in the Box 10-2 figure as O, is a sialic acid.

Svennerholm reported that “about 90% of the monosialo-gangliosides isolated from normal human brain” consisted of a compound with ceramide, hexose, N-acetylgalactosamine, and N-acetylneuraminic acid in the molar ratio 1:3:1:1.

(a) Which of the gangliosides (GM1 through GM3 and globoside) in Box 10-2, Figure 1, fits this description? Explain your reasoning.

(b) Svennerholm reported that 90% of the gangliosides from a patient with Tay-Sachs had a molar ratio (of the same four components given above) of 1:2:1:1. Is this consistent with the Box 10-2 figure? Explain your reasoning.

To determine the structure in more detail, Svennerholm treated the gangliosides with neuraminidase to remove the N-acetylneuraminic acid. This resulted in an asialoganglioside that was much easier to analyze. He hydrolyzed it with acid, collected the ceramide-containing products, and determined the molar ratio of the sugars in each product. He did this for both the normal and the Tay-Sachs gangliosides. His results are shown below.

</table>

(c) Based on these data, what can you conclude about the structure of the normal ganglioside? Is this consistent with the structure in Box 10-2? Explain your reasoning.

(d) What can you conclude about the structure of the Tay-Sachs ganglioside? Is this consistent with the structure in Box 10-2? Explain your reasoning.

Svennerholm also reported the work of other researchers who “permethylated” the normal asialoganglioside. Permethylation is the same as exhaustive methylation: a methyl group is added to every free hydroxyl group on a sugar. They found the following permethylated sugars: 2,3,6-trimethylglucopyranose; 2,3,4,6-tetramethylgalactopyranose; 2,4,6-trimethylgalactopyranose; and 4,6-dimethyl-2-deoxy-2-aminogalactopyranose.

(e) To which sugar of GM1 does each of the permethylated sugars correspond? Explain your reasoning.

(f) Based on all the data presented so far, what pieces of information about normal ganglioside structure are missing?

**Reference**

The first cell probably came into being when a membrane formed, enclosing a small volume of aqueous solution and separating it from the rest of the universe. Membranes define the external boundaries of cells and regulate the molecular traffic across that boundary (Fig. 11-1); in eukaryotic cells, they divide the internal space into discrete compartments to segregate processes and components. They organize complex reaction sequences and are central to both biological energy conservation and cell-to-cell communication. The biological activities of membranes flow from their remarkable physical properties. Membranes are flexible, self-sealing, and selectively permeable to polar solutes.

Membrane bilayer

FIGURE 11-1 Biological membranes. Viewed in cross section, all cell membranes share a characteristic trilaminar appearance. This erythrocyte was stained with osmium tetroxide and viewed with an electron microscope. The plasma membrane appears as a three-layer structure, 5 to 8 nm (50 to 80 Å) thick. The trilaminar image consists of two electron-dense layers (the osmium, bound to the inner and outer surfaces of the membrane) separated by a less dense central region.

Their flexibility permits the shape changes that accompany cell growth and movement (such as amoeboid movement). With their ability to break and reseal, two membranes can fuse, as in exocytosis, or a single membrane-enclosed compartment can undergo fission to yield two sealed compartments, as in endocytosis or cell division, without creating gross leaks through cellular surfaces. Because membranes are selectively permeable, they retain certain compounds and ions within cells and within specific cellular compartments, while excluding others.

Membranes are not merely passive barriers. They include an array of proteins specialized for promoting or catalyzing various cellular processes. At the cell surface, transporters move specific organic solutes and inorganic ions across the membrane; receptors sense extracellular signals and trigger molecular changes in the cell; adhesion molecules hold neighboring cells together. Within the cell, membranes organize cellular processes such as the synthesis of lipids and certain proteins, and the energy transductions in mitochondria and chloroplasts. Because membranes consist of just two layers of molecules, they are very thin—essentially two-dimensional. Intermolecular collisions are far more probable in this two-dimensional space than in three-dimensional space, so the efficiency of enzyme-catalyzed processes organized within membranes is vastly increased.

In this chapter we first describe the composition of cellular membranes and their chemical architecture—the molecular structures that underlie their biological functions. Next, we consider the remarkable dynamic features of membranes, in which lipids and proteins move relative to each other. Cell adhesion, endocytosis, and the membrane fusion accompanying neurotransmitter secretion illustrate the dynamic roles of membrane proteins. We then turn to the protein-mediated passage of solutes across membranes via transporters and ion channels. In later chapters we discuss the roles of membranes in signal transduction (Chapters 12 and 23), energy transduction (Chapter 19), lipid synthesis (Chapter 21), and protein synthesis (Chapter 27).
11.1 The Composition and Architecture of Membranes

One approach to understanding membrane function is to study membrane composition—to determine, for example, which components are common to all membranes and which are unique to membranes with specific functions. So before describing membrane structure and function we consider the molecular components of membranes: proteins and polar lipids, which account for almost all the mass of biological membranes, and carbohydrates, present as part of glycoproteins and glycolipids.

Each Type of Membrane Has Characteristic Lipids and Proteins

The relative proportions of protein and lipid vary with the type of membrane (Table 11-1), reflecting the diversity of biological roles. For example, certain neurons have a myelin sheath, an extended plasma membrane that wraps around the cell many times and acts as a passive electrical insulator. The myelin sheath consists primarily of lipids, whereas the plasma membranes of bacteria and the membranes of mitochondria and chloroplasts, the sites of many enzyme-catalyzed processes, contain more protein than lipid (in mass per total mass).

For studies of membrane composition, the first task is to isolate a selected membrane. When eukaryotic cells are subjected to mechanical shear, their plasma membranes are torn and fragmented, releasing cytoplasmic components and membrane-bounded organelles such as mitochondria, chloroplasts, lysosomes, and nuclei. Plasma membrane fragments and intact organelles can be isolated by techniques described in Chapter 1 (see Fig. 1-8) and in Worked Example 2-1, p. 53.

Cells clearly have mechanisms to control the kinds and amounts of membrane lipid they synthesize and to target specific lipids to particular organelles. Each kingdom, each species, each tissue or cell type, and the organelles of each cell type have a characteristic set of membrane lipids. Plasma membranes, for example, are enriched in cholesterol and contain no detectable cardiolipin (Fig. 11-2); this distribution is reversed in the inner mitochondrial membrane, which has very low cholesterol and high cardiolipin. In all but a few cases, the functional significance of these combinations is not yet known.

![FIGURE 11-2 Lipid composition of the plasma membrane and organelle membranes of a rat hepatocyte. The functional specialization of each membrane type is reflected in its unique lipid composition.](image)

Cholesterol is prominent in plasma membranes but barely detectable in mitochondrial membranes. Cardiolipin is a major component of the inner mitochondrial membrane but not of the plasma membrane. Phosphatidylycerine, phosphatidylinositol, and phosphatidylglycerol are relatively minor components (yellow) of most membranes but serve critical functions; phosphatidylinositol and its derivatives, for example, are important in signal transductions triggered by hormones. Sphingolipids, phosphatidylcholine, and phosphatidylethanolamine are present in most membranes, but in varying proportions. Glycolipids, which are major components of the chloroplast membranes of plants, are virtually absent from animal cells.

*Note: Values do not add up to 100% in every case, because there are components other than protein, phospholipids, and sterol; plants, for example, have high levels of glycolipids.*
The protein composition of membranes from different sources varies even more widely than their lipid composition, reflecting functional specialization. In addition, some membrane proteins are covalently linked to oligosaccharides. For example, in glycophorin, a glycoprotein of the erythrocyte plasma membrane, 60% of the mass consists of complex oligosaccharides covalently attached to specific amino acid residues. Ser, Thr, and Asn residues are the most common points of attachment (see Fig. 7-29). The sugar moieties of surface glycoproteins influence the folding of the proteins, as well as their stability and intracellular destination, and they play a significant role in the specific binding of ligands to glycoprotein surface receptors (see Fig. 7-35).

Some membrane proteins are covalently attached to one or more lipids, which serve as hydrophobic anchors that hold the proteins to the membrane, as we shall see.

**All Biological Membranes Share Some Fundamental Properties**

Membranes are impermeable to most polar or charged solutes, but permeable to nonpolar compounds; they are 5 to 8 nm (50 to 80 Å) thick and appear trilaminar when viewed in cross section with the electron microscope (Fig. 11-1). The combined evidence from electron microscopy and studies of chemical composition, as well as physical studies of permeability and the movement of individual protein and lipid molecules within membranes, led to the development of the fluid mosaic model for the structure of biological membranes (Fig. 11-3). Phospholipids form a bilayer in which the nonpolar regions of the lipid molecules in each layer face the core of the bilayer and their polar head groups face outward, interacting with the aqueous phase on either side. Proteins are embedded in this bilayer sheet, held by hydrophobic interactions between the membrane lipids and hydrophobic domains in the proteins. Some proteins protrude from only one side of the membrane; others have domains exposed on both sides. The orientation of proteins in the bilayer is asymmetric, giving the membrane "sidedness": the protein domains exposed on one side of the bilayer are different from those exposed on the other side, reflecting functional asymmetry. The individual lipid and protein units in a membrane form a fluid mosaic with a pattern that, unlike a mosaic of ceramic tile and mortar, is free to change constantly. The membrane mosaic is fluid because most of the interactions among its components are noncovalent, leaving individual lipid and protein molecules free to move laterally in the plane of the membrane.

We now look at some of these features of the fluid mosaic model in more detail and consider the experimental evidence that supports the basic model but has necessitated its refinement in several ways.
A Lipid Bilayer Is the Basic Structural Element of Membranes

Glycerophospholipids, sphingolipids, and sterols are virtually insoluble in water. When mixed with water, they spontaneously form microscopic lipid aggregates, clustering together, with their hydrophobic moieties in contact with each other and their hydrophilic groups interacting with the surrounding water. This clustering reduces the amount of hydrophobic surface exposed to water and thus minimizes the number of molecules in the shell of ordered water at the lipid-water interface (see Fig. 2–7), resulting in an increase in entropy. Hydrophobic interactions among lipid molecules provide the thermodynamic driving force for the formation and maintenance of these clusters.

Depending on the precise conditions and the nature of the lipids, three types of lipid aggregate can form when amphipathic lipids are mixed with water (Fig. 11–4). Micelles are spherical structures that contain anywhere from a few dozen to a few thousand amphipathic molecules. These molecules are arranged with their hydrophobic regions aggregated in the interior, where water is excluded, and their hydrophilic head groups at the surface, in contact with water. Micelle formation is favored when the cross-sectional area of the head group is greater than that of the acyl side chain(s), as in free fatty acids, lysophospholipids (phospholipids lacking one fatty acid), and detergents such as sodium dodecyl sulfate (SDS; p. 89).

A second type of lipid aggregate in water is the bilayer, in which two lipid monolayers (leaflet) form a two-dimensional sheet. Bilayer formation is favored if the cross-sectional areas of the head group and acyl side chain(s) are similar, as in glycerophospholipids and sphingolipids. The hydrophobic portions in each monolayer, excluded from water, interact with each other. The hydrophilic head groups interact with water at each surface of the bilayer. Because the hydrophobic regions at its edges (Fig. 11–4b) are in contact with water, the bilayer sheet is relatively unstable and spontaneously folds back on itself to form a hollow sphere, a vesicle (Fig. 11–4c). The continuous surface of vesicles eliminates exposed hydrophobic regions, allowing bilayers to achieve maximal stability in their aqueous environment. Vesicle formation also creates a separate aqueous compartment. It is likely that the precursors to the first living cells resembled lipid vesicles, their aqueous contents segregated from their surroundings by a hydrophobic shell.

The lipid bilayer is 3 nm (30 Å) thick. The hydrocarbon core, made up of the \(-\mathrm{CH}_2-\) and \(-\mathrm{CH}_3\) of the fatty acyl groups, is about as nonpolar as decane, and vesicles formed in the laboratory from pure lipids (liposomes) are essentially impermeable to polar solutes, as is the lipid bilayer of biological membranes (although the latter, as we shall see, are permeable to solutes for which they have specific transporters).

Plasma membrane lipids are asymmetrically distributed between the two monolayers of the bilayer, although the asymmetry, unlike that of membrane proteins, is not absolute. In the plasma membrane of the erythrocyte, for example, choline-containing lipids (phosphatidylcholine and sphingomyelin) are typically found in the outer (extracellular, or exoplasmic) leaflet (Fig. 11–5), whereas phosphatidylserine, phosphatidylethanolamine, and the phosphatidylinositol are much more common in the inner (cytoplasmic) leaflet. Changes in the distribution of lipids between plasma membrane leaflets have biological consequences. For example, only when the phosphatidylserine in the plasma membrane moves into the outer leaflet is a platelet able to play its role in formation of a blood clot. For many other cell types, phosphatidylserine exposure on the outer surface marks a cell for destruction by programmed cell death.

---

**FIGURE 11–4** Amphipathic lipid aggregates that form in water. (a) In micelles, the hydrophobic chains of the fatty acids are sequestered at the core of the sphere. There is virtually no water in the hydrophobic interior. (b) In an open bilayer, all acyl side chains except those at the edges of the sheet are protected from interaction with water. (c) When a two-dimensional bilayer folds on itself, it forms a closed bilayer, a three-dimensional hollow vesicle (liposome) enclosing an aqueous cavity.
Membrane phospholipid | Percent of total membrane phospholipid | Distribution in membrane
---|---|---
Phosphatidylethanolamine | 30 | Inner monolayer 100, Outer monolayer 0
Phosphatidylcholine | 27 | Inner monolayer 60, Outer monolayer 0
Sphingomyelin | 23 | Inner monolayer 100, Outer monolayer 100
Phosphatidylserine | 15 | Inner monolayer 100, Outer monolayer 100
Phosphatidylinositol 4-phosphate | 5 | Inner monolayer 100, Outer monolayer 100
Phosphatidylinositol 4,5-bisphosphate | 1 | Inner monolayer 100, Outer monolayer 100
Phosphatidic acid | 1 | Inner monolayer 100, Outer monolayer 100

**FIGURE 11-5** Asymmetric distribution of phospholipids between the inner and outer monolayers of the erythrocyte plasma membrane. The distribution of a specific phospholipid is determined by treating the intact cell with phospholipase C, which cannot reach lipids in the inner monolayer (leaflet) but removes the head groups of lipids in the outer monolayer. The proportion of each head group released provides an estimate of the fraction of each lipid in the outer monolayer.

**Three Types of Membrane Proteins Differ in Their Association with the Membrane**

**Integral membrane proteins** are very firmly associated with the lipid bilayer, and are removable only by agents that interfere with hydrophobic interactions, such as detergents, organic solvents, or denaturants (Fig. 11–6). **Peripheral membrane proteins** associate with the membrane through electrostatic interactions and hydrogen bonding with the hydrophilic domains of integral proteins and with the polar head groups of membrane lipids. They can be released by relatively mild treatments that interfere with electrostatic interactions or break hydrogen bonds; a commonly used agent is carbonate at high pH. **Amphitropic proteins** are found both in the cytosol and in association with membranes. Their affinity for membranes results in some cases from the protein’s noncovalent interaction with a membrane protein or lipid, and in other cases from the presence of one or more lipids covalently attached to the amphitropic protein (see Fig. 11–14). Generally, the reversible association of amphitropic proteins with the membrane is regulated; for example, phosphorylation or ligand binding can force a conformational change in the protein, exposing a membrane-binding site that was previously inaccessible.

**Many Membrane Proteins Span the Lipid Bilayer**

Membrane protein topology (the localization of protein domains relative to the lipid bilayer) can be determined with reagents that react with protein side chains but cannot cross membranes—polar chemical reagents that react with primary amines of Lys residues, for example, or enzymes such as trypsin that cleave proteins but cannot cross the membrane. The human erythrocyte is convenient for such studies because it has no membrane-bounded organelles; the plasma membrane is the only membrane present. If a membrane protein in an intact erythrocyte reacts with a membrane-impermeant reagent, that protein must have at least one domain exposed on the outer (extracellular) face of the membrane. Trypsin cleaves extracellular domains but does not affect domains buried within the bilayer or exposed on the inner surface only, unless the plasma membrane is broken to make these domains accessible to the enzyme.
Experiments with such topology-specific reagents show that the erythrocyte glycoprotein glycophorin spans the plasma membrane. Its amino-terminal domain (bearing the carbohydrate chains) is on the outer surface and is cleaved by trypsin. The carboxyl terminus protrudes on the inside of the cell, where it cannot react with impermeant reagents. Both the amino-terminal and carboxyl-terminal domains contain many polar or charged amino acid residues and are therefore hydrophilic. However, a segment in the center of the protein (residues 75 to 93) contains mainly hydrophobic amino acid residues, suggesting that glycophorin has a transmembrane segment arranged as shown in Figure 11-2.

These noncrystallographic experiments also revealed that the orientation of glycophorin in the membrane is asymmetric: its amino-terminal segment is always on the outside. Similar studies of other membrane proteins show that each has a specific orientation in the bilayer, giving the membrane a distinct sidedness. For glycophorin, and for all other glycoproteins of the plasma membrane, the glycosylated domains are invariably found on the extracellular face of the bilayer. As we shall see, the asymmetric arrangement of membrane proteins results in functional asymmetry. All the molecules of a given ion pump, for example, have the same orientation in the membrane and pump ions in the same direction.

**Integral Proteins Are Held in the Membrane by Hydrophobic Interactions with Lipids**

The firm attachment of integral proteins to membranes is the result of hydrophobic interactions between membrane lipids and hydrophobic domains of the protein. Some proteins have a single hydrophobic sequence in the middle (as in glycophorin) or at the amino or carboxyl terminus. Others have multiple hydrophobic sequences, each of which, when in the α-helical conformation, is long enough to span the lipid bilayer (Fig. 11-8).

One of the best-studied membrane-spanning proteins, bacteriorhodopsin, has seven very hydrophobic internal sequences and crosses the lipid bilayer seven times. Bacteriorhodopsin is a light-driven proton pump densely packed in regular arrays in the purple membrane of the bacterium *Halobacterium salinarum*. X-ray crystallography reveals a structure with seven α-helical segments, each traversing the lipid bilayer, connected by nonhelical loops at the inner and outer face of the membrane (Fig. 11-9). In the amino acid sequence of bacteriorhodopsin, seven segments of about 20 hydrophobic residues can be identified, each forming an α helix that spans the bilayer. The seven helices are clustered together and oriented not quite perpendicular to the bilayer plane, a pattern that (as we shall see in Chapter 12) is a common motif in membrane proteins involved in signal reception. Hydrophobic interactions between the nonpolar amino acids and the fatty acyl groups of the membrane lipids firmly anchor the protein in the membrane.

Crystallized membrane proteins solved (i.e., their molecular structure deduced) by crystallography often include molecules of phospholipids, which are presumed to be positioned in the crystals as they are in the native membranes. Many of these phospholipid molecules lie on the protein surface, their head groups interacting with polar amino acid residues at the inner and outer membrane–water interfaces and their side chains associated with nonpolar residues. These annular lipids form a bilayer shell (annulus) around the protein, oriented roughly as expected for phospholipids in a bilayer (Fig. 11-10). Other phospholipids are found at the interfaces between monomers of multisubunit membrane proteins, where they form a "grease seal." Yet others are embedded deep within a membrane protein, often with their head groups well below the plane of the bilayer. For example, succinate dehydrogenase (Complex II, found in mitochondria; see Fig. 19–10) has several deeply embedded phospholipid molecules.
Integral membrane proteins. For known proteins of the plasma membrane, the spatial relationships of protein domains to the lipid bilayer fall into six categories. Types I and II have a single transmembrane helix; the amino-terminal domain is outside the cell in type I proteins and inside in type II. Type III proteins have multiple transmembrane helices in a single polypeptide. In type IV proteins, transmembrane domains of several different polypeptides assemble to form a channel through the membrane. Type V proteins are held to the bilayer primarily by covalently linked lipids (see Fig. 11-14), and type VI proteins have both transmembrane helices and lipid (GPI) anchors.

In this figure, and in figures throughout the book, we represent transmembrane protein segments in their most likely conformations: as α helices of six to seven turns. Sometimes these helices are shown simply as cylinders. As relatively few membrane protein structures have been deduced by x-ray crystallography, our representation of the extramembrane domains is arbitrary and not necessarily to scale.

Lipid annuli associated with two integral membrane proteins. (a) The crystal structure of sheep aquaporin (PDB ID 2B60), a transmembrane water channel, includes a shell of phospholipids positioned with their head groups (blue) at the expected positions on the inner and outer membrane surfaces and their hydrophobic acyl chains (gold) intimately associated with the surface of the protein exposed to the bilayer. The lipid forms a “grease seal” around the protein, which is depicted as a green surface representation. (b) The crystal structure of the Fo integral protein complex of the V-type Na⁺-ATPase from Enterococcus hirae (PDB ID 2BL2) has 10 identical subunits, each with four transmembrane helices, surrounding a central cavity filled with phosphatidylglycerol (PG). Here five of the subunits have been cut away to reveal the PG molecules associated with each subunit around the interior of this structure.
The Topology of an Integral Membrane Protein Can Sometimes Be Predicted from Its Sequence

Determination of the three-dimensional structure of a membrane protein—that is, its topology—is generally much more difficult than determining its amino acid sequence, either directly or by gene sequencing. The amino acid sequences are known for thousands of membrane proteins, but relatively few three-dimensional structures have been established by crystallography or NMR spectroscopy. The presence of unbroken sequences of more than 20 hydrophobic residues in a membrane protein is commonly taken as evidence that these sequences traverse the lipid bilayer, acting as hydrophobic anchors or forming transmembrane channels. Virtually all integral proteins have at least one such sequence. Application of this logic to entire genomic sequences leads to the conclusion that in many species, 20% to 30% of all proteins are integral membrane proteins.

What can we predict about the secondary structure of the membrane-spanning portions of integral proteins? An α-helical sequence of 20 to 25 residues is just long enough to span the thickness (30 Å) of the lipid bilayer (recall that the length of an α helix is 1.5 Å (0.15 nm) per amino acid residue). A polypeptide chain surrounded by lipids, having no water molecules with which to hydrogen-bond, will tend to form α helices or β sheets, in which intrachain hydrogen bonding is maximized. If the side chains of all amino acids in a helix are nonpolar, hydrophobic interactions with the surrounding lipids further stabilize the helix.

Several simple methods of analyzing amino acid sequences yield reasonably accurate predictions of secondary structure for transmembrane proteins. The relative polarity of each amino acid has been determined experimentally by measuring the free-energy change accompanying the movement of that amino acid side chain from a hydrophobic solvent into water. This free energy of transfer, which can be expressed as a hydropathy index (see Table 3–1), ranges from very exergonic for charged or polar residues to very endergonic for amino acids with aromatic or aliphatic hydrocarbon side chains. The overall hydropathy index (hydrophobicity) of a sequence of amino acids is estimated by summing the free energies of transfer for the residues in the sequence. To scan a polypeptide sequence for potential membrane-spanning segments, an investigator calculates the hydropathy index for successive segments (called windows) of a given size, from 7 to 20 residues. For a window of seven residues, for example, the indices for residues 1 to 7, 2 to 8, 3 to 9, and so on, are plotted as in Figure 11–11 (plotted for the middle residue in each window—residue 4 for residues 1 to 7, for example). A region with more than 20 residues of high hydropathy index is presumed to be a transmembrane segment. When the sequences of membrane proteins of known three-dimensional structure are scanned in this way, we find a reasonably good correspondence between predicted and known membrane-spanning segments. Hydropathy analysis predicts a single hydrophobic helix for glycophorin (Fig. 11–11a) and seven transmembrane segments for bacteriorhodopsin (Fig. 11–11b)—in agreement with experimental studies.

On the basis of their amino acid sequences and hydropathy plots, many of the transport proteins described in this chapter are believed to have multiple membrane-spanning helical regions—that is, they are type III or type IV integral proteins (Fig. 11–8). When predictions are consistent with chemical studies of protein localization (such as those described above for glycophorin and bacteriorhodopsin), the assumption that hydrophobic regions correspond to membrane-spanning domains is much better justified.
I Charged residues
I Tyr and Trp residues of membrane proteins clustering at the water-lipid interface. The detailed structures of these five integral membrane proteins are known from crystallographic studies. The K+ channel (PDB ID 1BL8) is from the bacterium Streptomyces lividans (see Fig. 11–14); maltoporin (PDB ID 1AF6), outer membrane phospholipase A (PDB ID 1QD5), OmpX (PDB ID 1QJ9), and phosphoporin.

---

FIGURE 11–12 Tyr and Trp residues of membrane proteins clustering at the water-lipid interface. The detailed structures of these five integral membrane proteins are known from crystallographic studies. The K+ channel (PDB ID 1BL8) is from the bacterium Streptomyces lividans (see Fig. 11–48); maltoporin (PDB ID 1AF6), outer membrane phospholipase A (PDB ID 1QD5), OmpX (PDB ID 1QJ9), and phosphoporin.

---

A further remarkable feature of many transmembrane proteins of known structure is the presence of Tyr and Trp residues at the interface between lipid and water (Fig. 11–12). The side chains of these residues apparently serve as membrane interface anchors, able to interact simultaneously with the central lipid phase and the aqueous phases on either side of the membrane. Another generalization about amino acid location relative to the bilayer is described by the **positive-inside rule:** the positively charged Lys, His, and Arg residues of membrane proteins occur more commonly on the cytoplasmic face of membranes.

Not all integral membrane proteins are composed of transmembrane α helices. Another structural motif common in bacterial membrane proteins is the **β barrel** (see Fig. 4–17b), in which 20 or more transmembrane segments form β sheets that line a cylinder (Fig. 11–13). The same factors that favor α-helix formation in the hydrophobic interior of a lipid bilayer also stabilize β barrels: when no water molecules are available to hydrogen-bond with the carbonyl oxygen and nitrogen of the peptide bond, maximal intrachain hydrogen bonding gives the most stable conformation. Planar β sheets do not maximize these interactions and are generally not found in the membrane interior; β barrels allow all possible hydrogen bonds and are apparently common among membrane proteins. **Porins**, proteins that allow certain polar solutes to cross the outer membrane of gram-negative bacteria such as E. coli, have many-stranded β barrels lining the polar transmembrane passage.

A polypeptide is more extended in the β conformation than in an α helix; just seven to nine residues of β conformation are needed to span a membrane. Recall that in the β conformation, alternating side chains project above and below the sheet (see Fig. 4–6). In β strands of membrane proteins, every second residue in the membrane-spanning segment is hydrophobic and interacts with the lipid bilayer; aromatic side chains are commonly found at the lipid-protein interface. The other residues may or may not be hydrophilic. The hydropathy plot is not useful in predicting transmembrane segments for proteins with β barrel motifs, but as the database of known β-barrel motifs increases, sequence-based predictions of transmembrane β conformations have become feasible. For example, some outer membrane proteins of gram-negative bacteria (Fig. 11–13) have been correctly predicted, by sequence analysis, to contain β barrels.

---

**Covalently Attached Lipids Anchor Some Membrane Proteins**

Some membrane proteins contain one or more covalently linked lipids, which may be of several types: long-chain fatty acids, isoprenoids, sterols, or glycosylated

---

FIGURE 11–13 Membrane proteins with β-barrel structure. Three proteins of the E. coli outer membrane are shown, viewed in the plane of the membrane. FepA (PDB ID 1FEP), involved in iron uptake, has 22 membrane-spanning β strands. OmpLA (derived from PDB ID 1QD5), a phospholipase, is a 12-stranded β barrel that exists as a dimer in the membrane. Maltoporin (derived from PDB ID 1MAL), a maltose transporter, is a trimer; each monomer consists of 16 β strands.
derivatives of phosphatidylinositol (GPIs; Fig. 11-14). The attached lipid provides a hydrophobic anchor that inserts into the lipid bilayer and holds the protein at the membrane surface. The strength of the hydrophobic interaction between a bilayer and a single hydrocarbon chain linked to a protein is barely enough to anchor the protein securely, but many proteins have more than one attached lipid moiety. Other interactions, such as ionic attractions between positively charged Lys residues in the protein and negatively charged lipid head groups, probably contribute to the stability of the attachment. The association of these lipid-linked proteins with the membrane is certainly weaker than that for integral membrane proteins and is, in at least some cases, reversible. But treatment with alkaline carbonate does not release GPI-linked proteins, which are therefore, by the working definition, integral proteins.

Beyond merely anchoring a protein to the membrane, the attached lipid may have a more specific role. In the plasma membrane, proteins with GPI anchors are exclusively on the outer face and are clustered in certain regions, as we shall see (pp. 384–386), whereas other types of lipid-linked proteins (with farnesyl or geranylgeranyl groups attached; Fig. 11-14) are exclusively on the inner face. In polarized epithelial cells (such as intestinal epithelial cells, see Fig. 11-44), in which apical and basal surfaces have different roles, GPI-linked proteins are directed specifically to the apical surface. Attachment of a specific lipid to a newly synthesized membrane protein therefore has a targeting function, directing the protein to its correct membrane location.

**SUMMARY 11.1 The Composition and Architecture of Membranes**

- Biological membranes define cellular boundaries, divide cells into discrete compartments, organize complex reaction sequences, and act in signal reception and energy transformations.
- Membranes are composed of lipids and proteins in varying combinations particular to each species, cell type, and organelle. The lipid bilayer is the basic structural unit.
- Peripheral membrane proteins are loosely associated with the membrane through electrostatic interactions and hydrogen bonds or by covalently attached lipid anchors. Integral proteins associate firmly with membranes by hydrophobic interactions between the lipid bilayer and their nonpolar amino acid side chains, which are oriented toward the outside of the protein molecule. Amphitropic proteins associate reversibly with membranes.

**FIGURE 11-14 Lipid-linked membrane proteins.** Covalently attached lipids anchor membrane proteins to the lipid bilayer. A palmitoyl group is shown attached by thioester linkage to a Cys residue; an N-myristoyl group is generally attached to an amino-terminal Gly; the farnesyl and geranylgeranyl groups attached to carboxyl-terminal Cys residues are isoprenoids of 15 and 20 carbons, respectively. These three lipid-protein assemblies are found only on the inner face of the plasma membrane. Glycosyl phosphatidylinositol (GPI) anchors are derivatives of phosphatidylinositol in which the inositol bears a short oligosaccharide covalently joined to the carboxyl-terminal residue of a protein through phosphoethanolamine. GPI-linked proteins are always on the extracellular face of the plasma membrane.
11.2 Membrane Dynamics

One remarkable feature of all biological membranes is their flexibility—their ability to change shape without losing their integrity and becoming leaky. The basis for this property is the noncovalent interactions among lipids in the bilayer and the mobility allowed to individual lipids because they are not covalently anchored to one another. We turn now to the dynamics of membranes: the motions that occur and the transient structures allowed by these motions.

Acyl Groups in the Bilayer Interior Are Ordered to Varying Degrees

Although the lipid bilayer structure is quite stable, its individual phospholipid and sterol molecules have much freedom of motion (Fig. 11–15). The structure and flexibility of the lipid bilayer depend on the kinds of lipids present, and change with temperature. Below normal physiological temperatures, the lipids in a bilayer form a semisolid gel phase, in which all types of motion of individual lipid molecules are strongly constrained; the bilayer is paracrystalline (Fig. 11–15a). Above physiological temperatures, individual hydrocarbon chains of fatty acids are in constant motion produced by rotation about the carbon-carbon bonds of the long acyl side chains. In this liquid-disordered state, or fluid state, acyl chains undergo much thermal motion and have no regular organization. Intermediate between these extremes is the liquid-ordered state, in which individual phospholipid molecules can diffuse laterally but the acyl groups remain extended and more or less ordered.

Cells regulate their lipid composition to achieve a constant membrane fluidity under various growth conditions. For example, bacteria synthesize more unsaturated fatty acids and fewer saturated ones when cultured at low temperatures than when cultured at higher temperatures (Table 11–2). As a result of this adjustment in lipid composition, membranes of bacteria cultured at high or low temperatures have about the same degree of fluidity.

Transbilayer Movement of Lipids Requires Catalysis

At physiological temperatures, transbilayer—or “flip-flop”—diffusion of a lipid molecule from one leaflet of
the bilayer to the other (Fig. 11-16a) occurs very slowly if at all in most membranes, although lateral diffusion in the plane of the bilayer is very rapid (Fig. 11-16b). Transbilayer movement requires that a polar or charged head group leave its aqueous environment and move into the hydrophobic interior of the bilayer, a process with a large, positive free-energy change. There are, however, situations in which such movement is essential. For example, in the ER, membrane glycerophospholipids are synthesized on the cytosolic surface, whereas sphingolipids are synthesized or modified on the lumenal surface. To get from their site of synthesis to their eventual point of deposition, these lipids must undergo flip-flop diffusion.

Several families of proteins, including the flippases, floppases, and scramblases (Fig. 11-16c), facilitate the transbilayer movement of lipids, providing a path that is energetically more favorable and much faster than the uncatalyzed movement. The combination of asymmetric biosynthesis of membrane lipids, very slow uncatalyzed flip-flop diffusion, and the presence of selective, energy-dependent lipid translocators is responsible for the transbilayer asymmetry in lipid composition shown in Figure 11-5. Besides contributing to this asymmetry of composition, the energy-dependent transport of lipids to one bilayer leaflet may, by creating a larger surface on one side of the bilayer, be important in generating the membrane curvature essential in the budding of vesicles.

**Flippases** catalyze translocation of the aminophospholipids phosphatidylethanolamine and phosphatidylserine from the extracellular to the cytosolic leaflet of the plasma membrane, contributing to the asymmetric distribution of phospholipids: phosphatidylethanolamine and phosphatidylserine primarily in the cytosolic leaflet, and the sphingolipids and phosphatidycholine in the outer leaflet. Keeping phosphatidylserine out of the extracellular leaflet is important: its exposure on the outer

**FIGURE 11-16** Motion of single phospholipids in a bilayer. (a) Uncatalyzed movement from one leaflet to the other is very slow, but (b) lateral diffusion within the leaflet is very rapid, requiring no catalysis. (c) Three types of phospholipid translocators in the plasma membrane. Flippases translocate primarily aminophospholipids (phosphatidylethanolamine (PE), phosphatidylserine (PS)) from the outer (exoplasmic) leaflet to the inner (cytosolic) leaflet; they require ATP and are members of the P-type ATPase family. Floppases move phospholipids from the cytosolic to the outer leaflet, require ATP, and are members of the ABC transporter family. Scramblases equilibrate phospholipids across both leaflets; they do not require ATP but are activated by Ca²⁺.
surface triggers apoptosis (programmed cell death; see Chapter 12) and engulfment by macrophages that carry phosphatidylserine receptors. Flipases also act in the ER, where they move newly synthesized phospholipids from their site of synthesis in the cytosolic leaflet to the luminal leaflet. Flipases consume about one ATP per molecule of phospholipid translocated, and they are structurally and functionally related to the P-type ATPases (active transporters) described on page 306.

**Floppases** move plasma membrane phospholipids from the cytosolic to the extracellular leaflet, and like flipases are ATP-dependent. Floppases are members of the ABC transporter family described on page 400, all of which actively transport hydrophobic substrates outward across the plasma membrane. **Scramblases** are proteins that move any membrane phospholipid across the bilayer down its concentration gradient (from the leaflet where it has a higher concentration to the leaflet where it has a lower concentration); their activity is not dependent on ATP. Scramblase activity leads to controlled randomization of the head-group composition on the two faces of the bilayer. The activity rises sharply with an increase in cytosolic Ca\(^{2+}\) concentration, which may result from cell activation, cell injury, or apoptosis; as noted above, exposure of phosphatidylserine on the outer surface marks a cell for apoptosis and engulfment by macrophages. Finally, a group of proteins that act primarily to move phosphatidylinositol lipids across lipid bilayers, the phosphatidylinositol transfer proteins, are believed to have important roles in lipid signaling and membrane trafficking.

**Lipids and Proteins Diffuse Laterally in the Bilayer**

Individual lipid molecules can move laterally in the plane of the membrane by changing places with neighboring lipid molecules; that is, they undergo Brownian movement within the bilayer (Fig. 11-16b), which can be quite rapid. A molecule in the outer leaflet of the erythrocyte plasma membrane, for example, can diffuse laterally so fast that it circumnavigates the erythrocyte in seconds. This rapid lateral diffusion in the plane of the bilayer tends to randomize the positions of individual molecules in a few seconds.

Lateral diffusion can be shown experimentally by attaching fluorescent probes to the head groups of lipids and using fluorescence microscopy to follow the probes over time (Fig. 11-17). In one technique, a small region (5 \( \mu \text{m}^2 \)) of a cell surface with fluorescence-tagged lipids is bleached by intense laser radiation so that the irradiated patch no longer fluoresces when viewed with less-intense (nonbleaching) light in the fluorescence microscope. However, within milliseconds, the region recovers its fluorescence as unbleached lipid molecules diffuse into the bleached patch and bleached lipid molecules diffuse away from it. The rate of fluorescence recovery after photobleaching, or **FRAP**, is a measure of the rate of lateral diffusion of the lipids. Using the FRAP
technique, researchers have shown that some membrane lipids diffuse laterally at rates of up to 1 μm/s.

Another technique, single particle tracking, allows one to follow the movement of a single lipid molecule in the plasma membrane on a much shorter time scale. Results from these studies confirm rapid lateral diffusion within small, discrete regions of the cell surface and show that movement from one such region to a nearby region ("hop diffusion") is inhibited; membrane lipids behave as though corralled by fences that they can occasionally cross by hop diffusion (Fig. 11–18).

Many membrane proteins seem to be afloat in a sea of lipids. Like membrane lipids, these proteins are free to diffuse laterally in the plane of the bilayer and are in constant motion, as shown by the FRAP technique with fluorescence-tagged surface proteins. Some membrane proteins associate to form large aggregates ("patches") on the surface of a cell or organelle in which individual protein molecules do not move relative to one another; for example, acetylcholine receptors form dense, near-crystalline patches on neuronal plasma membranes at synapses. Other membrane proteins are anchored to internal structures that prevent their free diffusion. In the erythrocyte membrane, both glycophorin and the chloride-bicarbonate exchanger (p. 385) are tethered to spectrin, a filamentous cytoskeletal protein (Fig. 11–19).

One possible explanation for the pattern of lateral diffusion of lipid molecules shown in Figure 11–18 is that membrane proteins immobilized by their association with spectrin form the "fences" that define the regions of relatively unrestricted lipid motion.

Sphingolipids and Cholesterol Cluster Together in Membrane Rafts

We have seen that diffusion of membrane lipids from one bilayer leaflet to the other is very slow unless catalyzed, and that the different lipid species of the plasma membrane are asymmetrically distributed in the two leaflets of the bilayer (Fig. 11–5). Even within a single leaflet, the lipid distribution is not random. Glycosphingolipids (cerebrosides and gangliosides), which typically contain long-chain saturated fatty acids, form transient clusters in the outer leaflet that largely exclude glycerophospholipids, which typically contain one unsaturated fatty acyl group and a shorter saturated acyl group. The long, saturated acyl groups of sphingolipids can form more compact, more stable associations with the long ring system of cholesterol than can the shorter, often unsaturated, chains of phospholipids. The cholesterol-sphingolipid microdomains in the outer monolayer of the plasma membrane, visible with atomic force microscopy (Box 11–1), are slightly thicker and more ordered (less fluid) than neighboring microdomains rich in phospholipids and are more difficult to dissolve with nonionic detergents; they behave like liquid-ordered sphingolipid rafts adrift on an ocean of liquid-disordered phospholipids (Fig. 11–20, p. 386).

These lipid rafts are remarkably enriched in two classes of integral membrane proteins: those anchored to the membrane by two covalently attached long-chain saturated fatty acids (two palmitoyl groups or a palmitoyl and a myristoyl group) and GPI-anchored proteins.
In atomic force microscopy (AFM), the sharp tip of a microscopic probe attached to a flexible cantilever is drawn across an uneven surface such as a membrane (Fig. 1). Electrostatic and van der Waals interactions between the tip and the sample produce a force that moves the probe up and down (in the z dimension) as it encounters hills and valleys in the sample. A laser beam reflected from the cantilever detects motions of as little as 1 Å. In one type of atomic force microscope, the force on the probe is held constant (relative to a standard force, on the order of piconewtons) by a feedback circuit that causes the platform holding the sample to rise or fall to keep the force constant. A series of scans in the x and y dimensions (the plane of the membrane) yields a three-dimensional contour map of the surface with resolution near the atomic scale—0.1 nm in the vertical dimension, 0.5 to 1.0 nm in the lateral dimensions. The membrane rafts shown in Figure 11-20b were visualized by this technique.

In favorable cases, AFM can be used to study single membrane protein molecules. Single molecules of bacteriorhodopsin (see Fig. 11-9) in the purple membranes of the bacterium Halobacterium salinarum are seen as highly regular structures (Fig. 2a). When several images of individual units are superimposed with the help of a computer, the real parts of the image reinforce each other and the noise in individual images is averaged out, yielding a high-resolution image of the protein (inset in Fig. 2a). AFM of purified E. coli aquaporin, reconstituted into lipid bilayers and viewed as if from the outside of a cell, shows the fine details of the protein's periplasmic domains (Fig. 2b). And AFM reveals that F_o, the proton-driven rotor of the chloroplast ATP synthase (p. 760), is composed of many subunits (14 in Fig. 2c) arranged in a circle.

(Presumably these lipid anchors, like the acyl chains of sphingolipids, form more stable associations with the cholesterol and long acyl groups in rafts than with the surrounding phospholipids. (It is notable that other lipid-linked proteins, those with covalently attached isoprenyl groups such as farnesyl, are not preferentially associated with the outer leaflet of sphingolipid/cholesterol rafts (Fig. 11-20a).) The "raft" and "sea" domains of the plasma membrane are not rigidly separated; membrane proteins can move into and out of lipid rafts on a time scale of seconds. But in the shorter time scale (microseconds) more relevant to many membrane-mediated biochemical processes, many of these proteins reside primarily in a raft.

We can estimate the fraction of the cell surface occupied by rafts from the fraction of the plasma membrane that resists detergent solubilization, which can be as high as 50% in some cases: the rafts cover half of the ocean (Fig. 11-20b). Indirect measurements in cultured fibroblasts suggest a diameter of roughly 50 nm for an
Raft, enriched in sphingolipids, cholesterol

**FIGURE 11-20 Membrane microdomains (rafts).** (a) Stable associations of sphingolipids and cholesterol in the outer leaflet produce a microdomain, slightly thicker than other membrane regions, that is enriched with specific types of membrane proteins; GPI-linked proteins are common in the outer leaflet of these rafts, and proteins with one or several covalently attached long-chain acyl groups are common in the inner leaflet. Caveolin is especially common in inwardly curved rafts called caveolae (see Fig. 11-21). Proteins with attached prenyl groups (such as Ras; see Box 12-2) tend to be excluded from rafts. (b) In this artificial membrane—reconstituted (on a mica surface) from cholesterol, synthetic phospholipid (dioleoylphosphatidylcholine), and the GPI-linked protein placental alkaline phosphatase—the greater thickness of raft regions is visualized by atomic force microscopy (see Box 11-1). The rafts protrude from a lipid bilayer ocean (the black surface is the top of the upper monolayer; sharp peaks represent GPI-linked proteins. Note that these peaks are found almost exclusively in the rafts.

Caveolin is an integral membrane protein with two globular domains connected by a hairpin-shaped hydrophobic domain, which binds the protein to the cytoplasmic leaflet of the plasma membrane. Three palmitoyl groups attached to the carboxyl-terminal globular domain further anchor it to the membrane. Caveolin (actually, a family of related caveolins) binds cholesterol in the membrane, and the presence of caveolin forces the associated lipid bilayer to curve inward, forming caveolae (“little caves”) in the surface of the cell (Fig. 11-21). Caveolae are unusual rafts: they involve both leaflets of the bilayer—the cytoplasmic leaflet, from which the caveolin globular domains project, and the extracellular leaflet, a typical sphingolipid/cholesterol raft with associated GPI-anchored proteins. Caveolae are implicated in a variety of cellular functions, including membrane trafficking within cells and the transduction of external signals into cellular responses. The receptors for insulin and other growth factors, as well as certain GTP-binding proteins and protein kinases associated with transmembrane signaling, seem to be localized

**FIGURE 11-21 Caveolin forces inward curvature of a membrane.** Caveolae are small invaginations in the plasma membrane, as seen in (a) an electron micrograph of an adipocyte surface-labeled with an electron-dense marker. (b) Each caveolin monomer has a central hydrophobic domain and three long-chain acyl groups (red), which hold the molecule to the inside of the plasma membrane. When several caveolin dimers are concentrated in a small region (a raft), they force a curvature in the lipid bilayer, forming a caveola. Cholesterol molecules in the bilayer are shown in orange.
Membrane Curvature and Fusion Are Central to Many Biological Processes

Caveolin is not unique in its ability to induce curvature in membranes. Changes of curvature are central to one of the most remarkable features of biological membranes: their ability to undergo fusion with other membranes without losing their continuity. Although membranes are stable, they are by no means static. Within the eukaryotic endomembrane system (which includes the nuclear membrane, endoplasmic reticulum, Golgi, and various small vesicles), the membranous compartments constantly reorganize. Vesicles bud from the ER to carry newly synthesized lipids and proteins to other organelles and to the plasma membrane. Exocytosis, endocytosis, cell division, fusion of egg and sperm cells, and entry of a membrane-enveloped virus into its host cell all involve membrane reorganization in which the fundamental operation is fusion of two membrane segments without loss of continuity (Fig. 11-22). Most of these processes begin with a local increase in membrane curvature. Three mechanisms for inducing membrane curvature are shown in Figure 11-23. A protein that is intrinsically curved may force curvature in a bilayer by binding to it; the binding energy provides the driving force for the increase in bilayer curvature. Alternatively, many subunits of a scaffold protein may assemble into curved supramolecular complexes and stabilize curves that spontaneously form in the bilayer. Or, a protein may insert one or more hydrophobic helices into one face of the bilayer, expanding its area relative to the other face and thereby forcing curvature.

Specific fusion of two membranes requires that (1) they recognize each other; (2) their surfaces become closely apposed, which requires the removal of water molecules normally associated with the polar head groups of lipids; (3) their bilayer structures become locally disrupted, resulting in fusion of the outer leaflet of each membrane (hemifusion); and (4) their bilayers fuse to form a single continuous bilayer. The fusion occurring in receptor-mediated endocytosis, or regulated secretion, also requires that (5) the process is triggered at the appropriate time or in response to a specific signal. Integral proteins called fusion proteins mediate these events, bringing about specific recognition and a transient local distortion of the bilayer structure that favors membrane fusion. (Note that these fusion proteins are unrelated to the products encoded by two fused genes, also called fusion proteins, discussed in Chapter 9.)

![Diagram of membrane fusion](image)

**FIGURE 11-22** Membrane fusion. The fusion of two membranes is central to a variety of cellular processes involving organelles and the plasma membrane.

**FIGURE 11-23** Three models for protein-induced curvature of membranes.
A well-studied example of membrane fusion is that occurring at synapses, when intracellular vesicles loaded with neurotransmitter fuse with the plasma membrane. This process involves a family of proteins called SNARES (Fig. 11–24). SNAREs in the cytoplasmic face of the intracellular vesicle are called v-SNAREs; those in the target membrane with which the vesicle fuses (the plasma membrane during exocytosis) are t-SNAREs. Two other proteins, SNAP25 and NSF, are also involved. During fusion, a v-SNARE and t-SNARE bind to each other and undergo a structural change that produces a bundle of long thin rods made up of helices from both SNAREs and two helices from SNAP25 (Fig. 11–24). The two SNAREs initially interact at their ends, then zip up into the bundle of helices. This structural change pulls the two membranes into contact and initiates the fusion of their lipid bilayers.

The complex of SNAREs and SNAP25 is the target of the powerful Clostridium botulinum toxin, a protease that cleaves specific bonds in these proteins, preventing neurotransmission and thereby causing the death of the organism. Because of its very high specificity for these proteins, purified botulinum toxin has served as a powerful tool for dissecting the mechanism of neurotransmitter release in vivo and in vitro.

**Integral Proteins of the Plasma Membrane Are Involved in Surface Adhesion, Signaling, and Other Cellular Processes**

Several families of integral proteins in the plasma membrane provide specific points of attachment between cells, or between a cell and extracellular matrix proteins. **Integrins** are surface adhesion proteins that mediate a cell’s interaction with the extracellular matrix and with other cells, including some pathogens. Integrins also carry signals in both directions across the plasma membrane, integrating information about the extracellular and intracellular environments. All integrins are heterodimeric proteins composed of two unlike subunits, α and β, each anchored to the plasma membrane by a single transmembrane helix. The large extracellular domains of the α and β subunits combine to form a specific binding site for extracellular proteins such as collagen and fibronectin, which contain a common determinant of integrin binding, the sequence Arg–Gly–Asp (RGD). We discuss the signaling functions of integrins in more detail in Chapter 12 (p. 455).

Other plasma membrane proteins involved in surface adhesion are the **cadherins**, which undergo homophilic (“with same kind”) interactions with identical cadherins in an adjacent cell. **Selectins** have extracellular domains that, in the presence of Ca$^{2+}$, bind specific polysaccharides on the surface of an adjacent cell. Selectins are present primarily in the various types of blood cells and in the endothelial cells that line blood vessels (see Fig. 7–31). They are an essential part of the blood-clotting process.

Integral membrane proteins play roles in many other cellular processes. They serve as transporters and ion
channels (discussed in Section 11.3) and as receptors for hormones, neurotransmitters, and growth factors (Chapter 12). They are central to oxidative phosphorylation and photophosphorylation (Chapter 19) and to cell-cell and cell-antigen recognition in the immune system (Chapter 5). Integral proteins are also important players in the membrane fusion that accompanies exocytosis, endocytosis, and the entry of many types of viruses into host cells.

**SUMMARY 11.2 Membrane Dynamics**

- Lipids in a biological membrane can exist in liquid-ordered or liquid-disordered states; in the latter state, thermal motion of acyl chains makes the interior of the bilayer fluid. Fluidity is affected by temperature, fatty acid composition, and sterol content.
- Flip-flop diffusion of lipids between the inner and outer leaflets of a membrane is very slow except when specifically catalyzed by flipases, floppases, or scramblases.
- Lipids and proteins can diffuse laterally within the plane of the membrane, but this mobility is limited by interactions of membrane proteins with internal cytoskeletal structures and interactions of lipids with lipid rafts. One class of lipid rafts consists of sphingolipids and cholesterol with a subset of membrane proteins that are GPI-linked or attached to several long-chain fatty acyl moieties.

**11.3 Solute Transport across Membranes**

Every living cell must acquire from its surroundings the raw materials for biosynthesis and for energy production, and must release to its environment the byproducts of metabolism. A few nonpolar compounds can dissolve in the lipid bilayer and cross the membrane unassisted, but for transmembrane movement of any polar compound or ion, a membrane protein is essential. In some cases a membrane protein simply facilitates the diffusion of a solute down its concentration gradient, but transport can also occur against a gradient of concentration, electrical charge, or both, in which case the process requires energy (Fig. 11–25). The energy may come directly from ATP hydrolysis or may be supplied in the form of one solute moving down its electrochemical gradient, with the release of enough energy to drive another solute up its gradient. Ions may also move across membranes via ion channels formed by proteins, or they may be carried across by ionophores, small molecules that mask the charge of ions and allow them to diffuse through the lipid bilayer. With very few exceptions, the traffic of small molecules across the plasma membrane is mediated by proteins such as transmembrane channels, carriers, or pumps. Within the eukaryotic cell, different compartments have different concentrations of ions and of metabolic intermediates and products, and these, too, must move across intracellular membranes in tightly regulated, protein-mediated processes.

**FIGURE 11–25 Summary of transport types.**
Passive Transport Is Facilitated by Membrane Proteins

When two aqueous compartments containing unequal concentrations of a soluble compound or ion are separated by a permeable divider (membrane), the solute moves by simple diffusion from the region of higher concentration, through the membrane, to the region of lower concentration, until the two compartments have equal solute concentrations (Fig. 11–26a). When ions of opposite charge are separated by a permeable membrane, there is a transmembrane electrical gradient, a membrane potential, $V_m$ (expressed in millivolts). This membrane potential produces a force opposing ion movements that increase $V_m$ and driving ion movements that reduce $V_m$ (Fig. 11–26b). Thus the direction in which a charged solute tends to move spontaneously across a membrane depends on both the chemical gradient (the difference in solute concentration) and the electrical gradient ($V_m$) across the membrane. Together, these two factors are referred to as the electrochemical gradient or electrochemical potential. This behavior of solutes is in accord with the second law of thermodynamics: molecules tend to spontaneously assume the distribution of greatest randomness and lowest energy.

To pass through a lipid bilayer, a polar or charged solute must first give up its interactions with the water molecules in its hydration shell, then diffuse about 3 nm (30 Å) through a substance (lipid) in which it is poorly soluble (Fig. 11–27). The energy used to strip away the hydration shell and to move the polar compound from water into lipid, then through the lipid bilayer, is regained as the compound leaves the membrane on the other side and is rehydrated. However, the intermediate stage of transmembrane passage is a high-energy state comparable to the transition state in an enzyme-catalyzed chemical reaction. In both cases, an activation barrier must be overcome to reach the intermediate stage (Fig. 11–27; compare with Fig. 6–3). The energy of activation ($\Delta G^*$) for translocation of a polar solute across the bilayer is so large that pure lipid bilayers are virtually impermeable to polar and charged species over periods of time relevant to cell growth and division.

Membrane proteins lower the activation energy for transport of polar compounds and ions by providing an alternative path through the bilayer for specific solutes. Proteins that bring about this facilitated diffusion, or passive transport, are not enzymes in the usual sense; their “substrates” are moved from one compartment to another but are not chemically altered. Membrane proteins that speed
the movement of a solute across a membrane by facilitating diffusion are called transporters or permeases.

Like enzymes, transporters bind their substrates with stereochemical specificity through multiple weak, non-covalent interactions. The negative free-energy change associated with these weak interactions, \( \Delta G_{\text{binding}} \), counterbalances the positive free-energy change that accompanies loss of the water of hydration from the substrate, \( \Delta G_{\text{dehydration}} \), thereby lowering \( \Delta G^\circ \) for transmembrane passage (Fig. 11–27). Transporters span the lipid bilayer several times, forming a transmembrane channel lined with hydrophilic amino acid side chains. The channel provides an alternative path for a specific substrate to move across the lipid bilayer without its having to dissolve in the bilayer, further lowering \( \Delta G^\circ \) for transmembrane diffusion. The result is an increase of several to many orders of magnitude in the rate of transmembrane passage of the substrate.

### Transporters Can Be Grouped into Superfamilies Based on Their Structures

We know from genomic studies that transporters constitute a significant fraction of all proteins encoded in the genomes of both simple and complex organisms. There are probably a thousand or more different transporters in the human genome. Transporters fall within two very broad categories: carriers and channels (Fig. 11–28). **Carriers** bind their substrates with high stereospecificity, catalyze transport at rates well below the limits of free diffusion, and are saturable in the same sense as are enzymes: there is some substrate concentration above which further increases will not produce a greater rate of transport. **Channels** generally allow transmembrane movement at rates orders of magnitude greater than those typical of carriers, rates approaching the limit of unhindered diffusion. Channels typically show less stereospecificity than carriers and are usually not saturable. Most channels are oligomeric complexes of several, often identical, subunits, whereas many carriers function as monomeric proteins. The classification as carrier or channel is the broadest distinction among transporters. Within each of these categories are superfamilies of various types, defined not only by their primary sequences but by their secondary structures. Some channels are constructed primarily of helical transmembrane segments, others have \( \beta \)-barrel structures. Among the carriers, some simply facilitate diffusion down a concentration gradient; they are the **passive transporter** superfamily. **Active transporters** can drive substrates across the membrane against a concentration gradient, some using energy provided directly by a chemical reaction (primary active transporters) and some coupling uphill transport of one substrate with downhill transport of another (secondary active transporters). We now consider some well-studied representatives of the main transporter superfamilies. You will encounter some of these transporters again in later chapters in the context of the metabolic pathways in which they participate.

### The Glucose Transporter of Erythrocytes Mediates Passive Transport

Energy-yielding metabolism in erythrocytes depends on a constant supply of glucose from the blood plasma, where the glucose concentration is maintained at about 5 mM. Glucose enters the erythrocyte by facilitated diffusion via a specific glucose transporter, at a rate about 50,000 times greater than uncatalyzed transmembrane diffusion. The glucose transporter of erythrocytes (called GLUT1 to distinguish it from related glucose transporters in other tissues) is a type III integral protein \( (M_r \sim 45,000) \) with 12 hydrophobic segments, each of which is believed to form a membrane-spanning helix. The detailed structure of GLUT1 is not yet known, but one plausible model suggests that the side-by-side assembly of several helices produces a transmembrane channel lined with hydrophilic residues that can hydrogen-bond with glucose as it moves through the channel (Fig. 11–29).

The process of glucose transport can be described by analogy with an enzymatic reaction in which the “substrate” is glucose outside the cell \( (S_{\text{out}}) \), the “product” is glucose inside \( (S_{\text{in}}) \), and the “enzyme” is the transporter, \( T \). When the initial rate of glucose uptake is measured as a function of external glucose concentration (Fig. 11–30), the resulting plot is hyperbolic; at high external glucose concentrations the rate of uptake approaches \( V_{\text{max}} \). Formally, such a transport process can be described by the equations

\[
S_{\text{out}} + T_1 \xrightarrow{k_1} S_{\text{in}} \cdot T_1 \\
S_{\text{in}} + T_2 \xrightarrow{k_2} S_{\text{out}} \cdot T_2
\]

in which \( k_1, k_2, k_{-1}, \) and \( k_{-2} \), and so forth, are the forward and reverse rate constants for each step; \( T_1 \) is the transporter conformation in which the glucose-binding site faces...
out, and $T_3$ the conformation in which it faces in. The steps are summarized in Figure 11–31. Given that every step in this sequence is reversible, the transporter is, in principle, equally able to move glucose into or out of the cell. However, glucose always moves down its concentration gradient, which normally means into the cell. Glucose that enters a cell is generally metabolized immediately, and the intracellular glucose concentration is thereby kept low relative to its concentration in the blood.

**Figure 11–29 Proposed structure of GLUT1.** (a) Transmembrane helices are represented here as oblique (angled) rows of three or four amino acid residues, each row depicting one turn of the α helix. Nine of the 12 helices contain three or more polar or charged residues (blue or red), often separated by several hydrophobic residues (yellow). This representation of topology is not intended to represent three-dimensional structure. (b) A helical wheel diagram shows the distribution of polar and nonpolar residues on the surface of a helical segment. The helix is diagrammed as though observed along its axis from the amino terminus. Adjacent residues in the linear sequence are connected, and each residue is placed around the wheel in the position it occupies in the helix; recall that 3.6 residues are required to make one complete turn of the α helix. In this example, the polar residues (blue) are on one side of the helix and the hydrophobic residues (yellow) on the other. This is, by definition, an amphipathic helix. (c) Side-by-side association of four amphipathic helices, each with its polar face oriented toward the central cavity, can produce a transmembrane channel lined with polar (and charged) residues. This channel provides many opportunities for hydrogen bonding with glucose as it moves through.

**Figure 11–30 Kinetics of glucose transport into erythrocytes.** (a) The initial rate of glucose entry into an erythrocyte, $V_0$, depends on the initial concentration of glucose on the outside, $[S]_{	ext{out}}$. (b) Double-reciprocal plot of the data in (a). The kinetics of facilitated diffusion is analogous to the kinetics of an enzyme-catalyzed reaction. Compare these plots with Figure 6–11, and with Figure 1 in Box 6–1. Note that $K_1$ is analogous to $K_m$, the Michaelis constant.

**Figure 11–31 Model of glucose transport into erythrocytes by GLUT1.** The transporter exists in two conformations: $T_1$, with the glucose-binding site exposed on the outer surface of the plasma membrane, and $T_2$, with the binding site exposed on the inner surface. Glucose transport occurs in four steps. 1. Glucose in blood plasma binds to a stereospecific site on $T_1$; this lowers the activation energy for a conformational change from $T_1$ to $T_2$, effecting the transmembrane passage of the glucose. 2. Glucose is released from $T_2$ into the cytoplasm, and 3. the transporter returns to the $T_1$ conformation, ready to transport another glucose molecule.
The rate equations for glucose transport can be derived exactly as for enzyme-catalyzed reactions (Chapter 6), yielding an expression analogous to the Michaelis-Menten equation:

\[
V_0 = \frac{V_{\text{max}} [S]_{\text{out}}}{K_i + [S]_{\text{out}}}
\]

(11-1)
in which \(V_0\) is the initial velocity of accumulation of glucose inside the cell when its concentration in the surrounding medium is \([S]_{\text{out}}\) and \(K_i\) \((K_{\text{transport}})\) is a constant analogous to the Michaelis constant, a combination of rate constants that is characteristic of each transport system. This equation describes the initial velocity, the rate observed when \([S]_{\text{in}} = 0\). As is the case for enzyme-catalyzed reactions, the slope-intercept form of the equation describes a linear plot of \(1/V_0\) against \(1/[S]_{\text{out}}\), from which we can obtain values of \(K_i\) and \(V_{\text{max}}\) (Fig. 11-30b). When \([S]_{\text{out}} = K_i\), the rate of uptake is \(\frac{1}{2}V_{\text{max}}\), the transport process is half-saturated. The concentration of glucose in blood is 4.5 to 5 mM, about three times \(K_i\), which ensures that GLUT1 is nearly saturated with substrate and operates near \(V_{\text{max}}\).

Because no chemical bonds are made or broken in the conversion of \(S_{\text{out}}\) to \(S_{\text{in}}\), neither “substrate” nor “product” is intrinsically more stable, and the process of entry is therefore fully reversible. As \([S]_{\text{in}}\) approaches \([S]_{\text{out}}\), the rates of entry and exit become equal. Such a system is therefore incapable of accumulating glucose within a cell at concentrations above that in the surrounding medium; it simply equilibrates glucose on the two sides of the membrane much faster than would occur in the absence of a specific transporter. GLUT1 is specific for \(\alpha\)-glucose, with a measured \(K_i\) of 1.5 mM. For the close analogs \(\alpha\)-mannose and \(\alpha\)-galactose, which differ only in the position of one hydroxyl group, the values of \(K_i\) are 20 and 30 mM, respectively; and for \(\alpha\)-glucose, \(K_i\) exceeds 3,000 mM. Thus GLUT1 shows the three hallmarks of passive transport: high rates of diffusion down a concentration gradient, saturation, and specificity.

Twelve glucose transporters are encoded in the human genome, each with its unique kinetic properties, patterns of tissue distribution, and function (Table 11-3). In liver, GLUT2 transports glucose out of hepatocytes when liver glycogen is broken down to replenish blood glucose. GLUT2 has a \(K_i\) of about 66 mM and can therefore respond to increased levels of intracellular glucose (produced by glycogen breakdown) by increasing outward transport. Skeletal and heart muscle and adipose tissue have yet another glucose transporter, GLUT4 (\(K_i = 5\) mM), which is distinguished by its response to insulin: its activity increases when insulin signals a high blood glucose concentration, thus increasing the rate of glucose uptake into muscle and adipose tissue (Box 11-2 describes some malfunctions of this transporter).

The Chloride-Bicarbonate Exchanger Catalyzes Electroneutral Cotransport of Anions across the Plasma Membrane

The erythrocyte contains another facilitated diffusion system, an anion exchanger that is essential in CO\(_2\) transport to the lungs from tissues such as skeletal muscle and liver. Waste CO\(_2\) released from respiring tissues into the blood plasma enters the erythrocyte, where it is converted to bicarbonate (HCO\(_3^-\)) by the enzyme carbonic anhydrase. (Recall that HCO\(_3^-\) is the primary buffer of blood pH; see Fig. 2-20.) The HCO\(_3^-\) reenters the blood plasma for
When ingestion of a carbohydrate-rich meal causes blood glucose to exceed the usual concentration between meals (about 5 mM), excess glucose is taken up by the myocytes of cardiac and skeletal muscle (which store it as glycogen) and by adipocytes (which convert it to triacylglycerols). Glucose uptake into myocytes and adipocytes is mediated by the glucose transporter GLUT4. Between meals, some GLUT4 is present in the plasma membrane, but most is sequestered in the membranes of small intracellular vesicles (Fig. 1). Insulin released from the pancreas in response to high blood glucose triggers the movement of these intracellular vesicles to the plasma membrane, where they fuse, thus exposing GLUT4 molecules on the outer surface of the cell (see Fig. 12–16). With more GLUT4 molecules in action, the rate of glucose uptake increases 15-fold or more. When blood glucose levels return to normal, insulin release slows and most GLUT4 molecules are removed from the plasma membrane and stored in vesicles.

In type 1 (juvenile-onset) diabetes mellitus, the inability to release insulin (and thus to mobilize glucose transporters) results in low rates of glucose uptake into muscle and adipose tissue. One consequence is a prolonged period of high blood glucose after a carbohydrate-rich meal. This condition is the basis for the glucose tolerance test used to diagnose diabetes (Chapter 23).

The water permeability of epithelial cells lining the renal collecting duct in the kidney is due to the presence of an aquaporin (AQP-2) in their apical plasma membranes (facing the lumen of the duct). Vasopressin (antidiuretic hormone, ADH) regulates the retention of water by mobilizing AQP-2 molecules stored in vesicle membranes within the epithelial cells, much as insulin mobilizes GLUT4 in muscle and adipose tissue. When the vesicles fuse with the epithelial cell plasma membrane, water permeability greatly increases and more water is reabsorbed from the collecting duct and returned to the blood. When the vasopressin level drops, AQP-2 is resequestered within vesicles, reducing water retention. In the relatively rare human disease diabetes insipidus, a genetic defect in AQP-2 leads to impaired water reabsorption by the kidney. The result is excretion of copious volumes of very dilute urine.

**FIGURE 1** Transport of glucose into a myocyte by GLUT4 is regulated by insulin.
Chloride-bicarbonate exchange protein
In respiring tissues

\[ \text{CO}_2 + \text{H}_2\text{O} \rightarrow \text{HCO}_3^- + \text{H}^+ \]

In lungs

\[ \text{HCO}_3^- + \text{H}^+ \rightarrow \text{CO}_2 + \text{H}_2\text{O} \]

**FIGURE 11–32 Chloride-bicarbonate exchanger of the erythrocyte membrane.** This cotransport system allows the entry and exit of HCO$_3^-$ without changing the membrane potential. Its role is to increase the CO$_2$-carrying capacity of the blood.

transport to the lungs (Fig. 11–32). Because HCO$_3^-$ is much more soluble in blood plasma than is CO$_2$, this roundabout route increases the capacity of the blood to carry carbon dioxide from the tissues to the lungs. In the lungs, HCO$_3^-$ reenters the erythrocyte and is converted to CO$_2$, which is eventually released into the lung space and exhaled. To be effective, this shuttle requires very rapid movement of HCO$_3^-$ across the erythrocyte membrane.

The chloride-bicarbonate exchanger, also called the anion exchange (AE) protein, increases the rate of HCO$_3^-$ transport across the erythrocyte membrane more than a millionfold. Like the glucose transporter, it is an integral protein that probably spans the membrane at least 12 times. This protein mediates the simultaneous movement of two anions: for each HCO$_3^-$ ion that moves in one direction, one Cl$^- \text{ion moves in the opposite direction (Fig. 11–33), with no net transfer of charge; the exchange is electroneutral. The coupling of Cl$^- and HCO$_3^-$ movements is obligatory; in the absence of chloride, bicarbonate transport stops. In this respect, the anion exchanger is typical of those systems, called cotransport systems, that simultaneously carry two solutes across a membrane. When, as in this case, the two substrates move in opposite directions, the process is antiport. In symport, two substrates are moved simultaneously in the same direction. Transporters that carry only one substrate, such as the erythrocyte glucose transporter, are known as uniport systems (Fig. 11–33).

The human genome has genes for three closely related chloride-bicarbonate exchangers, all with the same predicted transmembrane topology. Erythrocytes contain the AE1 transporter, AE2 is prominent in liver, and AE3 is present in plasma membranes of the brain, heart, and retina. Similar anion exchangers are also found in plants and microorganisms.

**Active Transport Results in Solute Movement against a Concentration or Electrochemical Gradient**

In passive transport, the transported species always moves down its electrochemical gradient and is not accumulated above the equilibrium concentration. Active transport, by contrast, results in the accumulation of a solute above the equilibrium point. Active transport is thermodynamically unfavorable (endergonic) and takes place only when coupled (directly or indirectly) to an exergonic process such as the absorption of sunlight, an oxidation reaction, the breakdown of ATP, or the concomitant flow of some other chemical species down its electrochemical gradient. In primary active transport, solute accumulation is coupled directly to an exergonic chemical reaction, such as conversion of ATP to ADP + P$_i$ (Fig. 11–34).

**FIGURE 11–33 Three general classes of transport systems.** Transporters differ in the number of solutes (substrates) transported and the direction in which each solute moves. Examples of all three types of transporters are discussed in the text. Note that this classification tells us nothing about whether these are energy-requiring (active transport) or energy-independent (passive transport) processes.

**FIGURE 11–34 Two types of active transport.** (a) In primary active transport, the energy released by ATP hydrolysis drives solute movement against an electrochemical gradient. (b) In secondary active transport, a gradient of ion X (often Na$^+$) has been established by primary active transport. Movement of X down its electrochemical gradient now provides the energy to drive cotransport of a second solute (S) against its electrochemical gradient.
**Secondary active transport** occurs when endergonic (uphill) transport of one solute is coupled to the exergonic (downhill) flow of a different solute that was originally pumped uphill by primary active transport.

The amount of energy needed for the transport of a solute against a gradient can be calculated from the initial concentration gradient. The general equation for the free-energy change in the chemical process that converts $S$ to $P$ is

$$
\Delta G = \Delta G^\circ + RT \ln \left( \frac{[P]}{[S]} \right) 
$$

where $\Delta G^\circ$ is the standard free-energy change, $R$ is the gas constant, 8.315 J/mol·K, and $T$ is the absolute temperature. When the "reaction" is simply transport of a solute from a region where its concentration is $C_1$ to a region where its concentration is $C_2$, no bonds are made or broken and $\Delta G^\circ$ is zero. The free-energy change for transport, $\Delta G_t$, is then

$$
\Delta G_t = RT \ln \left( \frac{C_2}{C_1} \right)
$$

If there is a 10-fold difference in concentration between two compartments, the cost of moving 1 mol of an uncharged solute at 25 °C uphill across a membrane separating the compartments is

$$
\Delta G = (8.315 \text{ J/mol·K}) (298 \text{ K}) \ln (10/1) = 5,700 \text{ J/mol} = 5.7 \text{ kJ/mol}
$$

Equation 11-3 holds for all uncharged solutes.

**WORKED EXAMPLE 11-1 Energy Cost of Pumping an Uncharged Solute**

Calculate the energy cost (free-energy change) of pumping an uncharged solute against a 1.0 x 10^4-fold concentration gradient at 25 °C.

**Solution:** Begin with Equation 11-3. Substitute $1.0 \times 10^4$ for $(C_2/C_1)$, 8.315 J/mol·K for $R$, and 298 K for $T$:

$$
\Delta G_t = RT \ln \left( \frac{C_2}{C_1} \right)
$$

$$
= (8.315 \text{ J/mol·K})(298 \text{ K}) \ln (1.0 \times 10^4)
$$

$$
= 23 \text{ kJ/mol}
$$

When the solute is an ion, its movement without an accompanying counterion results in the endergonic separation of positive and negative charges, producing an electrical potential; such a transport process is said to be **electrogenic**. The energetic cost of moving an ion depends on the electrochemical potential (p. 390), the sum of the chemical and electrical gradients:

$$
\Delta G_t = RT \ln \left( \frac{C_2}{C_1} \right) + Z \mathcal{F} \Delta \psi
$$

where $Z$ is the charge on the ion, $\mathcal{F}$ is the Faraday constant (96,480 J/V·mol), and $\Delta \psi$ is the transmembrane electrical potential (in volts). Eukaryotic cells typically have plasma membrane potentials of about 0.05 V (with the inside negative relative to the outside), so the second term of Equation 11-4 can make a significant contribution to the total free-energy change for transporting an ion. Most cells maintain more than a 10-fold difference in ion concentrations across their plasma or intracellular membranes, and for many cells and tissues active transport is therefore a major energy-consuming process.

**WORKED EXAMPLE 11-2 Energy Cost of Pumping a Charged Solute**

Calculate the energy cost (free-energy change) of pumping Ca^{2+} from the cytosol, where its concentration is about 1.0 x 10^{-7} M, to the extracellular fluid, where its concentration is about 1.0 M. Assume a temperature of 37 °C (body temperature in a mammal) and a standard transmembrane potential of 50 mV (inside negative) for the plasma membrane.

**Solution:** In this calculation, both the concentration gradient and the electrical potential must be taken into account. In Equation 11-4, substitute 8.315 J/mol·K for $R$, 310 K for $T$, $1.0 \times 10^{-3}$ for $C_2$, $1.0 \times 10^{-7}$ for $C_1$, 96,500 J/V·mol for $\mathcal{F}$, +2 (the charge on a Ca^{2+} ion) for $Z$, and 0.050 V for $\Delta \psi$. Note that the transmembrane potential is 50 mV (inside negative), so the change in potential when an ion moves from inside to outside is 50 mV.

$$
\Delta G_t = RT \ln \left( \frac{C_2}{C_1} \right) + Z \mathcal{F} \Delta \psi
$$

$$
= (8.315 \text{ J/mol·K})(310 \text{ K}) \ln \left( \frac{1.0 \times 10^{-3}}{1.0 \times 10^{-7}} \right)
$$

$$
+ 2 (96,500 \text{ J/V·mol}) (0.050 \text{ V})
$$

$$
= 33 \text{ kJ/mol}
$$

The mechanism of active transport is of fundamental importance in biology. As we shall see in Chapter 19, ATP is formed in mitochondria and chloroplasts by a mechanism that is essentially ATP-driven ion transport operating in reverse. The energy made available by the spontaneous flow of protons across a membrane is calculable from Equation 11-4; remember that $\Delta G$ for flow down an electrochemical gradient has a negative value, and $\Delta G$ for transport of ions against an electrochemical gradient has a positive value.

**P-Type ATPases Undergo Phosphorylation during Their Catalytic Cycles**

The family of active transporters called **P-type ATPases** are cation transporters that are reversibly phosphorylated by ATP (thus the name P-type) as part of the transport cycle. Phosphorylation forces a conformational change that is central to movement of the cation across the membrane. The human genome encodes at least 70 P-type ATPases that share similarities in amino acid sequence and topology, especially near the Asp residue.
that undergoes phosphorylation. All are integral proteins with 8 or 10 predicted membrane-spanning regions in a single polypeptide (type III in Fig. 11–8), and all are sensitive to inhibition by the phosphate analog vanadate.

The P-type ATPases are widespread in eukaryotes and bacteria. In animal tissues, the Ca\(^{2+}\) ATPase (a uniporter for Ca\(^{2+}\) ions) and the Na\(^+\)K\(^+\) ATPase (an antiporter for Na\(^+\) and K\(^+\) ions) are P-type ATPases that maintain differences in ionic composition between the cytosol and the extracellular medium. Parietal cells in the lining of the mammalian stomach have a P-type ATPase that pumps H\(^+\) and K\(^+\) across the plasma membrane, thereby acidifying the stomach contents. Lipid flippases, as we noted above, are structurally and functionally related to P-type transporters. In vascular plants, a P-type ATPase pumps protons out of cells, establishing an electrochemical difference of as much as 2 pH units and 250 mV across the plasma membrane. A similar P-type ATPase in the bread mold Neurospora pumps protons out of cells to establish an inside-negative membrane potential, which is used to drive the uptake of substrates and ions from the surrounding medium by secondary active transport. Bacteria use P-type ATPases to pump out toxic heavy metal ions such as Cd\(^{2+}\) and Cu\(^{2+}\).

The best-understood P-type pumps are the Ca\(^{2+}\) pumps that maintain a low concentration of Ca\(^{2+}\) in the cytosol of virtually all cells. The plasma membrane Ca\(^{2+}\) pump moves calcium ions out of the cell, and another P-type pump in the endoplasmic reticulum moves Ca\(^{2+}\) into the ER lumen. (In muscle cells, Ca\(^{2+}\) is normally sequestered in a specialized form of ER called the sarcoplasmic reticulum; release of this Ca\(^{2+}\) triggers muscle contraction.)

The sarcoplasmic and endoplasmic reticulum calcium (SERCA) pumps are P-type ATPases closely related in structure and mechanism. The SERCA pump of the sarcoplasmic reticulum, which comprises 80% of the protein in that membrane, is a single polypeptide (\(M_r \sim 110,000\)) that spans the membrane 10 times (Fig. 11–35). Three cytosolic domains formed by long loops connect the transmembrane helices: the N domain, where the nucleotide ATP and Mg\(^{2+}\) bind; the P domain, which contains the phosphorylated Asp residue characteristic of all P-type ATPases; and the A (actuator) domain, which communicates movements of the N and P domains to the two Ca\(^{2+}\)-binding sites. The M domain contains the transmembrane helices and the Ca\(^{2+}\)-binding sites, which are located near the middle of the membrane bilayer, 40 to 50 Å from the phosphorylated Asp residue—thus Asp phosphorylation-dephosphorylation does not directly affect Ca\(^{2+}\) binding.

The mechanism postulated for SERCA pumps (Fig. 11–36) takes into account the large conformational changes and the phosphorylation-dephosphorylation of the critical Asp residue in the P domain that is known to occur during a catalytic cycle. Each catalytic cycle moves two Ca\(^{2+}\) ions across the membrane and converts an ATP to ADP and P\(_i\). The role of ATP binding and hydrolysis is to bring about the interconversion of two conformations (E1 and E2) of the transporter. In the E1 conformation, the two Ca\(^{2+}\)-binding sites are exposed on the cytosolic side of the ER or sarcoplasmic reticulum and bind Ca\(^{2+}\) with high affinity. ATP binding and Asp phosphorylation drive a conformational change from E1 to E2 in which the Ca\(^{2+}\)-binding sites are now exposed on the luminal side of the membrane and their affinity for Ca\(^{2+}\) is greatly reduced, causing Ca\(^{2+}\) release into the lumen. By this mechanism, the energy released by hydrolysis of ATP during one
phosphorylation-dephosphorylation cycle drives Ca$^{2+}$ across the membrane against a large electrochemical gradient.

A variation on this basic mechanism is seen in the Na$^+$K$^+$ ATPase of the plasma membrane, discovered by Jens Skou in 1957. This cotransporter couples phosphorylation-dephosphorylation of the critical Asp residue to the simultaneous movement of both Na$^+$ and K$^+$ against their electrochemical gradients (Fig. 11-37). The Na$^+$K$^+$ ATPase is responsible for maintaining low Na$^+$ and high K$^+$ concentrations in the cell relative to the extracellular fluid (Fig. 11-38). For each molecule of

**FIGURE 11-38 Role of the Na$^+$K$^+$ ATPase in animal cells.** In animal cells, this active transport system is primarily responsible for setting and maintaining the intracellular concentrations of Na$^+$ and K$^+$ and for generating the membrane potential. It does this by moving three Na$^+$ out of the cell for every two K$^+$ it moves in. The electrical potential across the plasma membrane is central to electrical signaling in neurons, and the gradient of Na$^+$ is used to drive the uphill cotransport of solutes in many cell types.
ATP converted to ADP and P₁, the transporter moves two K⁺ ions inward and three Na⁺ ions outward across the plasma membrane. Cotransport is therefore electrogenic—it creates a net separation of charge across the membrane; in animals, this produces the membrane potential of −50 to −70 mV (inside negative relative to outside) that is characteristic of most cells and is essential to the conduction of action potentials in neurons. The central role of the Na⁺K⁺-ATPase is reflected in the energy invested in this single reaction: about 25% of the total energy consumption of a human at rest!

F-Type ATPases Are Reversible, ATP-Driven Proton Pumps

F-type ATPase active transporters catalyze the uphill transmembrane passage of protons driven by ATP hydrolysis. The "F-type" designation derives from the identification of these ATPases as energy-coupling factors. The F₀ integral membrane protein complex (Fig. 11–39; subscript o denotes its inhibition by the drug oligomycin) provides a transmembrane pathway for protons, and the peripheral protein F₁ (subscript 1 indicating this was the first of several factors isolated from mitochondria) uses the energy of ATP to drive protons uphill (into a region of higher H⁺ concentration).

The F₀F₁ organization of proton-pumping transporters must have developed very early in evolution. Bacteria such as E. coli use an F₀F₁ ATPase complex in their plasma membrane to pump protons outward, and archaea have a closely homologous proton pump, the A₀A₁ ATPase.

The reaction catalyzed by F-type ATPases is reversible, so a proton gradient can supply the energy to drive the reverse reaction, ATP synthesis (Fig. 11–40). When functioning in this direction, the F-type ATPases are more appropriately named ATP synthases. ATP synthases are central to ATP production in mitochondria during oxidative phosphorylation and in chloroplasts during photophosphorylation, as well as in bacteria and archaea. The proton gradient needed to drive ATP synthesis is produced by other types of proton pumps powered by substrate oxidation or sunlight. We provide a detailed description of these processes in Chapter 19.

V-type ATPases, a class of proton-transporting ATPases structurally (and possibly mechanistically) related to the F-type ATPases, are responsible for acidifying intracellular compartments in many organisms (thus V for vacuolar). Proton pumps of this type maintain the vacuoles of fungi and higher plants at a pH between 3 and 6, well below that of the surrounding cytosol (pH 7.5). V-type ATPases are also responsible for the acidification of lysosomes, endosomes, the Golgi complex, and secretory vesicles in animal cells. All V-type ATPases have a similar complex structure, with an integral (transmembrane) domain (V₀) that serves as a proton channel and a peripheral domain (V₁) that contains the ATP-binding site and the ATPase activity. The mechanism by which V-type ATPases couple ATP hydrolysis to the uphill transport of protons is not understood in detail.
ABC transporters (Fig. 11–41) constitute a large family of ATP-dependent transporters that pump amino acids, peptides, proteins, metal ions, various lipids, bile salts, and many hydrophobic compounds, including drugs, out of cells against a concentration gradient. One ABC transporter in humans, the multi-drug transporter (MDR1), is responsible for the striking resistance of certain tumors to some generally effective antitumor drugs. MDR1 has a broad substrate specificity for hydrophobic compounds, including, for example, the chemotherapeutic drugs adriamycin, doxorubicin, and vinblastine. By pumping these drugs out of the cell, the transporter prevents their accumulation within a tumor and thus blocks their therapeutic effects. MDR1 is an integral membrane protein (M, 170,000) with 12 transmembrane segments and two ATP-binding domains ("cassettes"), which give the family its name: ATP-binding cassette transporters.

All ABC transporters have two nucleotide-binding domains (NBDs) and two transmembrane domains. In some cases, all these domains are in a single long polypeptide; other ABC transporters have two subunits, each contributing an NBD and a domain with six (or in some cases 10; Fig. 11–41) transmembrane helices. Many ABC transporters are in the plasma membrane, but some types are also found in the endoplasmic reticulum and in the membranes of mitochondria and lysosomes. Most ABC transporters act as pumps, but at least some members of the superfamily act as ion channels that are opened and closed by ATP hydrolysis. The CFTR transporter (see Box 11–3) is a Cl⁻ channel operated by ATP hydrolysis.

The NBDs of all ABC proteins are similar in sequence and presumably in three-dimensional structure; they are the conserved molecular motor that can be coupled to a wide variety of pumps and channels. When coupled with a pump, the ATP-driven motor moves solutes against a concentration gradient; when coupled with an ion channel, the motor opens and closes the channel, using ATP as energy source. The stoichiometry of ABC pumps is about one ATP hydrolyzed per molecule of substrate transported, but neither the mechanism of coupling nor the site of substrate binding is known.

Some ABC transporters have very high specificity for a single substrate; others are more promiscuous. The human genome contains at least 48 genes that encode ABC transporters, many of which are involved in maintaining the lipid bilayer and in transporting steroids, steroid derivatives, and fatty acids throughout the body. The flipases that move membrane lipids from one leaflet of the bilayer to the other are ABC transporters, and the cellular machinery for exporting excess cholesterol includes an ABC transporter. Mutations in the genes that encode some of these proteins contribute to several genetic diseases, including cystic fibrosis (Box 11–3), Tangier disease (p. 843), and liver failure.

ABC transporters are also present in simpler animals and in plants and microorganisms. Yeast has 31 genes that encode ABC transporters, *Drosophila* has 56, and *E. coli* has 80, representing 2% of its entire genome. The presence of ABC transporters that confer antibiotic resistance in pathogenic microbes (*Pseudomonas aeruginosa*, *Staphylococcus aureus*, *Candida albicans*, *Neisseria gonorrhoeae*, and *Plasmodium falciparum*) is a serious public health concern and makes these transporters attractive targets for drug design.

**Ion Gradients Provide the Energy for Secondary Active Transport**

The ion gradients formed by primary transport of Na⁺ or H⁺ can in turn provide the driving force for cotransport of other solutes. Many cell types contain transport systems that couple the spontaneous, downhill flow of these ions to the simultaneous uphill pumping of another ion, sugar, or amino acid (Table 11–4).

Cystic fibrosis (CF) is a serious and relatively common hereditary disease of humans. About 5% of white Americans are carriers, having one defective and one normal copy of the gene. Only individuals with two defective copies show the severe symptoms of the disease: obstruction of the gastrointestinal and respiratory tracts, commonly leading to bacterial infection of the airways and death due to respiratory insufficiency before the age of 30. In CF, the thin layer of mucus that normally coats the internal surfaces of the lungs is abnormally thick, obstructing air flow and providing a haven for pathogenic bacteria, particularly Staphylococcus aureus and Pseudomonas aeruginosa.

The defective gene in CF patients was discovered in 1989. It encodes a membrane protein called cystic fibrosis transmembrane conductance regulator, or CFTR. This protein has two segments, each containing six transmembrane helices, two nucleotide-binding domains (NBDs), and a regulatory region (Fig. 1). CFTR is therefore very similar to other ABC transporter proteins. The normal CFTR protein proved to be an ion channel specific for Cl⁻ ions. The channel conducts Cl⁻ across the plasma membrane when both NBDs have bound ATP, and it closes when the ATP on one of the NBDs is broken down to ADP and Pᵢ. The Cl⁻ channel is further regulated by phosphorylation of several Ser residues in the regulatory domain, catalyzed by cAMP-dependent protein kinase (Chapter 12). When the regulatory domain is not phosphorylated, the Cl⁻ channel is closed. The mutation responsible for CF in 70% of cases results from deletion of a Phe residue at position 508. The mutant protein folds incorrectly, which interferes with its insertion in the plasma membrane, resulting in reduced Cl⁻ movement across the plasma membranes of epithelial cells that line the airways (Fig. 2), the digestive tract, and exocrine glands (pancreas, sweat glands, bile ducts, and vas deferens).

Diminished export of Cl⁻ is accompanied by diminished export of water from cells, causing the mucus on their surfaces to become dehydrated, thick, and excessively sticky. In normal circumstances, cilia on the epithelial cells that line the inner surface of the lungs constantly sweep away bacteria that settle in this mucus, but the thick mucus in individuals with CF hinders this process. Frequent infections by bacteria such as S. aureus and P. aeruginosa result, causing progressive damage to the lungs and reduced respiratory efficiency. Respiratory failure is commonly the cause of death in people with CF.

**Figure 1** Three states of the cystic fibrosis transmembrane conductance regulator, CFTR. The protein has two segments, each with six transmembrane helices, and three functionally significant domains extend from the cytoplasmic surface: NBD₁ and NBD₂ (green) are nucleotide-binding domains that bind ATP, and a regulatory domain (blue) is the site of phosphorylation by cAMP-dependent protein kinase. When this R domain is phosphorylated but no ATP is bound to the NBDs (left), the channel is closed. The binding of ATP opens the channel (middle) until the bound ATP is hydrolyzed. When the regulatory domain is unphosphorylated (right), it binds the NBD domains and prevents ATP binding and channel opening. The most commonly occurring mutation leading to CF is the deletion of Phe⁵⁰⁸ in the NBD₁ domain (left). CFTR is a typical ABC transporter in all but two respects: most ABC transporters lack the regulatory domain, and CFTR acts as an ion channel (for Cl⁻), not as a typical transporter.

**Figure 2** Mucus lining the surface of the lungs traps bacteria. In healthy lungs (shown here), these bacteria are killed and swept away by the action of cilia. In CF, this mechanism is impaired, resulting in recurring infections and progressive damage to the lungs.
The lactose transporter (lactose permease) of *E. coli* is the well-studied prototype for proton-driven cotransporters. This protein consists of a single polypeptide chain (417 residues) that functions as a monomer to transport one proton and one lactose molecule into the cell, with the net accumulation of lactose (Fig. 11-42). *E. coli* normally produces a gradient of protons and charge across its plasma membrane by oxidizing fuels and using the energy of oxidation to pump protons outward. (This mechanism is discussed in detail in Chapter 19.) The lipid bilayer is impermeable to protons, but the lactose transporter provides a route for proton reentry, and lactose is simultaneously carried into the cell by symport. The endergonic accumulation of lactose is thereby coupled to the exergonic flow of protons into the cell, with a negative overall free-energy change.

The lactose transporter is one member of the major facilitator superfamily (MFS) of transporters, which comprises 28 families. Almost all proteins in this superfamily have 12 transmembrane domains (the few exceptions have 14). The proteins share relatively little sequence homology, but the similarity of their secondary structures and topology suggests a common tertiary structure. The crystallographic solution of the *E. coli* lactose transporter may provide a glimpse of this general structure (Fig. 11-43a). The protein has 12 transmembrane helices, and connecting loops protrude into the cytoplasm or the periplasmic space (between the plasma membrane and outer membrane or cell wall). The six amino-terminal and six carboxyl-terminal helices form very similar domains, to produce a structure with a rough twofold symmetry. In the crystallized form of the protein, a large aqueous cavity is exposed on the cytoplasmic side of the membrane. The substrate-binding site is in this cavity, more or less in the middle of the membrane. The side of the transporter facing outward (the periplasmic face) is closed tightly, with no channel big enough for lactose to enter. The proposed mechanism for dependent on this inflow of protons driven by the electrochemical gradient. (b) When the energy-yielding oxidation reactions of metabolism are blocked by cyanide (CN⁻), the lactose transporter allows equilibration of lactose across the membrane via passive transport. Mutations that affect Glu325 or Arg302 have the same effect as cyanide. The dashed line represents the concentration of lactose in the surrounding medium.

![Figure 11-42: Lactose uptake in *E. coli*. (a) The primary transport of H⁺ out of the cell, driven by the oxidation of a variety of fuels, establishes both a proton gradient and an electrical potential (inside negative) across the membrane. Secondary active transport of lactose into the cell involves symport of H⁺ and lactose by the lactose transporter. The uptake of lactose against its concentration gradient is entirely](image-a)

![Figure 11-43: The lactose transporter (lactose permease) of *E. coli*. (a) Ribbon representation viewed parallel to the plane of the membrane shows the 12 transmembrane helices arranged in two nearly symmetric domains, shown in different shades of purple, in the form of the protein for which the crystal structure was determined, the substrate sugar (red) is bound near the middle of the membrane where it is exposed to the cytoplasm (derived from PDB ID 1PV7). (b) The postulated second conformational change in which the substrate-binding site is exposed first to the periplasm (conformation on the right), where lactose is picked up, then to the cytoplasm (conformation on the left), where the lactose is released. The interconversion of the two forms is driven by changes in the pairing of charged (protonatable) side chains such as those of Glu325 and Arg302 (green), which is affected by the transmembrane proton gradient.](image-b)
transmembrane passage of the substrate (Fig. 11-43b) involves a rocking motion between the two domains, driven by substrate binding and proton movement, alternately exposing the substrate-binding domain to the cytoplasm and to the periplasm. This "rocking banana" model is similar to that shown in Figure 11-31 for GLUT1.

How is proton movement into the cell coupled with lactose uptake? Extensive genetic studies of the lactose transporter have established that of the 417 residues in the protein, only 6 are absolutely essential for cotransport of H⁺ and lactose—some for lactose binding, others for proton transport. Mutation in either of two residues (Glu³²⁵ and Arg³⁰²; Fig. 11-43) results in a protein still able to catalyze facilitated diffusion of lactose but incapable of coupling H⁺ flow to uphill lactose transport. A similar effect is seen in wild-type (unmutated) cells when their ability to generate a proton gradient is blocked with CN⁻: the transporter carries out facilitated diffusion normally, but it cannot pump lactose against a concentration gradient (Fig. 11-42b). The balance between the two conformations of the lactose transporter is affected by changes in charge pairing between side chains.

In intestinal epithelial cells, glucose and certain amino acids are accumulated by symport with Na⁺, down the Na⁺ gradient established by the Na⁺K⁺ ATPase of the plasma membrane (Fig. 11-44). The apical surface of the intestinal epithelial cell is covered with microvilli, long thin projections of the plasma membrane that greatly increase the surface area exposed to the intestinal contents. Na⁺-glucose symporters in the apical plasma membrane take up glucose from the intestine in a process driven by the downhill flow of Na⁺:

$$2\text{Na}^+_{\text{out}} + \text{glucose}_{\text{out}} \rightarrow 2\text{Na}^+_{\text{in}} + \text{glucose}_{\text{in}}$$

The energy required for this process comes from two sources: the greater concentration of Na⁺ outside than inside (the chemical potential) and the membrane (electrical) potential, which is inside negative and therefore draws Na⁺ inward.

**WORKED EXAMPLE 11-3**

**Energetics of Pumping by Symport**

Calculate the maximum concentration ratio that can be achieved by the plasma membrane Na⁺-glucose symporter of an epithelial cell, when [Na⁺]ₘₐₜ is 12 mM, [Na⁺]ₒᵤₜ is 145 mM, the membrane potential is -50 mV (inside negative), and the temperature is 37 °C.

**Solution:** Using Equation 11-4 (p. 396), we can calculate the energy inherent in an electrochemical Na⁺ gradient—that is, the cost of moving one Na⁺ ion up this gradient:

$$\Delta G_i = RT \ln \frac{[\text{Na}^+]_{\text{out}}}{[\text{Na}^+]_{\text{in}}} + ZF \Delta \psi$$

We then substitute standard values for $R$, $T$, and $F$, and the given values for [Na⁺] (expressed as molar concentrations), +1 for $Z$ (because Na⁺ has a positive charge), and 0.050 V for $\Delta \psi$. Note that the membrane potential is -50 mV (inside negative), so the change in potential when an ion moves from inside to outside is 50 mV.

$$\Delta G_i = (8.315 \text{ J/mol·K})(310 \text{ K}) \ln \frac{145 \times 10^{-1}}{1.2 \times 10^{-2}} + (96,500 \text{ J/V·mol})(0.050 \text{ V})$$

$$= 11.2 \text{ kJ/mol}$$

This $\Delta G_i$ is the potential energy per mole of Na⁺ in the Na⁺ gradient that is available to pump glucose. Given that two Na⁺ ions pass down their electrochemical gradient and into the cell for each glucose carried in by symport, the energy available to pump 1 mol of glucose is $2 \times 11.2 \text{ kJ/mol} = 22.4 \text{ kJ/mol}$. We can now calculate the concentration ratio of glucose that can be achieved by this pump (from Equation 11-3, p. 396):

$$\Delta G_i = RT \ln \frac{[\text{glucose}]_{\text{in}}}{[\text{glucose}]_{\text{out}}}$$

Rearranging, then substituting the values of $\Delta G_i$, $R$, and $T$, gives

$$\ln \frac{[\text{glucose}]_{\text{in}}}{[\text{glucose}]_{\text{out}}} = \frac{22.4 \text{ kJ/mol}}{8.315 \text{ J/mol·K}(310 \text{ K})} = 8.69$$

$$\frac{[\text{glucose}]_{\text{in}}}{[\text{glucose}]_{\text{out}}} = e^{8.69}$$

$$= 5.94 \times 10^8$$

Thus the cotransporter can pump glucose inward until its concentration inside the epithelial cell is about 6,000 times that outside (in the intestine).
As glucose is pumped from the intestine into the epithelial cell at the apical surface, it is simultaneously moved from the cell into the blood by passive transport through a glucose transporter (GLUT2) in the basal surface (Fig. 11–44). The crucial role of Na⁺ in symport and antiport systems such as this requires the continued outward pumping of Na⁺ to maintain the transmembrane Na⁺ gradient. Because of the essential role of ion gradients in active transport and energy conservation, compounds that collapse ion gradients across cellular membranes are effective poisons, and those that are specific for infectious microorganisms can serve as antibiotics. One such substance is valinomycin, a small cyclic peptide that neutralizes the K⁺ charge by surrounding it with six carbonyl oxygens (Fig. 11–45). The hydrophobic peptide then acts as a shuttle, carrying K⁺ across membranes down its concentration gradient and deflating that gradient. Compounds that shuttle ions across membranes in this way are called ionophores (“ion bearers”). Both valinomycin and monensin (a Na⁺-carrying ionophore) are antibiotics; they kill microbial cells by disrupting secondary transport processes and energy-conserving reactions. Monensin is widely used as an antifungal and antiparasitic agent.

Aquaporins Form Hydrophilic Transmembrane Channels for the Passage of Water

A family of integral membrane proteins discovered by Peter Agre, the aquaporins (AQPs), provide channels for rapid movement of water molecules across all plasma membranes. Eleven aquaporins are known in mammals, each with a specific localization and role (Table 11–5, p. 406). Erythrocytes, which swell or shrink rapidly in response to abrupt changes in extracellular osmolarity as blood travels through the renal medulla, have a high density of aquaporin in their plasma membrane (2 × 10⁶ copies of AQP-1 per cell). Water secretion by the exocrine glands that produce sweat, saliva, and tears occurs through aquaporins. Seven different aquaporins play roles in urine production and water retention in the nephron (the functional unit of the kidney). Each renal AQP has a specific localization in the nephron, and each has specific properties and regulatory features. For example, AQP-2 in the epithelial cells of the renal collecting duct is regulated by vasopressin (also called antidiuretic hormone): more water is reabsorbed in the kidney when the vasopressin level is high. Mutant mice with no AQP-1 gene have increased urine output (polyuria) and decreased urine-concentrating ability, the result of decreased water permeability of the proximal tubule. In humans, genetically defective AQPs are known to be responsible for a variety of diseases, including a relatively rare form of diabetes that is accompanied by polyuria (Box 11–2).

Aquaporins are found in all organisms. The plant Arabidopsis thaliana has 38 AQP genes, reflecting the critical roles of water movement in plant physiology. Changes in turgor pressure, for example, require rapid movement of water across a membrane (see p. 52).

Water molecules flow through an AQP-1 channel at a rate of about 10⁹ s⁻¹. For comparison, the highest known turnover number for an enzyme is that for catalase, 4 × 10⁷ s⁻¹, and many enzymes have turnover numbers between 1 s⁻¹ and 10⁴ s⁻¹ (see Table 6–7). The low activation energy for passage of water through aquaporin channels (ΔG° < 15 kJ/mol) suggests that water moves through the channels in a continuous stream, in the direction dictated by the osmotic gradient. (For a discussion of osmosis, see p. 52.) Aquaporins do not allow passage of protons (hydronium ions, H₃O⁺), which would collapse membrane electrochemical gradients. What is the basis for this extraordinary selectivity?

We find an answer in the structure of AQP-1, as determined by x-ray crystallography. AQP-1 (Fig. 11–46a) consists of four identical monomers (each M, 28,000), each of which forms a transmembrane pore with a
FIGURE 11-46 Aquaporin. The protein is a tetramer of identical subunits, each with a transmembrane pore. (a) A monomer of spinach aquaporin SoPIP2;1 (derived from PDB ID 285F), viewed in the plane of the membrane. The helices form a central pore, and two short helical segments (green) contain the Asn-Pro-Ala (NPA) sequences, found in all aquaporins, that form part of the water channel. (b) This cartoon of bovine aquaporin 1 (derived from PDB ID 1J4N) shows that the pore (brown; filled with water molecules shown in red and white) diameter sufficient to allow passage of water molecules in single file. Each monomer has six transmembrane helical segments and two shorter helices, both of which contain the sequence Asn-Pro-Ala (NPA). The six transmembrane helices form the pore through the monomer, and the two short loops containing the NPA sequences extend toward the middle of the bilayer from opposite sides. Their NPA regions overlap in the middle of the membrane to form part of the specificity filter—the structure that allows only water to pass (Fig. 11-46b).

The water channel narrows to a diameter of 2.8 Å near the center of the membrane, severely restricting the size of molecules that can travel through. The positive charge of a highly conserved Arg residue at this bottleneck discourages the passage of cations such as H$_3$O$^+$. The residues that line the channel of each AQP-1 monomer are generally nonpolar, but carbonyl oxygens in the peptide backbone, projecting into the narrow part of the channel at intervals, can hydrogen-bond with individual water molecules as they pass through; the two Asn residues (Asn$^{76}$ and Asn$^{102}$) in the NPA loops also form hydrogen bonds with the water. The structure of the channel does not permit formation of a chain of water molecules close enough to allow proton hopping (see Fig. 2-13), which would effectively move protons across the membrane. Critical Arg and His residues and electric dipoles formed by the short helices of the NPA loops provide positive charges in positions that repel any protons that might leak through the pore, and prevent hydrogen bonding between adjacent water molecules.

An aquaporin isolated from spinach is known to be "gated"—open when two critical Ser residues near the intracellular end of the channel are phosphorylated, and closed when they are dephosphorylated. Both the open and closed structures have been determined by crystallography. Phosphorylation favors a conformation that presses two nearby Leu residues and a His residue into the channel, blocking the movement of water past that point and effectively closing the channel. Other aquaporins are regulated in other ways, allowing rapid changes in membrane permeability to water.

Although generally highly specific for water, some AQPs also allow glycerol or urea to pass at high rates (Table 11-5); these AQPs are believed to be important in the metabolism of glycerol. AQP-7, for example, found in the plasma membranes of adipocytes (fat
Aquaporin  | Permeant (permeability) | Tissue distribution | Subcellular distribution* 
--- | --- | --- | ---
AQP-0 | Water (low) | Lens | Plasma membrane 
AQP-1 | Water (high) | Erythrocyte, kidney, lung, vascular endothelium, brain, eye | Plasma membrane

*Aquaporins that are present primarily in the apical or in the basolateral membrane are noted as localized in one of these membranes; those present in both membranes are described as localized in the plasma membrane.

⁺AQP-8 might also be permeated by urea.

cells), transports glycerol efficiently. Mice with defective AQP-7 develop obesity and adult-onset diabetes, presumably as a result of their inability to move glycerol into or out of adipocytes as triacylglycerols are converted to free fatty acids and glycerol, and vice versa.

**Ion-Selective Channels Allow Rapid Movement of Ions across Membranes**

**Ion-selective channels**—first recognized in neurons and now known to be present in the plasma membranes of all cells, as well as in the intracellular membranes of eukaryotes—provide another mechanism for moving inorganic ions across membranes. Ion channels, together with ion pumps such as the Na⁺K⁺ ATPase, determine a plasma membrane’s permeability to specific ions and regulate the cytosolic concentration of ions and the membrane potential. In neurons, very rapid changes in the activity of ion channels cause the changes in membrane potential (action potentials) that carry signals from one end of a neuron to the other. In myocytes, rapid opening of Ca²⁺ channels in the sarcoplasmic reticulum releases the Ca²⁺ that triggers muscle contraction. We discuss the signaling functions of ion channels in Chapter 12. Here we describe the structural basis for ion-channel function, using as examples a voltage-gated K⁺ channel, the neuronal Na⁺ channel, and the acetylcholine receptor ion channel.

Ion channels are distinct from ion transporters in at least three ways. First, the rate of flux through channels can be several orders of magnitude greater than the turnover number for a transporter—10⁷ to 10⁸ ions/s for an ion channel, approaching the theoretical maximum for unrestricted diffusion. By contrast, the turnover rate of the Na⁺ K⁺ ATPase is about 100 s⁻¹! Second, ion channels are not saturable: rates do not approach a maximum at high substrate concentration. Third, they are gated in response to some cellular event. In ligand-gated channels (which are generally oligomeric), binding of an extracellular or intracellular small molecule forces an allosteric transition in the protein, which opens or closes the channel. In voltage-gated ion channels, a change in transmembrane electrical potential (V_m) causes a charged protein domain to move relative to the membrane, opening or closing the channel. Both types of gating can be very fast. A channel typically opens in a fraction of a millisecond and may remain open for only milliseconds, making these molecular devices effective for very fast signal transmission in the nervous system.
Ion-Channel Function Is Measured Electrically

Because a single ion channel typically remains open for only a few milliseconds, monitoring this process is beyond the limit of most biochemical measurements. Ion fluxes must therefore be measured electrically, either as changes in $V_m$ (in the millivolt range) or as electric currents $I$ (in the microampere or picoampere range), using microelectrodes and appropriate amplifiers. In patch-clamping, a technique developed by Erwin Neher and Bert Sakmann in 1976, very small currents are measured through a tiny region of the membrane surface containing only one or a few ion-channel molecules (Fig. 11-47). The researcher can measure the size and duration of the current that flows during one opening of an ion channel and can determine how often a channel opens and how that frequency is affected by membrane potential, regulatory ligands, toxins, and other agents. Patch-clamp studies have revealed that as many as $10^4$ ions can move through a single ion channel in 1 ms. Such an ion flux represents a huge amplification of the initial signal; for example, only two acetylcholine molecules are needed to open an acetylcholine receptor channel (as described below).

The Structure of a K+ Channel Reveals the Basis for Its Specificity

The structure of a potassium channel from the bacterium *Streptomyces lividans*, determined crystallographically by Roderick MacKinnon in 1998, provides much insight into the way ion channels work. This bacterial ion channel is related in sequence to all other known K+ channels and serves as the prototype for such channels, including the voltage-gated K+ channel of neurons. Among the members of this protein family, the similarities in sequence are greatest in the “pore region,” which contains the ion selectivity filter that allows K+ (radius 1.33 Å) to pass 10,000 times more readily than Na+ (radius 0.95 Å)—at a rate (about $10^8$ ions/s) approaching the theoretical limit for unrestricted diffusion.

The K+ channel consists of four identical subunits that span the membrane and form a cone within a cone surrounding the ion channel, with the wide end of the double cone facing the extracellular space (Fig. 11-48). Each subunit has two transmembrane helices as well as a third, shorter helix that contributes to the pore region. The outer cone is formed by one of the transmembrane helices of each subunit. The inner cone, formed by the other four transmembrane helices, surrounds the ion channel and cradles the ion selectivity filter.

Both the ion specificity and the high flux through the channel are understandable from what we know of the channel’s structure. At the inner and outer plasma
membrane surfaces, the entryways to the channel have several negatively charged amino acid residues, which presumably increase the local concentration of cations such as K⁺ and Na⁺. The ion path through the membrane begins (on the inner surface) as a wide, water-filled channel in which the ion can retain its hydration sphere. Further stabilization is provided by the short helices in the pore region of each subunit, with the partial negative charges of their electric dipoles pointed at K⁺ in the channel. About two-thirds of the way through the membrane, this channel narrows in the region of the selectivity filter, forcing the ion to give up its hydrating water molecules. Carbonyl oxygen atoms in the backbone of the selectivity filter replace the water molecules in the hydration sphere, forming a series of perfect coordination shells through which the K⁺ moves. This favorable interaction with the filter is not possible for Na⁺, which is too small to make contact with all the potential oxygen ligands. The preferential stabilization of K⁺ is the basis for the ion selectivity of the filter, and mutations that change residues in this part of the protein eliminate the channel's ion selectivity. The K⁺-binding sites of the filter are flexible enough to collapse to fit any Na⁺ that enters the channel, and this conformational change closes the channel.

There are four potential K⁺-binding sites along the selectivity filter, each composed of an oxygen "cage" that provides ligands for the K⁺ ions (Fig. 11-49). In the crystal structure, two K⁺ ions are visible within the selectivity filter, about 7.5 Å apart, and two water molecules occupy the unfilled positions. K⁺ ions pass through the filter in single file; their mutual electrostatic repulsion most likely just balances the interaction of each ion with the selectivity filter and keeps them moving. Movement of the two K⁺ ions is concerted: first they occupy positions 1 and 3, then they hop to positions 2 and 4 (Fig. 11-48c). The energetic difference between

![Diagram of a K⁺ channel in cross section, showing the structural features critical to function. (See also Fig. 11-49.)](image-url)

...
these two configurations (1, 3 and 2, 4) is very small; energetically, the selectivity pore is not a series of hills and valleys but a flat surface, which is ideal for rapid ion movement through the channel. The structure of the channel seems to have been optimized during evolution to give maximal flow rates and high specificity.

Voltage-gated K⁺ channels are more complex structures than that illustrated in Figure 11–48, but they are variations on the same theme. For example, the mammalian voltage-gated K⁺ channels in the Shaker family have an ion channel like that of the bacterial channel shown in Figure 11–48, but with additional protein domains that sense the membrane potential, move in response to a change in potential, and in moving trigger

![Figure 11-50](image-url)

**Figure 11-50** Structural basis for voltage gating in the K⁺ channel. (PDB ID 2A79) This crystal structure of the Kv1.2-β2 subunit complex from rat brain shows the basic K⁺ channel (corresponding to that shown in Fig. 11–48) with the extra machinery necessary to make the channel sensitive to gating by membrane potential: four transmembrane helical extensions of each subunit and four β subunits. The entire complex, viewed (a) in the plane of the membrane and (b) perpendicular to the membrane plane (as viewed from outside the membrane), is represented as in Figure 11–48, with each subunit in a different color; each of the four β subunits is colored like the subunit with which it associates. In (b), each transmembrane helix of one subunit (red) is numbered, S1 to S6. S5 and S6 from each of four subunits form the channel itself, and are comparable to the two transmembrane helices of each subunit in Figure 11–48. S1 to S4 are four transmembrane helices. The S4 helix contains the highly conserved Arg residues and is believed to be the chief moving part of the voltage-sensing mechanism. (c) A schematic diagram of the voltage-gated channel, showing the basic pore structure (center) and the extra structures that make the channel voltage-sensitive; S4, the Arg-containing helix, is orange. For clarity, the β subunits are not shown in this view. Normally, the transmembrane electrical potential (inside negative) exerts a pull on positively charged Arg side chains in S4, toward the cytosolic side. When the membrane is depolarized the pull is lessened, and with complete reversal of the membrane potential, S4 is drawn toward the extracellular side. (d) This movement of S4 is physically coupled to opening and closing of the K⁺ channel, which is shown here in its open and closed conformations. Although K⁺ is present in the closed channel, the pore closes on the bottom, near the cytosol, preventing K⁺ passage.
with molecules smaller than proteins; for example, valinomycin (Fig. 11-45) can provide the precise fit that gives high specificity for the binding of one ion rather than another. Chemists have designed small molecules with very high specificity for binding of Li⁺ (radius 0.60 Å), Na⁺ (radius 0.95 Å), K⁺ (radius 1.33 Å), or Rb⁺ (radius 1.48 Å). The biological versions, however—the channel proteins—not only bind specifically but conduct ions across membranes in a gated fashion.

Gated Ion Channels Are Central in Neuronal Function

Virtually all rapid signaling between neurons and their target tissues (such as muscle) is mediated by the rapid opening and closing of ion channels in plasma membranes. For example, Na⁺ channels in neuronal plasma membranes sense the transmembrane electrical gradient and respond to changes by opening or closing. These voltage-gated ion channels are typically very selective for Na⁺ over other monovalent or divalent cations (by factors of 100 or more) and have very high flux rates (>10⁷ ions/s). Closed in the resting state, Na⁺ channels are opened—activated—by a reduction in the membrane potential; they then undergo very rapid inactivation. Within milliseconds of opening, a channel closes and remains inactive for many milliseconds. Activation followed by inactivation of Na⁺ channels is the basis for signaling by neurons (see Fig. 12-25).

Another very well-studied ion channel is the nicotinic acetylcholine receptor, which functions in the passage of an electrical signal from a motor neuron to a muscle fiber at the neuromuscular junction (signaling the muscle to contract). Acetylcholine released by the motor neuron diffuses a few micrometers to the plasma membrane of a myocyte, where it binds to an acetylcholine receptor. This forces a conformational change in the receptor, causing its ion channel to open. The resulting inward movement of positively charged ions into the myocyte depolarizes its plasma membrane and triggers contraction. The acetylcholine receptor allows Na⁺, Ca²⁺, and K⁺ to pass through its channel with equal ease, but other cations and all anions are unable to pass. Movement of Na⁺ through an acetylcholine receptor ion channel is unsaturable (its rate is linear with respect to extracellular [Na⁺]) and very fast—about 2 × 10⁷ ions/s under physiological conditions.

The acetylcholine receptor channel is typical of many other ion channels that produce or respond to electrical signals: it has a "gate" that opens in response to stimulation by a signal molecule (in this case acetylcholine) and an intrinsic timing mechanism that closes the gate after a split second. Thus the acetylcholine signal is transient—an essential feature of all electrical signal conduction.

Based on similarities between the amino acid sequences of other ligand-gated ion channels and the acetylcholine receptor, neuronal receptor channels that respond to the extracellular signals γ-aminobutyric acid (GABA), glycine, and serotonin are grouped together in the acetylcholine receptor superfamily, and probably share three-dimensional structure and gating mechanisms. The GABA₆ and glycine receptors are anion channels specific for Cl⁻ or HCO₃⁻, whereas the serotonin receptor, like the acetylcholine receptor, is cation-specific.

Another class of ligand-gated ion channels respond to intracellular ligands: 3',5'-cyclic guanosine mononucleotide (cGMP) in the vertebrate eye, cGMP and cAMP in olfactory neurons, and ATP and inositol 1,4,5-trisphosphate (IP₃) in many cell types. These channels are composed of multiple subunits, each with six transmembrane helical domains. We discuss the signaling functions of these ion channels in Chapter 12.

Table 11-6 shows some transporters discussed in other chapters in the context of the pathways in which they act.

Defective Ion Channels Can Have Severe Physiological Consequences

The importance of ion channels to physiological processes is clear from the effects of mutations in specific ion-channel proteins (Table 11-7, Box 11-3). Genetic defects in the voltage-gated Na⁺ channel of the myocyte plasma membrane result in diseases in which muscles are periodically either paralyzed (as in hyperkalemic periodic paralysis) or stiff (as in paramyotonia congenita). Cystic fibrosis is the result of a mutation that changes one amino acid in the protein CFTR, a Cl⁻ ion channel; the defective process here is not neurotransmission but secretion by various exocrine gland cells with activities tied to Cl⁻ ion fluxes.

Many naturally occurring toxins act on ion channels, and the potency of these toxins further illustrates the importance of normal ion-channel function. Tetrodotoxin (produced by the puffer fish, Sphaeroides rubripes) and saxitoxin (produced by the marine dinoflagellate Gonyaulax, which causes "red tides") act by binding to the voltage-gated Na⁺ channels of neurons and preventing normal action potentials. Puffer fish is an ingredient of the Japanese delicacy fugu, which may be prepared only by chefs specially trained to separate succulent morsel from deadly poison. Eating shellfish that have fed on Gonyaulax can also be fatal; shellfish are not sensitive to saxitoxin, but they concentrate it in their muscles, which become highly poisonous to organisms higher up the food chain. The venom of the black mamba snake contains dendrotoxin, which interferes with voltage-gated K⁺ channels. Tubocurarine, the active
component of curare (used as an arrow poison in the Amazon region), and two other toxins from snake venoms, cobrotoxin and bungarotoxin, block the acetylcholine receptor or prevent the opening of its ion channel. By blocking signals from nerves to muscles, all these toxins cause paralysis and possibly death. On the positive side, the extremely high affinity of bungarotoxin for the acetylcholine receptor (\(K_a = 10^{-15} \text{ M}\)) has

**SUMMARY 11.3 Solute Transport across Membranes**

- Movement of polar compounds and ions across biological membranes requires transporter proteins. Some transporters simply facilitate passive diffusion across the membrane from the side with higher concentration to the side with lower. Others transport solutes against an electrochemical gradient; this requires a source of metabolic energy.

- Carriers, like enzymes, show saturation and stereospecificity for their substrates. Transport via these systems may be passive or active. Primary active transport is driven by ATP or electron-transfer reactions; secondary active transport is driven by coupled flow of two solutes, one of which (often H⁺ or Na⁺) flows down its electrochemical gradient as the other is pulled up its gradient.

- The GLUT transporters, such as GLUT1 of erythrocytes, carry glucose into cells by facilitated diffusion. These transporters are uniproters, carrying only one substrate. Symporters permit simultaneous passage of two substances in the same direction; examples are the lactose transporter of *E. coli*, driven by the energy of a proton gradient (lactose-H⁺ symport), and the glucose transporter of intestinal epithelial cells, driven by a Na⁺ gradient (glucose-Na⁺ symport). Antiporters mediate simultaneous passage of two substances in opposite directions; examples are the chloride-bicarbonate exchanger of erythrocytes and the ubiquitous Na⁺K⁺ ATPase.

- In animal cells, Na⁺K⁺ ATPase maintains the differences in cytosolic and extracellular concentrations of Na⁺ and K⁺, and the resulting Na⁺ gradient is used as the energy source for a variety of secondary active transport processes.

- The Na⁺K⁺ ATPase of the plasma membrane and the Ca²⁺ transporters of the sarcoplasmic and endoplasmic reticulum (the SERCA pumps) are examples of P-type ATPases; they undergo reversible phosphorylation during their catalytic cycle. F-type ATPase proton pumps (ATP synthases) are central to energy-conserving
mechanisms in mitochondria and chloroplasts. V-type ATPases produce gradients of protons across some intracellular membranes, including plant vacuolar membranes.

- ABC transporters carry a variety of substrates (including many drugs) out of cells, using ATP as an energy source.
- Ionophores are lipid-soluble molecules that bind specific ions and carry them passively across membranes, dissipating the energy of electrochemical ion gradients.
- Water moves across membranes through aquaporins. Some aquaporins are regulated; some also transport glycerol or urea.
- Ion channels provide hydrophilic pores through which select ions can diffuse, moving down their electrical or chemical concentration gradients; they characteristically are unsaturable, have very high flux rates, and are highly specific for one ion. Most are voltage- or ligand-gated. The neuronal Na⁺ channel is voltage-gated, and the acetylcholine receptor ion channel is gated by acetylcholine, which triggers conformational changes that open and close the transmembrane path.

### Further Reading

**Composition and Architecture of Membranes**

  - Intermediate-level review of phospholipid asymmetry and factors that influence it.
  - Short review of how the notion of a lipid bilayer membrane was developed and confirmed.
  - Good discussion of the secondary and tertiary structures of membrane proteins and the factors that stabilize them.
  - Brief, intermediate-level review of the forces that shape transmembrane helices.
  - Intermediate-level review.

**Membrane Dynamics**

  - Intermediate-level review.
  - Intermediate-level review of studies of membrane dynamics, with fluorescent and other probes.
  - Advanced review.
  - The classic demonstration of membrane protein mobility.
  - Intermediate review of flippase function.
  - Excellent intermediate-level review of the role of SNAREs in membrane fusion, and the fusion mechanism itself.

Intermediate-level review.

Intermediate-level review of the methods and results of studies on molecular motions in the membrane.

Advanced review of membrane fusion, with emphasis on the conserved general features.

A concise historical review of caveolae, caveolin, and rafts.

Advanced review of the role of these proteins in lipid signaling and membrane trafficking.

Intermediate-level review.

Transporters

The supplementary materials available with the online version of this article include an excellent model of the putative gating mechanism.

Ion Channels

A short review of the many known cases in which genetic defects in ion channels lead to disease in humans.

The first crystal structure of an ion channel is described.

Advanced discussion of the conformational changes induced by acetylcholine.

This is one of seven excellent reviews of ion channels published together in this issue of Nature.

Short review of the architectural features of channels and pumps that give each protein its ion specificity.

Intermediate-level text emphasizing the function of ion channels.

Intermediate-level review of the localization of aquaporins in mammalian tissues and the effects of aquaporin defects on physiology.

These two articles by Long and coauthors describe the structural studies that led to models for voltage sensing and gating in the K⁺ channel.

Intermediate-level review.

Clear description of the electrophysiological methods used to measure the activity of single ion channels, by the Nobel Prize-winning developers of this technique.

One of 11 reviews in this journal issue on the CFTR chloride channel; the reviews cover structure, activity, regulation, biosynthesis, and pathophysiology.

Crystallographic study of an ion channel that admits both Na⁺ and K⁺, and the structural explanation for this dual specificity.

Advanced review of the mechanisms of voltage gating of ion channels.

**Problems**

1. **Determining the Cross-Sectional Area of a Lipid Molecule** When phospholipids are layered gently onto the surface of water, they orient at the air-water interface with their head groups in the water and their hydrophobic tails in the air. An experimental apparatus (a) has been devised that reduces the surface area available to a layer of lipids. By measuring the force necessary to push the lipids together, it is possible to determine when the molecules are packed tightly in a continuous monolayer; as that area is approached, the force needed to further reduce the surface area increases sharply (b). How would you use this apparatus to determine the average area occupied by a single lipid molecule in the monolayer?

2. **Evidence for a Lipid Bilayer** In 1925, E. Gorter and F. Grendel used an apparatus like that described in Problem 1 to determine the surface area of a lipid monolayer formed by lipids extracted from erythrocytes of several animal species. They used a microscope to measure the dimensions of individual cells, from which they calculated the average surface area of one erythrocyte. They obtained the data shown in the table. Were these investigators justified in concluding that “chromocytes [erythrocytes] are covered by a layer of fatty substances that is two molecules thick” (i.e., a lipid bilayer)?

3. **Number of Detergent Molecules per Micelle** When a small amount of the detergent sodium dodecyl sulfate (SDS; Na⁺CH₃(CH₂)₉SO₃⁻) is dissolved in water, the detergent ions enter the solution as monomeric species. As more detergent is added, a concentration is reached (the critical micelle concentration) at which the monomers associate to form micelles. The critical micelle concentration of SDS is 8.2 mM. The micelles have an average particle weight (the sum of the molecular weights of the constituent monomers) of 18,000. Calculate the number of detergent molecules in the average micelle.

4. **Properties of Lipids and Lipid Bilayers** Lipid bilayers formed between two aqueous phases have this important property: they form two-dimensional sheets, the edges of which close upon each other and undergo self-sealing to form vesicles (liposomes).

(a) What properties of lipids are responsible for this property of bilayers? Explain.

(b) What are the consequences of this property for the structure of biological membranes?

5. **Length of a Fatty Acid Molecule** The carbon–carbon bond distance for single-bonded carbons such as those in a saturated fatty acyl chain is about 1.5 Å. Estimate the length of a single molecule of palmitate in its fully extended form. If two molecules of palmitate were placed end to end, how would their total length compare with the thickness of the lipid bilayer in a biological membrane?

6. **Temperature Dependence of Lateral Diffusion** The experiment described in Figure 11–17 was performed at 37 °C. If the experiment were carried out at 10 °C, what effect would you expect on the rate of diffusion? Why?

7. **Synthesis of Gastric Juice: Energetics** Gastric juice (pH 1.5) is produced by pumping HCl from blood plasma (pH 7.4) into the stomach. Calculate the amount of free energy
required to concentrate the H⁺ in 1 L of gastric juice at 37 °C. Under cellular conditions, how many moles of ATP must be hydrolyzed to provide this amount of free energy? The free-energy change for ATP hydrolysis under cellular conditions is about \(-58 \text{kJ/mol}\) (as explained in Chapter 13). Ignore the effects of the transmembrane electrical potential.

8. Energetics of the Na⁺K⁺ ATPase For a typical vertebrate cell with a membrane potential of \(-0.070 \text{V}\) (inside negative), what is the free-energy change for transporting 1 mol of Na⁺ from the cell into the blood at 37 °C? Assume the concentration of Na⁺ inside the cell is 12 mm and that in blood plasma is 145 mm.

9. Action of Ouabain on Kidney Tissue Ouabain specifically inhibits the Na⁺K⁺ ATPase activity of animal tissues but is not known to inhibit any other enzyme. When ouabain is added to thin slices of living kidney tissue, it inhibits oxygen consumption by 66%. Why? What does this observation tell us about the use of respiratory energy by kidney tissue?

10. Energetics of Symport Suppose you determined experimentally that a cellular transport system for glucose, driven by symport of Na⁺, could accumulate glucose to concentrations 25 times greater than in the external medium, while the external [Na⁺] was only 10 times greater than the intracellular [Na⁺]. Would this violate the laws of thermodynamics? If not, how could you explain this observation?

11. Location of a Membrane Protein The following observations are made on an unknown membrane protein, X. It can be extracted from disrupted erythrocyte membranes into a concentrated salt solution, and it can be cleaved into fragments by proteolytic enzymes. Treatment of erythrocytes with proteolytic enzymes followed by disruption and extraction of membrane components yields intact X. However, treatment of erythrocyte "ghosts" (which consist of just plasma membranes, produced by disrupting the cells and washing out the hemoglobin) with proteolytic enzymes followed by disruption and extraction yields extensively fragmented X. What do these observations indicate about the location of X in the plasma membrane? Do the properties of X resemble those of an integral or peripheral membrane protein?

12. Membrane Self-sealing Cellular membranes are self-sealing—if they are punctured or disrupted mechanically, they quickly and automatically reseal. What properties of membranes are responsible for this important feature?

13. Lipid Melting Temperatures Membrane lipids in tissue samples obtained from different parts of the leg of a reindeer have different fatty acid compositions. Membrane lipids from tissue near the hooves contain a larger proportion of unsaturated fatty acids than those from tissue in the upper leg. What is the significance of this observation?

14. Flip-Flop Diffusion The inner leaflet (monolayer) of the human erythrocyte membrane consists predominantly of phosphatidylethanolamine and phosphatidylserine, while the outer leaflet consists predominantly of phosphatidylcholine and sphingomyelin. Although the phospholipid components of the membrane can diffuse in the fluid bilayer, this sidedness is preserved at all times. How?

15. Membrane Permeability At pH 7, tryptophan crosses a lipid bilayer at about one-thousandth the rate of indole, a closely related compound:

Suggest an explanation for this observation.

16. Water Flow through an Aquaporin A human erythrocyte has about \(2 \times 10^{8}\) AQP-1 monomers. If water molecules flow through the plasma membrane at a rate of \(5 \times 10^{8}\) per AQP-1 tetramer per second, and the volume of an erythrocyte is \(5 \times 10^{-11}\) mL, how rapidly could an erythrocyte halve its volume as it encountered the high osmolarity (1 M) in the interstitial fluid of the renal medulla? Assume that the erythrocyte consists entirely of water.

17. Labeling the Lactose Transporter A bacterial lactose transporter, which is highly specific for lactose, contains a Cys residue that is essential to its transport activity. Covalent reaction of N-ethylmaleimide (NEM) with this Cys residue irreversibly inactivates the transporter. A high concentration of lactose in the medium prevents inactivation by NEM, presumably by sterically protecting the Cys residue, which is in or near the lactose-binding site. You know nothing else about the transporter protein. Suggest an experiment that might allow you to determine the \(M_r\) of the Cys-containing transporter polypeptide.

18. Predicting Membrane Protein Topology from Sequence You have cloned the gene for a human erythrocyte protein, which you suspect is a membrane protein. From the nucleotide sequence of the gene, you know the amino acid sequence. From this sequence alone, how would you evaluate the possibility that the protein is an integral protein? Suppose the protein proves to be an integral protein, either type I or type II. Suggest biochemical or chemical experiments that might allow you to determine which type it is.

19. Intestinal Uptake of Leucine You are studying the uptake of l-leucine by epithelial cells of the mouse intestine. Measurements of the rate of uptake of l-leucine and several of its analogs, with and without Na⁺ in the assay buffer, yield the results given in the table. What can you conclude about the properties and mechanism of the leucine transporter? Would you expect l-leucine uptake to be inhibited by ouabain?

20. Effect of an Ionophore on Active Transport
Consider the leucine transporter described in Problem 19. Would $V_{\text{max}}$ and/or $K_t$ change if you added a Na$^+$ ionophore to the assay solution containing Na$^+$? Explain.

21. Surface Density of a Membrane Protein
E. coli can be induced to make about 10,000 copies of the lactose transporter ($M$, 31,000) per cell. Assume that $E$. coli is a cylinder 1 $\mu$m in diameter and 2 $\mu$m long. What fraction of the plasma membrane surface is occupied by the lactose transporter molecules? Explain how you arrived at this conclusion.

22. Use of the Helical Wheel Diagram
A helical wheel is a two-dimensional representation of a helix, a view along its central axis (see Fig. 11-29b; see also Fig. 4-4d). Use the helical wheel diagram below to determine the distribution of amino acid residues in a helical segment with the sequence -Val-Asp-Arg-Val-Phe-Ser-Asn-Val-Cys-Thr-His-Leu-Lys-Thr-Leu-Gln-Asp-Lys-

What can you say about the surface properties of this helix? How would you expect the helix to be oriented in the tertiary structure of an integral membrane protein?

23. Molecular Species in the E. coli Membrane
The plasma membrane of $E$. coli is about 75% protein and 25% phospholipid by weight. How many molecules of membrane lipid are present for each molecule of membrane protein? Assume an average protein $M$, of 50,000 and an average phospholipid $M$, of 750. What more would you need to know to estimate the fraction of the membrane surface that is covered by lipids?

Biochemistry on the Internet

24. Membrane Protein Topology
The receptor for the hormone epinephrine in animal cells is an integral membrane protein ($M$, 64,000) that is believed to have seven membrane-spanning regions.

(a) Show that a protein of this size is capable of spanning the membrane seven times.

(b) Given the amino acid sequence of this protein, how would you predict which regions of the protein form the membrane-spanning helices?

(c) Go to the Protein Data Bank (www.rcsb.org). Use the PDB identifier 1DEP to retrieve the data page for a portion of the $\alpha$-adrenergic receptor (one type of epinephrine receptor) isolated from a turkey. Using Jmol to explore the structure, predict whether this portion of the receptor is located within the membrane or at the membrane surface. Explain.

(d) Retrieve the data for a portion of another receptor, the acetylcholine receptor of neurons and myocytes, using the PDB identifier 1AC. As in (c), predict where this portion of the receptor is located and explain your answer.

If you have not used the PDB, see Box 4-4 (p. 129) for more information.

Data Analysis Problem

25. The Fluid Mosaic Model of Biological Membrane Structure
Figure 11-3 shows the currently accepted fluid mosaic model of biological membrane structure. This model was presented in detail in a review article by S. J. Singer in 1971. In the article, Singer presented the three models of membrane structure that had been proposed by that time:

A. The Davson-Danielli-Robertson Model. This was the most widely accepted model in 1971, when Singer's review was published. In this model, the phospholipids are arranged as a bilayer. Proteins are found on both surfaces of the bilayer, attached to it by ionic interactions between the charged head groups of the phospholipids and charged groups in the proteins. Crucially, there is no protein in the interior of the bilayer.

B. The Benson Lipoprotein Subunit Model. Here, the proteins are globular and the membrane is a protein-lipid mixture. The hydrophobic tails of the lipids are embedded in the hydrophobic parts of the proteins. The lipid head groups are exposed to the solvent. There is no lipid bilayer.

C. The Fluid Mosaic Model. This model proposes that the membrane is a fluid mosaic, with proteins and lipids intermingled. The proteins are embedded in the lipid bilayer, but they are not fixed in place and can move laterally within the membrane.
C. The Lipid-Globular Protein Mosaic Model. This is the model shown in Figure 11-3. The lipids form a bilayer and proteins are embedded in it, some extending through the bilayer and others not. Proteins are anchored in the bilayer by hydrophobic interactions between the hydrophobic tails of the lipids and hydrophobic portions of the protein.

For the data given below, consider how each piece of information aligns with each of the three models of membrane structure. Which model(s) are supported, which are not supported, and what reservations do you have about the data or their interpretation? Explain your reasoning.

(a) When cells were fixed, stained with osmium tetroxide, and examined in the electron microscope, they gave images like that in Figure 11-1: the membranes showed a "railroad track" appearance, with two dark-staining lines separated by a light space.

(b) The thickness of membranes in cells fixed and stained in the same way was found to be 5 to 9 nm. The thickness of a "naked" phospholipid bilayer, without proteins, was 4 to 4.5 nm. The thickness of a single monolayer of proteins was about 1 nm.

(c) In Singer's words: "The average amino acid composition of membrane proteins is not distinguishable from that of soluble proteins. In particular, a substantial fraction of the residues is hydrophobic" (p. 165).

(d) As described in Problems 1 and 2 of this chapter, researchers had extracted membranes from cells, extracted the lipids, and compared the area of the lipid monolayer with the area of the original cell membrane. The interpretation of the results was complicated by the issue illustrated in the graph of Problem 1: the area of the monolayer depended on how hard it was pushed. With very light pressures, the ratio of monolayer area to cell membrane area was about 2.0. At higher pressures—thought to be more like those found in cells—the ratio was substantially lower.

(e) Circular dichroism spectroscopy uses changes in polarization of UV light to make inferences about protein secondary structure (see Fig. 4-9). On average, this technique showed that membrane proteins have a large amount of α helix and little or no β sheet. This finding was consistent with most membrane proteins having a globular structure.

(f) Phospholipase C is an enzyme that removes the polar head group (including the phosphate) from phospholipids. In several studies, treatment of intact membranes with phospholipase C removed about 70% of the head groups without disrupting the "railroad track" structure of the membrane.

(g) Singer described a study in which "a glycoprotein of molecular weight about 31,000 in human red blood cell membranes is cleaved by trypsin treatment of the membranes into soluble glycopeptides of about 10,000 molecular weight, while the remaining portions are quite hydrophobic" (p. 199). Trypsin treatment did not cause gross changes in the membranes, which remained intact.

Singer's review also included many more studies in this area. In the end, though, the data available in 1971 did not conclusively prove Model C was correct. As more data have accumulated, this model of membrane structure has been accepted by the scientific community.

Reference

medium. In multicellular organisms, cells with different functions exchange a wide variety of signals. Plant cells respond to growth hormones and to variations in sunlight. Animal cells exchange information about the concentrations of ions and glucose in extracellular fluids, the interdependent metabolic activities taking place in different tissues, and, in an embryo, the correct placement of cells during development. In all these cases, the signal represents information that is detected by specific receptors and converted to a cellular response, which always involves a chemical process. This conversion of information into a chemical change, signal transduction, is a universal property of living cells.

12.1 General Features of Signal Transduction

Signal transductions are remarkably specific and exquisitely sensitive. Specificity is achieved by precise molecular complementarity between the signal and receptor molecules (Fig. 12–1a), mediated by the same kinds of weak (noncovalent) forces that mediate enzyme-substrate and antigen-antibody interactions. Multicellular organisms have an additional level of specificity, because the receptors for a given signal, or the intracellular targets of a given signal pathway, are present only in certain cell types. Thyrotropin-releasing hormone, for example, triggers responses in the cells of the anterior pituitary but not in hepatocytes, which lack receptors for this hormone. Epinephrine alters glycogen metabolism in hepatocytes but not in adipocytes; in this case, both cell types have receptors for the hormone, but whereas hepatocytes contain glycogen and the glycogen-metabolizing enzyme that is stimulated by epinephrine, adipocytes contain neither.

Three factors account for the extraordinary sensitivity of signal transducers: the high affinity of receptors for signal molecules, cooperativity (often but not always) in the ligand-receptor interaction, and amplification of the signal by enzyme cascades. The affinity
(a) **Specificity**
Signal molecule fits binding site on its complementary receptor; other signals do not fit.

(b) **Amplification**
When enzymes activate enzymes, the number of affected molecules increases geometrically in an enzyme cascade.

(c) **Desensitization/Adaptation**
Receptor activation triggers a feedback circuit that shuts off the receptor or removes it from the cell surface.

(d) **Integration**
When two signals have opposite effects on a metabolic characteristic such as the concentration of a second messenger $X$, or the membrane potential $V_m$, the regulatory outcome results from the integrated input from both receptors.

**FIGURE 12–1** Four features of signal-transducing systems.

between signal (ligand) and receptor can be expressed as the dissociation constant $K_d$, usually $10^{-10}$ M or less—meaning that the receptor detects picomolar concentrations of a signal molecule. Receptor-ligand interactions are quantified by Scatchard analysis, which yields a quantitative measure of affinity ($K_d$) and the number of ligand-binding sites in a receptor sample (Box 12–1).

**Cooperativity** in receptor-ligand interactions results in large changes in receptor activation with small changes in ligand concentration (recall the effect of cooperativity on oxygen binding to hemoglobin; see Fig. 5–12). Amplification by enzyme cascades results when an enzyme associated with a signal receptor is activated and, in turn, catalyzes the activation of many molecules of a second enzyme, each of which activates many molecules of a third enzyme, and so on (Fig. 12–1b). Such cascades can produce amplifications of several orders of magnitude within milliseconds. The response to a signal must also be terminated such that the downstream effects are in proportion to the strength of the original stimulus.

The sensitivity of receptor systems is subject to modification. When a signal is present continuously, desensitization of the receptor system results (Fig. 12–1c); when the stimulus falls below a certain threshold, the system again becomes sensitive. Think of what happens to your visual transduction system when you walk from bright sunlight into a darkened room or from darkness into the light.

A final noteworthy feature of signal-transducing systems is integration (Fig. 12–1d), the ability of the system to receive multiple signals and produce a unified response appropriate to the needs of the cell or organism. Different signaling pathways converse with each other at several levels, generating a wealth of interactions that maintain homeostasis in the cell and the organism.

One of the revelations of research on signaling is the remarkable degree to which signaling mechanisms have been conserved during evolution. Although the number of different biological signals (Table 12–1) is probably in the thousands, and the kinds of responses elicited by these signals are comparably numerous, the machinery for transducing all of these signals is built from about 10 basic types of protein components.

In this chapter we examine some examples of the major classes of signaling mechanisms, looking at how they are integrated in specific biological functions such as the transmission of nerve signals; responses to hormones and growth factors; the senses of sight, smell, and taste; and control of the cell cycle. Often, the end result of a signaling pathway is the phosphorylation of a few specific target-cell proteins, which changes their activities and thus the activities of the cell. Throughout our discussion we emphasize the conservation of fundamental mechanisms for the transduction of biological signals and the adaptation of these basic mechanisms to a wide range of signaling pathways.

We consider the molecular details of several representative signal-transduction systems, classified according

12.1 General Features of Signal Transduction

The cellular actions of a hormone begin when the hormone (ligand, L) binds specifically and tightly to its protein receptor (R) on or in the target cell. Binding is mediated by noncovalent interactions (hydrogen-bonding, hydrophobic, and electrostatic) between the complementary surfaces of ligand and receptor. Receptor-ligand interaction brings about a conformational change that alters the biological activity of the receptor, which may be an enzyme, an enzyme regulator, an ion channel, or a regulator of gene expression.

Receptor-ligand binding is described by the equation

\[ R + L \rightleftharpoons RL \]

This binding, like that of an enzyme to its substrate, depends on the concentrations of the interacting components and can be described by an equilibrium constant:

\[ K_a = \frac{[RL]}{[R][L]} = \frac{k_{+1}}{k_{-1}} = 1/K_d \]

where \( K_a \) is the association constant and \( K_d \) is the dissociation constant.

Like enzyme-substrate binding, receptor-ligand binding is saturable. As more ligand is added to a fixed amount of receptor, an increasing fraction of receptor molecules is occupied by ligand (Fig. 1a). A rough measure of receptor-ligand affinity is given by the concentration of ligand needed to give half-saturation of the receptor. Using Scatchard analysis of receptor-ligand binding, we can estimate both the dissociation constant \( K_d \) and the number of receptor-binding sites in a given preparation. When binding has reached equilibrium, the total number of possible binding sites, \( B_{\text{max}} \), equals the number of unoccupied sites, represented by \( [R] \), plus the number of occupied or ligand-bound sites, \( [RL] \); that is, \( B_{\text{max}} = [R] + [RL] \). The number of unbound sites can be expressed in terms of total sites minus occupied sites: \( [R] = B_{\text{max}} - [RL] \). The equilibrium expression can now be written

\[ K_a = \frac{[RL]}{[L](B_{\text{max}} - [RL])} \]

Rearranging to obtain the ratio of receptor-bound ligand to free (unbound) ligand, we get

\[ \frac{[\text{Bound}]}{[\text{Free}]} = \frac{[RL]}{[L]} = K_d(B_{\text{max}} - [RL]) \]

\[ = \frac{1}{K_d} (B_{\text{max}} - [RL]) \]

From this slope-intercept form of the equation, we can see that a plot of [bound ligand]/[free ligand] versus [bound ligand] should give a straight line with a slope of \(-K_a(-1/K_d)\) and an intercept on the abscissa of \( B_{\text{max}} \), the total number of binding sites (Fig. 1b). Hormone-ligand interactions typically have \( K_d \) values of \( 10^{-9} \) to \( 10^{-11} \) M, corresponding to very tight binding.

Scatchard analysis is reliable for the simplest cases, but as with Lineweaver-Burk plots for enzymes, when the receptor is an allosteric protein, the plots deviate from linearity.
to the type of receptor. The trigger for each system is different, but the general features of signal transduction are common to all: a signal interacts with a receptor; the activated receptor interacts with cellular machinery, producing a second signal or a change in the activity of a cellular protein; the metabolic activity of the target cell undergoes a change; and finally, the transduction event ends. To illustrate these general features of signaling systems, we will look at examples of six basic receptor types (Fig. 12-2).

1. **G protein-coupled receptors** that indirectly activate (through GTP-binding proteins, or G proteins) enzymes that generate intracellular second messengers. This type of receptor is illustrated by the β-adrenergic receptor system that detects epinephrine (adrenaline) (Section 12.2).

2. **Receptor tyrosine kinases**, plasma membrane receptors that are also enzymes. When one of these receptors is activated by its extracellular ligand, it catalyzes the phosphorylation of several cytosolic or plasma membrane proteins. The insulin receptor is one example (Section 12.3); the receptor for epidermal growth factor (EGF-R) is another.

3. **Receptor guanylyl cyclases**, which are also plasma membrane receptors with an enzymatic cytoplasmic domain. The intracellular second messenger for these receptors, cyclic guanosine monophosphate (cGMP), activates a cytosolic protein kinase that phosphorylates cellular proteins and thereby changes their activities (Section 12.4).

4. **Gated ion channels** of the plasma membrane that open and close (hence the term “gated”) in response to the binding of chemical ligands or changes in transmembrane potential. These are the simplest signal transducers. The acetylcholine receptor ion channel is an example of this mechanism (Section 12.6).

5. **Adhesion receptors** that interact with macromolecular components of the extracellular matrix (such as collagen) and convey instructions to the cytoskeletal system about cell migration or adherence to the matrix. Integrins illustrate this general type of transduction mechanism (Section 12.7).

6. **Nuclear receptors** (steroid receptors) that bind specific ligands (such as the hormone estrogen) and alter the rate at which specific genes are transcribed and translated into cellular proteins. Because steroid hormones function through mechanisms intimately related to the regulation of gene expression, we consider them here only briefly (Section 12.8) and defer a detailed discussion of their action until Chapter 28.

As we begin this discussion of biological signaling, a word about the nomenclature of signaling proteins is in order. These proteins are typically discovered in one context and named accordingly, then prove to be involved in a broader range of biological functions for which the original name is not helpful. For example, the retinoblastoma protein, pRb, was initially identified as the site of a mutation that contributes to cancer of the retina (retinoblastoma), but it is now known to function in many pathways essential to cell division in all cells, not just those of the retina. Some genes and proteins are
12.2 G Protein-Coupled Receptors and 5econd Messengers

Three essential components define signal transduction through G protein-coupled receptors (GPCRs): a plasma membrane receptor with seven transmembrane helical segments, an effector enzyme in the plasma membrane that generates an intracellular second messenger, and a guanosine nucleotide-binding protein (G protein) that activates the effector enzyme. The G protein, stimulated by the activated receptor, exchanges bound GDP for GTP, the GTP-protein dissociates from the occupied receptor and binds to a nearby enzyme, altering its activity. The human genome encodes about 350 GPCRs for detecting hormones, growth factors, and other endogenous ligands, and perhaps 500 that serve as olfactory (smell) and gustatory (taste) receptors.

GPCRs have been implicated in many common human diseases, including allergies, depression, blindness, diabetes, and various cardiovascular defects with serious health consequences. Close to half of all drugs on the market target one GPCR or another. For example, the β-adrenergic receptor, which mediates the effects of epinephrine, is the target of the “beta blockers,” prescribed for such diverse conditions as hypertension, cardiac arrhythmia, glaucoma, anxiety, and migraine headache. At least 150 of the GPCRs found in the human genome are still “orphan receptors”: their natural ligands are not yet identified, and so we know nothing about their biology. The β-adrenergic receptor, with well-understood biology and pharmacology, is the prototype for all GPCRs, and our discussion of signal-transducing systems begins there.

The β-Adrenergic Receptor System Acts through the Second Messenger cAMP

Epinephrine sounds the alarm when some threat requires the organism to mobilize its energy-generating machinery; it signals the need to fight or flee. Epinephrine action begins when the hormone binds to a protein receptor in the plasma membrane of an epinephrine-sensitive cell. Adrenergic receptors (“adrenergic” reflects the alternative name for epinephrine, adrenaline) are of four general types, α1, α2, β1, and β2, defined by differences in their affinities and responses to a group of agonists and antagonists. Agonists are structural analogs that bind to a receptor and mimic the effects of its natural ligand; antagonists are analogs that bind the receptor without triggering the normal effect and thereby block the effects of agonists, including the biological ligand. In some cases, the affinity of the synthetic agonist or antagonist for the receptor is greater than that of the natural agonist (Fig. 12-3). The four types of adrenergic receptors are found in different target tissues and mediate different responses to epinephrine. Here we focus on the β-adrenergic receptors of muscle, liver, and adipose tissue. These

![Figure 12-3 Epinephrine and its synthetic analogs.](image-url)
receptors mediate changes in fuel metabolism, as described in Chapter 23, including the increased breakdown of glycogen and fat. Adrenergic receptors of the \( \beta_1 \) and \( \beta_2 \) subtypes act through the same mechanism, so in our discussion, "\( \beta \)-adrenergic" applies to both types.

The \( \beta \)-adrenergic receptor is an integral protein with seven hydrophobic regions of 20 to 28 amino acid residues that "snake" back and forth across the plasma membrane seven times (thus the alternative names for GPCRs: serpentine receptors or heptahelical receptors). The binding of epinephrine to a site on the receptor deep within the plasma membrane (Fig. 12-4a, step 1) promotes a conformational change in the receptor's intracellular domain that affects its interaction with the second protein in the signal-transduction pathway, stimulatory G protein, or \( G_s \), on the cytoplasmic side of the membrane. Alfred G. Gilman and Martin Rodbell discovered that active \( G_s \) stimulates the production of cAMP (cyclic AMP) by adenylyl cyclase (see below) in the plasma membrane. \( G_s \), the prototype for a family of G proteins that act in biosignaling (see Box 12–2), is heterotrimeric, with subunit structure \( \alpha \beta \gamma \). When the nucleotide-binding site of \( G_s \) (on the \( \alpha \) subunit) is occupied by GTP, \( G_s \) is turned on and can activate adenylyl cyclase (AC in Fig. 12–4a); with GDP bound to the site, \( G_s \) is switched off. The activated \( \beta \)-adrenergic receptor interacts with \( G_s \), catalyzing replacement of bound GDP with GTP and converting \( G_s \) to its active form (step 2). As this occurs, the \( \beta \) and \( \gamma \) subunits of \( G_s \) dissociate from the \( \alpha \) subunit as a \( \beta \gamma \) dimer, and \( G_{sa} \), with its bound GTP, moves in the plane of the membrane from the receptor to a nearby molecule of adenylyl cyclase (step 3). \( G_{sa} \) is held to the membrane by a covalently attached palmitoyl group (see Fig. 11–14).

![Figure 12-4](image-url)
Alfred G. Gilman and Martin Rodbell (Fig. 1) discovered the critical roles of guanosine nucleotide–binding proteins (G proteins) in a wide variety of cellular processes, including sensory perception, signaling for cell division, growth and differentiation, intracellular movements of proteins and membrane vesicles, and protein synthesis. The human genome encodes nearly 200 of these proteins, which differ in size and subunit structure, intracellular location, and function. But all G proteins share a common feature: they can become activated and then, after a brief period, can inactivate themselves, thereby serving as molecular binary switches with built-in timers. This superfamily of proteins includes the trimeric G proteins involved in adrenergic signaling (G<sub>s</sub> and G<sub>1</sub>) and vision (transducin); small G proteins such as that involved in insulin signaling (Ras) and others that function in vesicle trafficking (ARF and Rab), transport into and out of the nucleus (Ran; see Fig. 27–42), and timing of the cell cycle (Rho); and several proteins involved in protein synthesis (initiation factor IF2 and elongation factors EF-Tu and EF-G; see Chapter 26). Many G proteins have covalently bound lipids, which give them an affinity for membranes and dictate their locations in the cell.

All G proteins have the same core structure and use the same mechanism for switching between an inactive conformation, favored when GDP is bound, and an active conformation, favored when GTP is bound. We can use the Ras protein (~20 kDa), a minimal signaling unit, as a prototype for all members of this superfamily (Fig. 2).

In the GTP-bound conformation, the G protein exposes previously buried regions (called **switch I** and **switch II**) that interact with proteins downstream in the signaling pathway, until the G protein inactivates itself by hydrolyzing its bound GTP to GDP. The critical determinant of G-protein conformation is the γ phosphate of GTP, which interacts with a region called the P loop (phosphate-binding; Fig. 3). In Ras, GTP phosphates bind to a Lys residue in the P loop and to two critical residues, Thr<sup>35</sup> in switch I and Gly<sup>50</sup> in switch II, that hydrogen-bond with the oxygens of the γ phosphate of GTP. These hydrogen bonds act like a pair of springs (continued on next page)
holding the protein in its active conformation. When GTP is cleaved to GDP and P_i is released, these hydrogen bonds are lost; the protein relaxes into its inactive conformation, burying the sites that interact with other partners in its active state. Ala^{146} hydrogen-bonds to the guanine oxygen, allowing GTP, but not ATP, to bind.

The intrinsic GTPase activity of G proteins is increased up to 10^5-fold by GTPase activator proteins (GAPs), also called, in the case of heterotrimeric G proteins, regulators of G protein signaling (RGSs; Fig. 4). GAPs (and RGSs) thus determine how long the switch remains "on." They contribute a critical Arg residue that reaches into the G-protein GTPase active site and assists in catalysis. The intrinsically slow process of replacing bound GDP with GTP, switching the protein on, is catalyzed by guanosine nucleotide-exchange factors (GEFs) associated with the G protein (Fig. 4).

Because G proteins play crucial roles in so many signaling processes, it is not surprising that defects in G proteins lead to a variety of diseases. In about 25% of all human cancers (and in a much higher proportion of certain types of cancer), there is a mutation in a Ras protein—typically in one of the critical residues around the GTP-binding site or in the P loop—that virtually eliminates its GTPase activity. Once activated by GTP binding, this Ras protein remains constitutively active, promoting cell division in cells that should not divide. The tumor suppressor gene NF1 encodes a GAP that enhances the GTPase activity of normal Ras. Mutations in NF1 that result in a nonfunctioning GAP leave Ras with only its intrinsic GTPase activity; once activated by GTP binding, Ras stays active, continuing to send the signal: divide.

Defective heterotrimeric G proteins can also lead to disease. Mutations in the gene that encodes the α subunit of G_{s} (which mediates changes in [cAMP] in response to hormonal stimuli) may result in a G_{α} that is permanently active or permanently inactive. “Activating” mutations generally occur in residues crucial to GTPase activity; they lead to a continuously elevated [cAMP], with significant downstream consequences, including undesirable cell proliferation. For example, such mutations are found in about 40% of pituitary tumors (adenomas). Individuals with “inactivating” mutations in G_{α} are unresponsive to hormones (such as thyroid hormone) that act through cAMP. Mutation in the gene for the transducin α subunit (T_{α}), which is involved in visual signaling, leads to a type of night blindness, apparently due to defective interaction between the activated T_{α} subunit and the phosphodiesterase of the rod outer segment (see Fig. 12-38). A sequence variation in the gene encoding the β subunit of a heterotrimeric G protein is commonly found in individuals with hypertension (high blood pressure), and this variant gene is suspected of involvement in obesity and atherosclerosis.

The pathogenic bacteria that cause cholera and pertussis (whooping cough) produce toxins that target G proteins, interfering with normal signaling in host cells. Cholera toxin, secreted by *Vibrio cholerae* in the intestine of an infected person, is a heterodimeric protein. Subunit B recognizes and binds to specific gangliosides on the surface of intestinal epithelial cells and provides a route for subunit A to enter these cells. After entry, subunit A is broken into two pieces: the A1 fragment and adenyl cyclase is possible only when the “switch” regions of G_{αs} are exposed by a GTP-induced conformational change.

The stimulation by G_{αs} is self-limiting; G_{αs} is a GTPase that turns itself off by converting its bound GTP to GDP (Fig. 12–5). The now inactive G_{αs} dissociates
12.2 G Protein-Coupled Receptors and Second Messengers

Normal Gα: GTPase activity terminates the signal from receptor to adenylyl cyclase.

ADP-ribosylated Gα: GTPase activity is inactivated; Gα constantly activates adenylyl cyclase.

FIGURE 5 The bacterial toxins that cause cholera and whooping cough (pertussis) are enzymes that catalyze transfer of the ADP-ribose moiety of NAD⁺ to an Arg residue of Gα (in the case of cholera toxin, as shown here) or a Cys residue of Gβ (pertussis toxin). The G proteins thus modified fail to respond to normal hormonal stimuli. The pathology of both diseases results from defective regulation of adenylyl cyclase and overproduction of cAMP.

and the A2 fragment. A1 then associates with the ADP-ribosylation factor ARF6, a small G protein in host cells, through residues in its switch I and switch II regions—which are accessible only when ARF6 is in its active (GTP-bound) form. This association with ARF6 activates A1, which catalyzes the transfer of ADP-ribose from NAD⁺ to the critical Arg residue in the P loop of the α subunit of Gα (Fig. 5). ADP-ribosylation blocks the GTPase activity of Gα and thereby renders Gα permanently active. This results in continuous activation of the adenylyl cyclase of intestinal epithelial cells, chronically high [cAMP], and chronically active PKA. PKA phosphorylates the CFTR Cl⁻ channel (see Box 11–3) and a Na⁺-H⁺ exchanger in the intestinal epithelial cells. The resultant efflux of NaCl triggers massive water loss through the intestine as cells respond to the ensuing osmotic imbalance. Severe dehydration and electrolyte loss are the major pathologies in cholera. These can be fatal in the absence of prompt rehydration therapy.

The pertussis toxin, produced by Bordetella pertussis, catalyzes ADP-ribosylation of the α subunit of Gβ in this case preventing GDP-GTP exchange and blocking inhibition of adenylyl cyclase by Gα. The bacterium infects the respiratory tract, where it destroys the ciliated epithelial cells that normally sweep away mucus. Without this ciliary action, vigorous coughing is needed to clear the tract; this is the gasping cough that gives the disease its name (and spreads the bacterium to others). How the defect in G-protein signaling kills ciliated epithelial cells is not yet clear.

Given the large number of G protein–coupled receptors in the human genome, it seems likely that future studies will reveal many more examples of how defective G-protein signaling affects human health.

from adenylyl cyclase, rendering the cyclase inactive. Gαα reassociates with the βγ dimer (Gαβγ), and inactive Gα is again available to interact with a hormone-bound receptor. A variety of G proteins act as binary switches in signaling systems with GPCRs and in many processes that involve membrane fusion or fission (Box 12–2). Trimeric G Proteins: Molecular On/Off Switches

Epinephrine exerts its downstream effects through the increase in [cAMP] that results from the activation of adenylyl cyclase. Cyclic AMP, in turn, allosterically activates cAMP-dependent protein kinase, also called
protein kinase A or PKA (Fig. 12-4a, step 5), which catalyzes the phosphorylation of other proteins, including glycogen phosphorylase b kinase. This enzyme is active when phosphorylated and can begin the process of mobilizing glycogen stores in muscle and liver in anticipation of the need for energy.

The inactive form of PKA contains two identical catalytic subunits (C) and two identical regulatory subunits (R) (Fig. 12-6a). The tetrameric \( R_2C_2 \) complex is catalytically inactive, because an autoinhibitory domain of each R subunit occupies the substrate-binding cleft of each C subunit. When cAMP binds to the R subunits, they undergo a conformational change that moves the autoinhibitory domain of R out of the catalytic domain of C, and the \( R_2C_2 \) complex dissociates to yield two free, catalytically active C subunits. This same basic mechanism—displacement of an autoinhibitory domain—mediates the allosteric activation of many types of protein kinases by their second messengers (as in Figs 12-14 and 12-22, for example). The structure of the substrate-binding cleft in PKA is the prototype for all known protein kinases (Fig. 12-6b); certain residues in this cleft region have identical counterparts in all of the more than 1,000 known protein kinases.

As indicated in Figure 12-4a (step 5), PKA regulates several enzymes downstream in the signaling pathway (Table 12-2). Although these downstream targets...
have diverse functions, they share a region of sequence similarity around the Ser or Thr residue that undergoes phosphorylation, a sequence that marks them for regulation by PKA. The substrate-binding cleft of PKA recognizes these sequences and phosphorylates their Thr or Ser residue. Comparison of the sequences of various protein substrates for PKA has yielded the consensus sequence—the neighboring residues needed to mark a Ser or Thr residue for phosphorylation (see Table 12–2).

Signal transduction by adenylyl cyclase entails several steps that amplify the original hormone signal (Fig. 12–7). First, the binding of one hormone molecule to one receptor molecule catalytically activates several $G_{s}$ molecules. Next, by activating a molecule of adenylyl cyclase, each active $G_{s}$ molecule stimulates the catalytic synthesis of many molecules of cAMP. The second messenger cAMP now activates PKA, each molecule of which catalyzes the phosphorylation of many molecules of the target protein—phosphorylase $b$ kinase in Figure 12–7. This kinase activates glycogen phosphorylase $b$, which leads to the rapid mobilization of glucose from glycogen. The net effect of the cascade is amplification of the hormonal signal by several orders of magnitude, which

**FIGURE 12–7 Epinephrine cascade.** Epinephrine triggers a series of reactions in hepatocytes in which catalysts activate catalysts, resulting in great amplification of the signal. Binding of a small number of molecules of epinephrine to specific $\beta$-adrenergic receptors on the cell surface activates adenylyl cyclase. The numbers of molecules shown are simply to illustrate amplification and are probably gross underestimates. (Because two molecules of cAMP are required to activate one PKA catalytic subunit, this step does not amplify the signal.)
accounts for the very low concentration of epinephrine (or any other hormone) required for hormone activity.

Several Mechanisms Cause Termination of the β-Adrenergic Response

To be useful, a signal-transducing system has to turn off after the hormonal or other stimulus has ended, and mechanisms for shutting off the signal are intrinsic to all signaling systems. Most systems also adapt to the continued presence of the signal by becoming less sensitive to it, in the process of desensitization. The β-adrenergic system illustrates both. When the concentration of epinephrine in the blood drops below the $K_d$ for its receptor, the hormone dissociates from the receptor and the latter resumes the inactive conformation, in which it can no longer activate $G_o$.

A second means of ending the response to β-adrenergic stimulation is the hydrolysis of GTP bound to the $G_o$, subunit, catalyzed by the intrinsic GTPase activity of the G protein. Conversion of bound GTP to GDP favors the return of $G_o$ to the conformation in which it binds the $G_{βγ}$ subunits—the conformation in which the G protein is unable to interact with or stimulate adenylyl cyclase. This ends the production of cAMP. The rate of inactivation of $G_o$ depends on the GTPase activity, which for $G_o$ alone is very feeble. However, GTPase activator proteins (GAPs) strongly stimulate this GTPase activity, causing more rapid inactivation of the G protein (see Box 12–2). GAPs can themselves be regulated by other factors, providing a fine-tuning of the response to β-adrenergic stimulation. A third mechanism for terminating the response is to remove the second messenger: hydrolysis of cAMP to 5’-AMP (not active as a second messenger) by cyclic nucleotide phosphodiesterase (Fig. 12–4a, step 7; 12–4b).

Finally, at the end of the signaling pathway, the metabolic effects that result from enzyme phosphorylation are reversed by the action of phosphoprotein phosphatases, which hydrolyze phosphorylated Ser, Thr, or Tyr residues, releasing inorganic phosphate ($P_i$). About 150 genes in the human genome encode phosphoprotein phosphatases, fewer than the number encoding protein kinases (~500). Some of these phosphatases are known to be regulated; others may act constitutively. When [cAMP] drops and PKA returns to its inactive form (step 7 in Fig. 12–4a), the balance between phosphorylation and dephosphorylation is tipped toward dephosphorylation by these phosphatases.

The β-Adrenergic Receptor Is Desensitized by Phosphorylation and by Association with Arrestin

The mechanisms for signal termination described above take effect when the stimulus ends. A different mechanism, desensitization, damps the response even while the signal persists. Desensitization of the β-adrenergic receptor is mediated by a protein kinase that phosphorylates the receptor on the intracellular domain that normally interacts with $G_o$ (Fig. 12–8). When the receptor is

![Diagram of desensitization of the β-adrenergic receptor](image)

FIGURE 12–8 Desensitization of the β-adrenergic receptor in the continued presence of epinephrine. This process is mediated by two proteins: β-adrenergic protein kinase (βARK) and β-arrestin (βarr; also known as arrestin 2).
occupied by epinephrine, \textit{\beta}-adrenergic receptor kinase, or \textit{\beta}ARK (also commonly called GRK2; see below), phosphorylates several Ser residues near the carboxyl terminus of the receptor, which is on the cytoplasmic side of the plasma membrane. Normally located in the cytosol, \textit{\beta}ARK is drawn to the plasma membrane by its association with the G\textsubscript{\alpha\beta} subunits and is thus positioned to phosphorylate the receptor. Receptor phosphorylation creates a binding site for the protein \textit{\beta}-arrestin, or \textit{\beta}arr (also called arrestin 2), and binding of \textit{\beta}-arrestin effectively prevents further interaction between the receptor and the G protein. The binding of \textit{\beta}-arrestin also facilitates receptor sequestration, the removal of receptor molecules from the plasma membrane by endocytosis into small intracellular vesicles. Receptors in the endocytotic vesicles are eventually dephosphorylated and returned to the plasma membrane, completing the circuit and resensitizing the system to epinephrine. \textit{\beta}-Adrenergic receptor kinase is a member of a family of \textbf{G protein–coupled receptor kinases (GRKs)}, all of which phosphorylate GPCRs on their carboxyl-terminal cytoplasmic domains and play roles similar to that of \textit{\beta}ARK in desensitization and resensitization of their receptors. At least five different GRKs and four different arrestins are encoded in the human genome; each GRK is capable of desensitizing a particular subset of GPCRs, and each arrestin can interact with many different types of phosphorylated receptors.

\textbf{Cyclic AMP Acts as a Second Messenger for Many Regulatory Molecules}

Epinephrine is just one of many hormones, growth factors, and other regulatory molecules that act by changing the intracellular [cAMP] and thus the activity of PKA (Table 12–3). For example, glucagon binds to its receptors in the plasma membrane of adipocytes, activating (via a G\textsubscript{\alpha} protein) adenyl cyclase. PKA, stimulated by the resulting rise in [cAMP], phosphorylates and activates two proteins critical to the mobilization of the fatty acids of stored fats (see Fig. 17–3). Similarly, the peptide hormone ACTH (adrenocorticotropic hormone, also called corticotropin), produced by the anterior pituitary, binds to specific receptors in the adrenal cortex, activating adenyl cyclase and raising the intracellular [cAMP]. PKA then phosphorylates and activates several of the enzymes required for the synthesis of cortisol and other steroid hormones. In many cell types, the catalytic subunit of PKA can also move into the nucleus, where it phosphorylates the \textbf{cAMP response element binding protein (CREB)}, which alters the expression of specific genes regulated by cAMP.

Some hormones act by \textit{inhibiting} adenyl cyclase, thus lowering [cAMP] and \textit{suppressing} protein phosphorylation. For example, the binding of somatostatin to its receptor leads to activation of an \textbf{inhibitory G protein}, or G\textsubscript{i}, structurally homologous to G\textsubscript{s}, that inhibits adenyl cyclase and lowers [cAMP]. Somatostatin therefore counterbalances the effects of glucagon. In adipose tissue, prostaglandin E\textsubscript{1} (PGE\textsubscript{1}; see Fig. 10–18) inhibits adenyl cyclase, thus lowering [cAMP] and slowing the mobilization of lipid reserves triggered by epinephrine and glucagon. In certain other tissues PGE\textsubscript{1} stimulates cAMP synthesis: its receptors are coupled to adenyl cyclase through a stimulatory G protein, G\textsubscript{s}. In tissues with \textgalpha\textsubscript{2}-adrenergic receptors, epinephrine lowers [cAMP]; in this case, the receptors are coupled to adenyl cyclase through an inhibitory G protein, G\textsubscript{i}. In short, an extracellular signal such as epinephrine or PGE\textsubscript{1} can have quite different effects on different tissues or cell types, depending on three factors: the type of receptor in the tissue, the type of G protein (G\textsubscript{s} or G\textsubscript{i}) with which the receptor is coupled, and the set of PKA target enzymes in the cells. By summing the influences that tend to increase and decrease [cAMP], a cell achieves the integration of signals that we noted as a general feature of signal-transducing mechanisms (Fig. 12–1d).

A fourth factor that explains how so many types of signals can be mediated by a single second messenger (cAMP) is the confinement of the signaling process to a specific region of the cell by \textbf{adaptor proteins}—noncatalytic proteins that hold together other protein molecules that function in concert (further described below). \textbf{AKAPs (A kinase anchoring proteins)} are multivalent adaptor proteins; one part binds to the R subunits of PKA (see Fig. 12–6a) and another to a specific structure in the cell, confining the PKA to the vicinity of that structure. For example, specific AKAPs bind PKA to microtubules, actin filaments, ion channels, mitochondria, or the nucleus. Different types of cells

\textbf{Note:} Receptor subtypes in square brackets. Subtypes may have different transduction mechanisms. For example, serotonin is detected in some tissues by receptor subtypes 5-HT-1a and 5-HT-1d, which act through adenyl cyclase and cAMP, and in other tissues by receptor subtype 5-HT-1c, acting through the phospholipase C-IP\textsubscript{3} mechanism (see Table 12–4).
FIGURE 12–9 Nucleation of supramolecular complexes by A kinase anchoring proteins (AKAPs). Several types of AKAPs (green) act as multivalent scaffolds, holding PKA catalytic subunits (blue), through the AKAP's interaction with the PKA regulatory subunits (red), in proximity to a particular region or organelle in the cell. AKAP79, at the cytoplasmic surface of the plasma membrane, binds both PKA and adenyl cyclase (AC). The cAMP produced by AC reaches the nearby PKA quickly and with very little dilution. AKAP79 can also bind (not shown here) PKA, PKA's target protein (an ion channel), and phosphoprotein phosphatase, which removes phosphate from the target protein. AKAP250, also known as gravin, holds PKA to the plasma membrane while also binding cAMP phosphodiesterase (PDE), which terminates the PKA signal by converting cAMP to AMP. In both examples, the AKAP brings about a high local concentration of enzymes and second messengers so that the signaling circuit remains highly localized.

have different complements of AKAPs, so cAMP might stimulate phosphorylation of mitochondrial proteins in one cell and phosphorylation of actin filaments in another. In some cases, an AKAP connects PKA with the enzyme that triggers PKA activation (adenyl cyclase) or terminates PKA action (cAMP phosphodiesterase or phosphoprotein phosphatase) (Fig. 12–9). The very close proximity of these activating and inactivating enzymes presumably achieves a highly localized, and very brief, response. We will see later that some membrane-bound signaling proteins (including adenyl cyclase) are localized to specific areas of the membrane in rafts or caveolae (see Section 12.5).

As is now clear, to fully understand cellular signaling researchers need tools precise enough to detect and study the spatiotemporal aspects of signaling processes at the subcellular level and in real time. In studies of the intracellular localization of biochemical changes, biochemistry meets cell biology, and techniques that cross this boundary have become essential in understanding signaling pathways. Fluorescent probes have found wide application in signaling studies. Labeling of functional proteins with a fluorescent tag such as the green fluorescent protein (GFP) reveals their subcellular localizations (see Fig. 9–15a). Changes in the state of association of two proteins (such as the R and C subunits of PKA) can be seen by measuring the nonradiative transfer of energy between fluorescent probes attached to each protein, a technique called fluorescence resonance energy transfer (FRET; Box 12–3).

Diacylglycerol, Inositol Trisphosphate, and Ca$^{2+}$ Have Related Roles as Second Messengers

A second broad class of GPCRs are coupled through a G protein to a plasma membrane phospholipase C (PLC) that is specific for the membrane phospholipid phosphatidylinositol 4,5-bisphosphate, or PIP$_2$ (see Fig. 10–16). When one of the hormones that acts by this mechanism (Table 12–4) binds its specific receptor in the plasma membrane (Fig. 12–10, step 1), the receptor-hormone complex catalyzes GTP-GDP exchange on an associated G protein, $G_o$ (step 2), activating it much like the $\beta$-adrenergic receptor activates $G_o$ (Fig. 12–4). The activated $G_o$ in turn activates the PIP$_2$-specific PLC (Fig. 12–10, step 3), which catalyzes (step 4) the production of two potent second messengers, diacylglycerol and inositol 1,4,5-trisphosphate, or IP$_3$ (not to be confused with PIP$_3$, p. 441).

![Diagram of Inositol 1,4,5-trisphosphate (IP$_3$)](image)

| Auxin | Oxytocin | |

Note: Receptor subtypes are in square brackets; see footnote to Table 12-3.
Inositol trisphosphate, a water-soluble compound, diffuses from the plasma membrane to the endoplasmic reticulum (ER), where it binds to specific IP₃-gated Ca²⁺ channels, causing them to open. The action of the SERCA pump (see Fig. 11–36) ensures that [Ca²⁺] in the ER is orders of magnitude higher than that in the cytosol, so when these gated Ca²⁺ channels open, Ca²⁺ rushes into the cytosol (Fig. 12–10, step 5), and the cytosolic [Ca²⁺] rises sharply to about 10⁻⁶ M. One effect of elevated [Ca²⁺] is the activation of protein kinase C (PKC). Diacylglycerol cooperates with Ca²⁺ in activating PKC, thus also acting as a second messenger (step 6). Activation involves the movement of a PKC domain (the pseudosubstrate domain) away from its location in the substrate-binding region of the enzyme, allowing the enzyme to bind and phosphorylate proteins that contain a PKC consensus sequence—Ser or Thr residues embedded in an amino acid sequence recognized by PKC (step 7). There are several isozymes of PKC, each with a characteristic tissue distribution, target protein specificity, and role. Their targets include cytoskeletal proteins, enzymes, and nuclear proteins that regulate gene expression. Taken together, this family of enzymes has a wide range of cellular actions, affecting neuronal and immune function and the regulation of cell division, for example.
Fluorescent probes are commonly used to detect rapid biochemical changes in single living cells. They can be designed to give an essentially instantaneous report (within nanoseconds) on the changes in intracellular concentration of a second messenger or in the activity of a protein kinase. Furthermore, fluorescence microscopy has sufficient resolution to reveal where in the cell such changes are occurring. In one widely used procedure, the fluorescent probes are derived from a naturally occurring fluorescent protein, the **green fluorescent protein** (GFP) of the jellyfish *Aequorea victoria* (Fig. 1).

When excited by absorption of a photon of light, GFP emits a photon (that is, it fluoresces) in the green region of the spectrum. GFP is an 11-stranded β barrel, and the light-absorbing/emitting center of the protein (its chromophore) comprises a modified (oxidized) form of the tripeptide -Ser⁶⁵–Tyr⁶⁶–Gly⁶⁷– located within the barrel (Fig. 2). Oxidation of the tripeptide is catalyzed by the GFP protein itself (Fig. 3), with no other protein or cofactors required (other than molecular oxygen), so it is possible to clone the protein into virtually any cell, where it can serve as a fluorescent marker for itself or for any protein to which it is fused (see Fig. 9–15a). Variants of GFP, with different fluorescence spectra, are produced by genetic engineering of its gene. For example, in the yellow fluorescent protein (YFP), Ala²⁰⁰ in GFP is replaced by a Lys residue, changing the wavelength of light absorption and fluorescence. Other variants of GFP fluoresce blue (BFP) or cyan (CFP) light, and a related protein (mRFP1) fluoresces red light (Fig. 4). GFP and its variants are compact structures that retain their ability to fold into their native β-barrel conformation even when fused with another protein. Investigators are using these fluorescent hybrid proteins as spectroscopic rulers to measure distances between...
interacting components within a cell and, indirectly, to measure local concentrations of compounds that change the distance between two proteins.

An excited fluorescent molecule such as GFP or YFP can dispose of the energy from the absorbed photon in either of two ways: (1) by fluorescence, emitting a photon of slightly longer wavelength (lower energy) than the exciting light, or (2) by nonradiative fluorescence resonance energy transfer (FRET), in which the energy of the excited molecule (the donor) passes directly to a nearby molecule (the acceptor) without emission of a photon, exciting the acceptor (Fig. 5). The acceptor can now decay to its ground state by fluorescence; the emitted photon has a longer wavelength (lower energy) than both the original exciting light and the fluorescence emission of the donor. This second mode of decay (FRET) is possible only when donor and acceptor are close to each other (within 1 to 50 Å); the efficiency of FRET is inversely proportional to the sixth power of the distance between donor and acceptor. Thus very small changes in the distance between donor and acceptor register as very large changes in FRET, measured as the fluorescence of the acceptor molecule when the donor is excited. With sufficiently sensitive light detectors, this fluorescence signal can be located to specific regions of a single, living cell.

FRET has been used to measure [cAMP] in living cells. The gene for GFP is fused with that for the regulatory subunit (R) of cAMP-dependent protein kinase (PKA), and the gene for BFP is fused with that for the catalytic subunit (C) (Fig. 6). When these two hybrid proteins are expressed in a cell, BFP (donor; excitation at 380 nm, emission at 460 nm) and GFP (acceptor; excitation at 475 nm, emission at 545 nm) in the inactive

(continued on next page)
FRET: Biochemistry Visualized in a Living Cell (continued from previous page)

PKA (R₂C₂ tetramer) are close enough to undergo FRET. Wherever in the cell [cAMP] increases, the R₂C₂ complex dissociates into R₂ and C₂ and the FRET signal is lost, because donor and acceptor are now too far apart for efficient FRET. Viewed in the fluorescence microscope, the region of higher [cAMP] has a minimal GFP signal and higher BFP signal. Measuring the ratio of emission at 460 nm and 545 nm gives a sensitive measure of the change in [cAMP]. By determining this ratio for all regions of the cell, the investigator can generate a false color image of the cell in which the ratio, or relative [cAMP], is represented by the intensity of the color. Images recorded at timed intervals reveal changes in [cAMP] over time.

A variation of this technology has been used to measure the activity of PKA in a living cell (Fig. 7). Researchers create a phosphorylation target for PKA by producing a hybrid protein containing four elements: YFP (acceptor); a short peptide with a Ser residue surrounded by the consensus sequence for phosphorylation by PKA, and the 14-3-3 [P]-Ser-binding domain. Active PKA phosphorylates the Ser residue, which docks with the 14-3-3 binding domain, bringing the fluorescence proteins close enough to allow FRET to occur, revealing the presence of active PKA.

Active in the cell, it phosphorylates the Ser residue of the hybrid protein, and 14-3-3 binds to the [P]-Ser. In doing so, it draws YFP and CFP together and a FRET signal is detected with the fluorescence microscope, revealing the presence of active PKA.

The action of a group of compounds known as tumor promoters is attributable to their effects on PKC. The best understood of these are the phorbol esters, synthetic compounds that are potent activators of PKC. They apparently mimic cellular diacylglycerol as second messengers, but unlike the naturally occurring diacylglycerols they are not rapidly removed by metabolism. By continuously activating PKC, these synthetic tumor promoters interfere with the normal regulation of cell growth and division (as discussed in Section 12.12), thus promoting the formation of tumors.

Calcium Is a Second Messenger That May Be Localized in Space and Time

There are many variations on this basic scheme for Ca²⁺ signaling. In many cell types that respond to extracellular signals, Ca²⁺ serves as a second messenger that triggers intracellular responses, such as exocytosis in neurons and endocrine cells, contraction in muscle, and cytoskeletal rearrangements during amoeboid movement. In unstimulated cells, cytosolic [Ca²⁺] is kept very low (<10⁻⁷ M) by the action of Ca²⁺ pumps in the ER, mitochondria, and plasma membrane (as further discussed below). Hormonal, neural, or other stimuli cause either an influx of Ca²⁺ into the cell through specific Ca²⁺ channels in the plasma membrane or the release of sequestered Ca²⁺ from the ER or mitochondria, in either case raising the cytosolic [Ca²⁺] and triggering a cellular response.

Changes in intracellular [Ca²⁺] are detected by Ca²⁺-binding proteins that regulate a variety of Ca²⁺-dependent enzymes. Calmodulin (CaM; Mr 17,000) is an acidic protein with four high-affinity Ca²⁺-binding sites. When intracellular [Ca²⁺] rises to about 10⁻⁷ M (1 µM), the binding of Ca²⁺ to calmodulin drives a conformational change in the protein (Fig. 12-11a). Calmodulin associates with a variety of proteins and,
FIGURE 12-11 Calmodulin. This is the protein mediator of many Ca²⁺-stimulated enzymatic reactions. Calmodulin has four high-affinity Ca²⁺-binding sites (Kᵦ = 0.1 to 1 μM). (a) A ribbon model of the crystal structure of calmodulin (PDB ID 1CLL). The four Ca²⁺-binding sites are occupied by Ca²⁺ (purple). The amino-terminal domain is on the left; the carboxyl-terminal domain on the right. (b) Calmodulin associated with a helical domain (red) of one of the many enzymes it regulates, calmodulin-dependent protein kinase II (PDB ID 1CDL). Notice that the long central α helix of calmodulin visible in (a) has bent back on itself in binding to the helical substrate domain. The central helix of calmodulin is clearly more flexible in solution than in the crystal. (e) Each of the four Ca²⁺-binding sites occurs in a helix-loop-helix motif called the EF hand, also found in many other Ca²⁺-binding proteins.

Calmodulin is an integral subunit of the Ca²⁺/calmodulin-dependent protein kinases (CaM kinases, types I through IV). When intracellular [Ca²⁺] increases in response to a stimulus, calmodulin binds Ca²⁺, undergoes a change in conformation, and activates the CaM kinase. The kinase then phosphorylates target enzymes, regulating their activities. Calmodulin is also a regulatory subunit of phosphorylase b kinase of muscle, which is activated by Ca²⁺. Thus Ca²⁺ triggers ATP-requiring muscle contraction while also activating glycogen breakdown, providing fuel for ATP synthesis. Many other enzymes are also known to be modulated by Ca²⁺ through calmodulin (Table 12-5). The activity of the second messenger Ca²⁺, like that of cAMP, can be spatially restricted; after its release triggers a local response, Ca²⁺ is generally removed before it can diffuse to distant parts of the cell.

Very commonly, Ca²⁺ level does not simply rise and then decrease, but rather oscillates with a period of a few seconds (Fig. 12-12)—even when the extracellular concentration of the triggering hormone remains constant. The mechanism underlying [Ca²⁺] oscillations presumably entails feedback regulation by Ca²⁺ on some part of the Ca²⁺-release process. Whatever the mechanism, the effect is that one kind of signal (hormone concentration, for example) is converted into another (frequency and amplitude of intracellular [Ca²⁺] “spikes”). Another variation is the occurrence of localized Ca²⁺ “blips,” “puffs,” and “waves”—transient increases in [Ca²⁺] that are limited to specific subcellular regions (Fig. 12-13). The Ca²⁺ signal diminishes as Ca²⁺ diffuses away from the initial source (the Ca²⁺ channel), is sequestered in the ER, or is pumped out of the cell.

There is significant cross-talk between the Ca²⁺ and cAMP signaling systems. In some tissues, both the enzyme that produces cAMP (adenylyl cyclase) and the enzyme that degrades cAMP (phosphodiesterase) are stimulated by Ca²⁺. Temporal and spatial changes in [Ca²⁺] can therefore produce transient, localized changes in [cAMP]. We have noted already that PKA, the enzyme that responds to cAMP, is often part of a highly localized supramolecular complex assembled on scaffold proteins such as AKAPs. This subcellular localization of target enzymes, combined with temporal and spatial gradients in [Ca²⁺] and [cAMP], allow a cell to respond to one or several signals with subtly nuanced metabolic changes, localized in space and time.

FIGURE 12-12 Triggering of oscillations in intracellular $[\text{Ca}^{2+}]$ by extracellular signals. (a) A dye (fura) that undergoes fluorescence changes when it binds Ca$^{2+}$ is allowed to diffuse into cells, and its instantaneous light output is measured by fluorescence microscopy. Fluorescence intensity is represented by color; the color scale relates intensity of color to $[\text{Ca}^{2+}]$, allowing determination of the absolute $[\text{Ca}^{2+}]$. In this case, thymocytes (cells of the thymus) have been stimulated with extracellular ATP, which raises their internal $[\text{Ca}^{2+}]$. The cells are heterogeneous in their responses; some have high intracellular $[\text{Ca}^{2+}]$ (red), others much lower (blue). (b) When such a probe is used in a single hepatocyte, the agonist norepinephrine (added at the arrow) causes oscillations of $[\text{Ca}^{2+}]$ from 200 to 500 nM. Similar oscillations are induced in other cell types by other extracellular signals.

FIGURE 12-13 Transient and highly localized increases in $[\text{Ca}^{2+}]$. (a) The IP$_3$-gated Ca$^{2+}$ channels of the endoplasmic reticulum occur in clusters, each capable of independently responding to the IP$_3$ signal. A relatively weak stimulus that produces a small rise in [IP$_3$] may cause a single channel to open briefly, resulting in a highly localized and transient “blip” in $[\text{Ca}^{2+}]$. (b) A somewhat stronger stimulus that generates a larger increase in [IP$_3$] may cause all the Ca$^{2+}$ channels in a cluster to open, producing a “puff” of Ca$^{2+}$ in which the increase in $[\text{Ca}^{2+}]$, its duration, and the area (volume) affected are larger than in a blip. (c) A sufficiently large puff produces elevated $[\text{Ca}^{2+}]$ over an area great enough to include neighboring clusters of Ca$^{2+}$ channels. Opening of the channels in neighboring clusters propagates this effect, and the result is a wave of elevated $[\text{Ca}^{2+}]$ moving along the ER.
SUMMARY 12.2 G Protein–Coupled Receptors and Second Messengers

- G protein–coupled receptors (GPCRs) act through heterotrimeric G proteins. On ligand binding, GPCRs catalyze the exchange of GTP for GDP on the G protein, causing dissociation of the $G_o$ subunit; $G_o$ then stimulates or inhibits the activity of an effector enzyme, changing the level of its second-messenger product.

- The $\beta$-adrenergic receptor activates a stimulatory G protein, $G_o$, thereby activating adenyl cyclase and raising the concentration of the second messenger cAMP. Cyclic AMP stimulates cAMP-dependent protein kinase to phosphorylate key target enzymes, changing their activities.

- Enzyme cascades, in which a single molecule of hormone activates a catalyst to activate another catalyst, and so on, result in the large signal amplification that is characteristic of hormone receptor systems.

- Cyclic AMP concentration is eventually reduced by cAMP phosphodiesterase, and $G_o$ turns itself off by hydrolysis of its bound GTP to GDP, acting as a self-limiting binary switch.

- When the epinephrine signal persists, $\beta$-adrenergic receptor–specific protein kinase and $\beta$-arrestin temporarily desensitize the receptor and cause it to move into intracellular vesicles.

- Some receptors stimulate adenyl cyclase through $G_o$; others inhibit it through $G_i$. Thus cellular [cAMP] reflects the integrated input of two (or more) signals.

- Noncatalytic adaptor proteins such as AKAPs hold together proteins involved in a signaling process, increasing the efficiency of their interactions and in some cases confining the process to a specific subcellular location.

- Some GPCRs act via a plasma membrane phospholipase C that cleaves PIP2 to diacylglycerol and IP3. By opening Ca$^{2+}$ channels in the endoplasmic reticulum, IP3 raises cytosolic [Ca$^{2+}$]. Diacylglycerol and Ca$^{2+}$ act together to activate protein kinase C, which phosphorylates and changes the activity of specific cellular proteins. Cellular [Ca$^{2+}$] also regulates (often through calmodulin) many other enzymes and proteins involved in secretion, cytoskeleton rearrangements, or contraction.

12.3 Receptor Tyrosine Kinases

The receptor tyrosine kinases (RTKs), a large family of plasma membrane receptors with intrinsic protein kinase activity, transduce extracellular signals by a mechanism fundamentally different from that of GPCRs. RTKs have a ligand-binding domain on the extracellular face of the plasma membrane and an enzyme active site on the cytoplasmic face, connected by a single transmembrane segment. The cytoplasmic domain is a protein kinase that phosphorylates Tyr residues in specific target proteins—a Tyr kinase. The receptors for insulin and epidermal growth factor are prototypes for this group.

Stimulation of the Insulin Receptor Initiates a Cascade of Protein Phosphorylation Reactions

Insulin regulates both metabolic enzymes and gene expression. Insulin does not enter cells, but initiates a signal that travels a branched pathway from the plasma membrane receptor to insulin-sensitive enzymes in the cytosol and to the nucleus, where it stimulates the transcription of specific genes. The active insulin receptor protein (INS-R) consists of two identical $\alpha$ subunits protruding from the outer face of the plasma membrane and two transmembrane $\beta$ subunits with their carboxyl termini protruding into the cytosol (Fig. 12–14). The $\alpha$ subunits contain the insulin-binding domain, and the intracellular domains of the $\beta$ subunits contain the protein kinase activity that transfers a phosphoryl group from ATP to the hydroxyl group of Tyr residues in specific target proteins. Signaling through INS-R begins when the binding of insulin activates the Tyr kinase activity, and each $\beta$ subunit phosphorylates three critical Tyr residues near the carboxyl terminus of the other $\beta$ subunit in the $\alpha\beta_2$ dimer. This autophosphorylation opens up the active site so that the enzyme can phosphorylate Tyr residues of other target proteins. The mechanism of activation of the INS-R protein kinase is similar to that described for PKA and PKC: a region of the cytoplasmic domain (an autoinhibitory sequence) that normally occludes the active site moves out of the active site after being phosphorylated, opening up the site for the binding of target proteins (Fig. 12–14).

One of the target proteins of INS-R (Fig. 12–15, step ①) is insulin receptor substrate-1 (IRS-1; step ②). Once phosphorylated on several of its Tyr residues, IRS-1 becomes the point of nucleation for a complex of proteins (step ③) that carry the message from the insulin receptor to end targets in the cytosol and nucleus, through a long series of intermediate proteins. First, a $\Phi$–Tyr residue of IRS-1 binds to the SH2 domain of the protein Grb2. (SH2 is an abbreviation of Src homology 2, so named because the sequence of an SH2 domain is similar to that of a domain in Src [pronounced sark], another protein Tyr kinase.) Several signaling proteins contain SH2 domains, all of which bind $\Phi$–Tyr residues in a protein partner. Grb2 is an adaptor protein, with no intrinsic enzymatic activity. Its function is to bring together two proteins (in this case, IRS-1 and the protein Sos) that must interact to enable signal transduction. In addition to its SH2 (Φ–Tyr-binding) domain, Grb2 also contains a second protein-binding domain, SH3, that binds to a proline-rich region of Sos, recruiting Sos to the growing receptor complex. When bound to Grb2,
**FIGURE 12–14** Activation of the insulin-receptor tyrosine kinase by autophosphorylation. (a) The insulin-binding region of the insulin receptor lies outside the cell and comprises (b) two α subunits and the extracellular portions of two β subunits, intertwined to form the insulin binding site (pink; shown as a surface contour model of the crystal structure, derived from PDB ID 2DTC). (The structure of the transmembrane domain has not been solved by crystallography.) The binding of insulin (red; PDB ID 2CEU) is communicated through the single transmembrane helix of each β subunit to the paired Tyr kinase domains inside the cell, activating them to phosphorylate each other on three Tyr residues. (c) In the inactive form of the Tyr kinase domain (PDB ID 1IRK), the activation loop (blue) sits in the active site, and none of the critical Tyr residues (black and red ball-and-stick structures) are phosphorylated. This conformation is stabilized by hydrogen bonding between Tyr162 and Asp132. (d) Activation of the Tyr kinase allows each β subunit to phosphorylate three Tyr residues (Tyr158, Tyr162, Tyr163) on the other β subunit, shown here (PDB ID 1IR3). (Phosphoryl groups are depicted as an orange space-filling phosphorus atom and red ball-and-stick oxygen atoms.) The introduction of three highly charged @Tyr residues forces a 30 Å change in the position of the activation loop, away from the substrate-binding site, which becomes available to bind and phosphorylate a target protein, shown here as a red arrow.

Sos acts as a guanosine nucleotide-exchange factor (GEF), catalyzing the replacement of bound GDP with GTP on Ras, a G protein. Ras is the prototype of a family of small G proteins that mediate a wide variety of signal transductions (see Box 12–2). Like the trimeric G protein that functions with the β-adrenergic system (Fig. 12–5), Ras can exist in either the GTP-bound (active) or GDP-bound (inactive) conformation, but Ras (~20 kDa) acts as a monomer. When GTP binds, Ras can activate a protein kinase, Raf-1 (Fig. 12–15, step 4), the first of three protein kinases—Raf-1, MEK, and ERK—that form a cascade in which each kinase activates the next by phosphorylation (step 5). The protein kinases MEK and ERK are activated by phosphorylation of both a Thr and a Tyr residue. When activated, ERK mediates some of the biological effects of insulin by entering the nucleus and phosphorylating transcription factors, such as Elk1 (step 6), that modulate the transcription of about 100 insulin-regulated genes (step 7).

The proteins Raf-1, MEK, and ERK are members of three larger families, for which several nomenclatures are employed. ERK is in the MAPK family (mitogen-activated protein kinases; mitogens are extracellular signals that induce mitosis and cell division). Soon after discovery of the first MAPK enzyme, that enzyme was found to be activated by another protein kinase, which was named MAP kinase kinase (MEK belongs to this family); and when a third kinase that activated MAP kinase kinase was discovered, it was given the slightly ludicrous family name MAP kinase kinase kinase (Raf-1 is in this family; Fig. 12–15, step 4). Somewhat less cumbersome are the abbreviations for these three families: MAPK, MAPKK, and MAPKKK. Kinases in the MAPK and
Insulin receptor binds insulin and undergoes autophosphorylation on its carboxyl-terminal Tyr residues.

Insulin receptor phosphorylates IRS-1 on its Tyr residues.

SH2 domain of Grb2 binds to (P)-Tyr of IRS-1. Sos binds to Grb2, then to Ras, causing GDP release and GTP binding to Ras.

Activated Ras binds and activates Raf-1.

Raf-1 phosphorylates MEK on two Ser residues, activating it. MEK phosphorylates ERK on a Thr and a Tyr residue, activating it.

ERK moves into the nucleus and phosphorylates nuclear transcription factors such as Elk1, activating them.

Phosphorylated Elk1 joins SRF to stimulate the transcription and translation of a set of genes needed for cell division.

MAPK cascades (Fig. 12–15) mediate signaling initiated by a variety of growth factors, such as platelet-derived growth factor (PDGF) and epidermal growth factor (EGF). Another general scheme exemplified by the insulin receptor pathway is the use of nonenzymatic adaptor proteins to bring together the components of a branched signaling pathway, to which we now turn.

FIGURE 12–15 Regulation of gene expression by insulin through a MAP kinase cascade. The insulin receptor (INS-R) consists of two α subunits on the outer face of the plasma membrane and two β subunits that traverse the membrane and protrude from the cytosolic face. Binding of insulin to the α subunits triggers a conformational change that allows the autophosphorylation of Tyr residues in the carboxyl-terminal domain of the β subunits. Autophosphorylation further activates the Tyr kinase domain, which then catalyzes phosphorylation of other target proteins. The signaling pathway by which insulin regulates the expression of specific genes consists of a cascade of protein kinases, each of which activates the next. INS-R is a Tyr-specific kinase; the other kinases (all shown in blue) phosphorylate Ser or Thr residues. MEK is a dual-specificity kinase, which phosphorylates both a Thr and a Tyr residue in ERK (extracellular regulated kinase); MEK is mitogen-activated, ERK-activating kinase; SRF is serum response factor.

MAPKK families are specific for Ser or Thr residues, and MAPKKs (here, MEK) phosphorylate both a Ser and a Tyr residue in their substrate, a MAPK (here, ERK).

Biochemists now recognize the insulin pathway as but one instance of a more general scheme in which hormone signals, via pathways similar to that shown in Figure 12–15, result in phosphorylation of target enzymes by protein kinases. The target of phosphorylation is often another protein kinase, which then phosphorylates a third protein kinase, and so on. The result is a cascade of reactions that amplifies the initial signal by many orders of magnitude (see Fig. 12–1b). MAPK cascades (Fig. 12–15) mediate signaling initiated by a variety of growth factors, such as platelet-derived growth factor (PDGF) and epidermal growth factor (EGF). Another general scheme exemplified by the insulin receptor pathway is the use of nonenzymatic adaptor proteins to bring together the components of a branched signaling pathway, to which we now turn.

The Membrane Phospholipid PIP_3 Functions at a Branch in Insulin Signaling

The signaling pathway from insulin branches at IRS-1 (Fig. 12–15, step 3). Grb2 is not the only protein that associates with phosphorylated IRS-1. The enzyme phosphoinositide 3-kinase (PI-3K) binds IRS-1 through PI-3K’s SH2 domain (Fig. 12–16). Thus activated, PI-3K converts the membrane lipid phosphatidylinositol 4,5-bisphosphate (PIP_2; see Fig. 10–16) to phosphatidylinositol 3,4,5-trisphosphate (PIP_3). The multiply charged head group of PIP_3, protruding on the cytoplasmic side of the plasma membrane, is the starting point for a second signaling branch involving another cascade of protein kinases. When bound to PIP_3, protein kinase B (PKB; also called Akt) is phosphorylated and activated by yet another protein kinase, PDK1. The activated PKB then phosphorylates Ser or Thr residues in its target proteins, one of which is glycogen synthase kinase 3 (GSK3). In its active, nonphosphorylated form, GSK3 phosphorylates glycogen synthase, inactivating it and thereby contributing to the slowing of glycogen synthesis. (This mechanism is only part of the explanation for the effects of insulin on glycogen metabolism.) When phosphorylated by PKB, GSK3 is inactivated. By thus preventing inactivation of glycogen synthase in liver and muscle, the cascade of protein phosphorylations initiated by insulin stimulates glycogen synthesis (Fig. 12–16). In a third signaling branch in muscle and fat tissue, PKB triggers the movement of glucose transporters (GLUT4) from internal vesicles to the plasma...
FIGURE 12-16 Activation of glycogen synthase by insulin.
Transmission of the signal is mediated by PI-3 kinase (PI-3K) and protein kinase B (PKB).

1. IRS-1, phosphorylated by the insulin receptor, activates PI-3K by binding to its SH2 domain. PI-3K converts PIP2 to PIP3.
2. PKB bound to PIP3 is phosphorylated by PDK1 (not shown). Thus activated, PKB phosphorylates GSK3 on a Ser residue, inactivating it.
3. GSK3, inactivated by phosphorylation, cannot convert glycogen synthase (GS) to its inactive form by phosphorylation, so GS remains active.
4. Synthesis of glycogen from glucose is accelerated.
5. PKB stimulates movement of glucose transporter GLUT4 from internal membrane vesicles to the plasma membrane, increasing the uptake of glucose.

As in all signaling pathways, there is a mechanism for terminating the activity of the PI-3K–PKB pathway. A PIP3-specific phosphatase (PTEN in humans) removes the phosphoryl group at the 3 position of PIP3 to produce PIP2, which no longer serves as a binding site for PKB, and the signaling chain is broken. In various types of cancer, it is often found that the PTEN gene has undergone mutation, resulting in a defective regulatory circuit and abnormally high levels of PIP3 and of PKB activity. The result seems to be a continuing signal for cell division and thus tumor growth.

In addition to the many receptors that act as protein Tyr kinases (the RTKs), several receptorlike plasma membrane proteins have protein Tyr phosphatase activity. Based on the structures of these proteins, we can surmise that their ligands are components of the extracellular matrix or are surface molecules on other cells. Although their signaling roles are not yet as well understood as those of the RTKs, they clearly have the potential to reverse the actions of signals that stimulate RTKs.

The insulin receptor is the prototype for several receptor enzymes with a similar structure and RTK activity (Fig. 12–17). The receptors for EGF and PDGF, for example, have structural and sequence similarities to INS-R, and both have a protein Tyr kinase activity that phosphorylates IRS-1. Many of these receptors dimerize after binding ligand; INS-R is the exception, as it is already an (αβ)2 dimer before insulin binds. (The protomer of the insulin receptor is one αβ unit.) The binding of adaptor proteins such as Grb2 to P–Tyr residues...
Receptor tyrosine kinases. Growth factor receptors that signal through Tyr kinase activity include those for insulin (INS-R), vascular epidermal growth factor (VEGF-R), platelet-derived growth factor (PDGF-R), epidermal growth factor (EGF-R), nerve growth factor (NGF-R), and fibroblast growth factor (FGF-R). All these receptors have a Tyr kinase domain on the cytoplasmic side of the plasma membrane (blue). The extracellular domain is unique to each type of receptor, reflecting the different growth-factor specificities. These extracellular domains are typically combinations of structural motifs such as cysteine- or leucine-rich segments and segments containing one of several motifs common to immunoglobulins (lg-like domains; see p. 137). Many other receptors of this type are encoded in the human genome, each with a different extracellular domain.

The JAK-STAT Signaling System Also Involves Tyrosine Kinase Activity

A variation on the basic theme of receptor Tyr kinases is receptors that have no intrinsic protein kinase activity but, when occupied by their ligand, bind a cytosolic Tyr kinase. One example is the system that regulates the formation of erythrocytes in mammals. The developmental signal, or cytokine, for this system is erythropoietin (EPO), a 165 amino acid protein produced in the kidneys. When EPO binds to its plasma membrane receptor (Fig. 12–18) the receptor dimerizes, and the dimer can bind and activate the soluble protein kinase JAK (Janus kinase). The activated JAK phosphorylates several Tyr residues in the cytoplasmic domain of the EPO receptor. A family of transcription factors, collectively called STATs (signal transducers and activators of transcription), are also targets of JAK. An SH2 domain in STAT5 binds P-Tyr residues in the EPO receptor, positioning the STAT for phosphorylation by JAK in
response to EPO. The phosphorylated STAT5 forms dimers, exposing a signal that causes it to be transported into the nucleus. There, STAT5 induces the expression (transcription) of specific genes essential for erythrocyte maturation. This JAK-STAT system also operates in other signaling pathways, including that for the hormone leptin, described in detail in Chapter 23 (see Fig. 23–37). Activated JAK can also trigger, through Grb2, the MAPK cascade (Fig. 12–18b), which leads to altered expression of specific genes.

Src is another soluble protein Tyr kinase that associates with certain receptors when they bind their ligands. Src was the first protein found to have the characteristic P-Tyr-binding domain that was subsequently named the Src homology (SH2) domain.

Cross Talk among Signaling Systems
Is Common and Complex

Although, for simplicity, we have treated individual signaling pathways as separate sequences of events leading to separate metabolic consequences, there is in fact extensive cross talk among signaling systems. The regulatory circuitry that governs metabolism is richly interwoven and multilayered. We have discussed the signaling pathways for insulin and epinephrine separately, but they do not operate independently. Insulin opposes the metabolic effects of epinephrine in most tissues, and activation of the insulin signaling pathway directly attenuates signaling through the β-adrenergic signaling system. For example, the INS-R kinase directly phosphorylates two Tyr residues in the cytoplasmic tail of a β2-adrenergic receptor, and PKB, activated by insulin (Fig. 12–19), phosphorylates two Ser residues in the same region. Phosphorylation of these four residues triggers internalization of the β2-adrenergic receptor, taking it out of service and lowering the cell's sensitivity to epinephrine. A second type of cross talk between these receptors occurs when P-Tyr residues on the β2-adrenergic receptor, phosphorylated by INS-R, serve as nucleation points for SH2 domain–containing proteins such as Grb2 (Fig. 12–19, left side). Activation of the MAPK ERK by insulin (see Fig. 12–15) is 5- to 10-fold greater in the presence of the β2-adrenergic receptor, presumably because of this cross talk. Signaling systems that use cAMP and Ca2+ also show extensive interaction; each second messenger affects the generation and concentration of the other. One of the major challenges of systems biology is to sort out the effects of such interactions on the overall metabolic patterns in each tissue—a daunting task!

**SUMMARY 12.3 Receptor Tyrosine Kinases**

- The insulin receptor, INS-R, is the prototype of receptor enzymes with Tyr kinase activity. When insulin binds, each αβ unit of INS-R phosphorylates the β subunit of its partner, activating the receptor’s Tyr kinase activity. The kinase catalyzes the phosphorylation of Tyr residues on other proteins such as IRS-1.

- Phosphotyrosine residues in IRS-1 serve as binding sites for proteins with SH2 domains. Some of these proteins, such as Grb2, have two or more protein-binding domains and can serve as adaptors that bring two proteins into proximity.

- Sos bound to Grb2 catalyzes GDP-GTP exchange on Ras (a small G protein), which in turn activates a MAPK cascade that ends with the phosphorylation of IRS-1.
of target proteins in the cytosol and nucleus. The result is specific metabolic changes and altered gene expression.

- The enzyme PI-3K, activated by interaction with IRS-1, converts the membrane lipid PIP₂ to PIP₃, which becomes the point of nucleation for proteins in a second and third branch of insulin signaling.

- In the JAK-STAT signaling system, a soluble protein Tyr kinase (JAK) is activated by association with a receptor, and then phosphorylates the transcription factor STAT, which enters the nucleus and alters the expression of a set of genes.

- There are extensive interconnections among signaling pathways, allowing integration and fine-tuning of multiple hormonal effects.

12.4 Receptor Guanylyl Cyclases, cGMP, and Protein Kinase G

Guanylyl cyclases (Fig. 12-20) are receptor enzymes that, when activated, convert GTP to the second messenger **guanosine 3',5'-cyclic monophosphate** (cyclic GMP, cGMP):

![Guanylyl cyclase enzyme](image)

Many of the actions of cGMP in animals are mediated by **cGMP-dependent protein kinase** (PKG). On activation by cGMP, PKG phosphorylates Ser and Thr residues in target proteins.

**FIGURE 12-20** Two isozymes of guanylyl cyclase that participate in signal transduction. (a) One isozyme exists in two similar membrane-spanning forms that are activated by their extracellular ligands: atrial natriuretic factor (ANF; receptors in cells of the renal collecting ducts and vascular smooth muscle) and guanylin (receptors in intestinal epithelial cells). The guanylin receptor is also the target of a bacterial endotoxin that triggers severe diarrhea. (b) The other isozyme is a soluble heme-containing enzyme that is activated by intracellular nitric oxide (NO); this form is found in many tissues, including smooth muscle of the heart and blood vessels.

The catalytic and regulatory domains of this enzyme are in a single polypeptide ($M_r \sim 80,000$). Part of the regulatory domain fits snugly in the substrate-binding cleft. Binding of cGMP forces this pseudo-substrate out of the binding site, opening the site to target proteins containing the PKG consensus sequence.

Cyclic GMP carries different messages in different tissues. In the kidney and intestine it triggers changes in ion transport and water retention; in cardiac muscle (a type of smooth muscle) it signals relaxation; in the brain it may be involved both in development and in adult brain function. Guanylyl cyclase in the kidney is activated by the peptide hormone **atrial natriuretic factor** (ANF), which is released by cells in the cardiac atrium when the heart is stretched by increased blood volume. Carried in the blood to the kidney, ANF activates guanylyl cyclase in cells of the collecting ducts (Fig. 12-20a). The resulting rise in [cGMP] triggers increased renal excretion of Na⁺ and consequently of water, driven by the change in osmotic pressure. Water loss reduces the blood volume, countering the stimulus that initially led to ANF secretion. Vascular smooth muscle also has an ANF receptor–guanylyl cyclase; on binding to this receptor, ANF causes relaxation (vasodilation) of the blood vessels, which increases blood flow while decreasing blood pressure.
A similar receptor guanylyl cyclase in the plasma membrane of epithelial cells lining the intestine is activated by the peptide guanylin (Fig. 12–20a), which regulates Cl⁻ secretion in the intestine. This receptor is also the target of a heat-stable peptide endotoxin produced by *Escherichia coli* and other gram-negative bacteria. The elevation in [cGMP] caused by the endotoxin increases Cl⁻ secretion and consequently decreases reabsorption of water by the intestinal epithelium, producing diarrhea.

A distinctly different type of guanylyl cyclase is a cytosolic protein with a tightly associated heme group (Fig. 12–20b), an enzyme activated by nitric oxide (NO). Nitric oxide is produced from arginine by Ca²⁺-dependent NO synthase, present in many mammalian tissues, and diffuses from its cell of origin into nearby cells.

Cyclic GMP has another mode of action in the vertebrate eye: it causes ion-specific channels to open in the retinal rod and cone cells. We return to this role of cGMP in the discussion of vision in Section 12.10.

**SUMMARY 12.4 Receptor Guanylyl Cyclases, cGMP, and Protein Kinase G**

- Several signals, including atrial natriuretic factor and guanylin, act through receptor enzymes with guanylyl cyclase activity. The cGMP so produced is a second messenger that activates cGMP-dependent protein kinase (PKG). This enzyme alters metabolism by phosphorylating specific enzyme targets.

- Nitric oxide is a short-lived messenger that stimulates a soluble guanylyl cyclase, raising [cGMP] and stimulating PKG.

**12.5 Multivalent Adaptor Proteins and Membrane Rafts**

Two generalizations have emerged from studies of signaling systems such as those we have discussed so far: (1) protein kinases that phosphorylate Tyr, Ser, and Thr residues are central to signaling, and (2) reversible protein-protein interactions brought about by the reversible phosphorylation of Tyr, Ser, and Thr residues in signaling proteins create docking sites for other proteins. In fact, many signaling proteins are multivalent—they can interact with several different proteins simultaneously to form multiprotein signaling complexes. In this section we present a few examples to illustrate the general principles of phosphorylation-dependent protein interactions in signaling pathways.

**Protein Modules Bind Phosphorylated Tyr, Ser, or Thr Residues in Partner Proteins**

The protein Grb2 in the insulin signaling pathway (Figs 12–15 and 12–19) binds through its SH2 domain to other proteins that have exposed P-Tyr residues. The human genome encodes at least 87 SH2-containing proteins, many already known to participate in signaling. The
favors a certain sequence around the phosphorylated residue, so the domains represent families of highly specific recognition sites, able to bind to a specific subset of phosphorylated proteins.

In some cases, the region on a protein that binds \( \mathbb{P} \)-Tyr of a substrate protein is masked by its interaction with a \( \mathbb{P} \)-Tyr in the same protein. For example, the soluble protein Tyr kinase Src, when phosphorylated on a critical Tyr residue, is rendered inactive; an SH2 domain needed to bind to the substrate protein instead binds to the internal \( \mathbb{P} \)-Tyr. When this \( \mathbb{P} \)-Tyr residue is hydrolyzed by a phosphoprotein phosphatase, the Tyr kinase activity of Src is activated (Fig. 12-22a). Similarly, glycogen synthase kinase 3 (GSK3) is inactive when phosphorylated on a Ser residue in its autoinhibitory domain (Fig. 12-22b). Dephosphorylation of that domain frees the enzyme to bind (and then phosphorylate) its target proteins.

Phosphotyrosine-binding domains (PTB domains) are another binding partner for \( \mathbb{P} \)-Tyr proteins, but their critical sequences and three-dimensional structure distinguish them from SH2 domains. The human genome encodes 24 proteins that contain PTB domains, including IRS-1, which we have already encountered in its role as an adaptor protein in insulin-signal transduction (Fig. 12-15). The \( \mathbb{P} \)-Tyr binding sites for SH2 and PTB domains on partner proteins are created by Tyr kinases and eliminated by phosphoprotein phosphatases (PTPases).

Other signaling protein kinases, including PKA, PKC, PKG, and members of the MAPK cascade, phosphorylate Ser or Thr residues in their target proteins, which in some cases acquire the ability to interact with partner proteins through the phosphorylated residue, triggering a downstream process. An alphabet soup of domains that bind \( \mathbb{P} \)-Ser or \( \mathbb{P} \)-Thr residues has been identified, and more are sure to be found. Each domain

\[
\begin{align*}
\text{PTB domain} & \quad \text{SH2 domain} \\
\text{事关精确的识别位点} & \quad \text{SH2 domain} \\
\text{SH2 domain} & \quad \text{SH2 domain} \\
\text{SH2 domain} & \quad \text{SH2 domain} \\
\text{SH2 domain} & \quad \text{SH2 domain} \\
\end{align*}
\]
In addition to the three commonly phosphorylated residues in proteins, there is a fourth structure that nucleates the formation of supramolecular complexes of signaling proteins: the phosphorylated head group of the membrane phosphatidylinositols. Many signaling proteins contain domains such as SH3 and PH (plextrin homology domain) that bind tightly to PIP3 protruding from the inner leaflet of the plasma membrane. Whenever the enzyme PI-3K creates this head group (as it does in response to the insulin signal), proteins that bind it will congregate at the membrane surface.

Most of the proteins involved in signaling at the plasma membrane have one or more protein- or phospholipid-binding domains; many have three or more, and thus are multivalent in their interactions with other signaling proteins. Figure 12-23 shows just a few of the multivalent proteins known to participate in signaling. Many of the complexes include components with membrane-binding domains. Given the location of so many signaling processes at the inner surface of the plasma membrane, the molecules that must collide to produce the signaling response are effectively confined to two-dimensional space—the membrane surface; collisions here are far more likely than in the three-dimensional space of the cytosol.

In summary, a remarkable picture of signaling pathways has emerged from studies of many signaling proteins and their multiple binding domains. An initial signal results in phosphorylation of the receptor or a target protein, triggering the assembly of large multiprotein complexes, held together on scaffolds made from adaptor proteins with multivalent binding capacities. Some of these complexes contain several protein kinases that activate each other in turn, producing a cascade of phosphorylation and a great amplification of the initial signal. The interactions between cascade kinases are not left to the vagaries of random collisions in three-dimensional space. In the MAPK cascade, for example, a family of adaptor proteins binds all three kinases (MAPK, MAPKK, and MAPKKK), assuring their activities. The name of each protein is given at its carboxyl-terminal end. These signaling proteins interact with phosphorylated proteins or phospholipids in many permutations and combinations to form integrated signaling complexes.
proximity and correct orientation and even conferring allosteric properties on the interactions among the kinases, which makes their serial phosphorylation sensitive to very small stimuli.

Phosphotyrosine phosphatases remove the phosphate from \( \mathbf{P} \)-Tyr residues, reversing the effect of phosphorylation. Some of these are receptorlike membrane proteins, presumably controlled by extracellular factors not yet identified; other PTPases are soluble and contain SH2 domains. In addition, animal cells have protein \( \mathbf{P} \)-Ser and \( \mathbf{P} \)-Thr phosphatases, which reverse the effects of Ser- and Thr-specific protein kinases. We can see, then, that signaling occurs in protein circuits, which are effectively hard-wired from signal receptor to response effector and can be switched off instantly by the hydrolysis of a single upstream phosphate ester bond.

The multivalency of signaling proteins allows for the assembly of many different combinations of signaling modules, each combination suited to particular signals, cell types, and metabolic circumstances, yielding diverse signaling circuits of extraordinary complexity.

**Membrane Rafts and Caveolae Segregate Signaling Proteins**

Membrane rafts (Chapter 11) are regions of the membrane bilayer enriched in sphingolipids, sterols, and certain proteins, including many attached to the bilayer by GPI anchors. The \( \beta \)-adrenergic receptor is segregated in rafts that contain G proteins, adenyl cyclase, PKA, and a specific protein phosphatase, PP2, which together provide a highly integrated signaling unit. By segregating in a small region of the plasma membrane all of the elements required for responding to and ending the signal, the cell is able to produce a highly localized and brief “puff” of second messenger.

Some RTKs (EGF-R and PDGF-R) seem to be localized in rafts, and this sequestration is very probably functionally significant. When cholesterol is removed from rafts by treatment of the membrane with cydextrin (which binds and removes cholesterol), the rafts are disrupted and the RTK signaling pathways become defective.

If an RTK in a raft is phosphorylated, and the only locally available PTPase that reverses this phosphorylation is in another raft, then dephosphorylation of the RTK is slowed or prevented. Interactions between adaptor proteins might be strong enough to recruit into a raft a signaling protein not normally located there, or might even be strong enough to pull receptors out of a raft. For example, the EGF-R in isolated fibroblasts is normally concentrated in specialized rafts called caveolae (see Fig. 11–21), but treatment with EGF causes the receptor to leave the raft. This migration depends on the receptor’s protein kinase activity; mutant receptors lacking this activity remain in the raft during treatment with EGF. Caveolin, an integral membrane protein localized in caveolae, is phosphorylated on Tyr residues in response to insulin, and the now-activated EGF-R may be able to draw its binding partners into the raft. Spatial segregation of signaling proteins in rafts adds yet another dimension to the already complex processes initiated by extracellular signals.

**SUMMARY 12.5 Multivalent Adaptor Proteins and Membrane Rafts**

- Many signaling proteins have domains that bind phosphorylated Tyr, Ser, or Thr residues in other proteins; the binding specificity for each domain is determined by sequences that adjoin the phosphorylated residue in the substrate.
- SH2 and PTB domains bind to proteins containing \( \mathbf{P} \)-Tyr residues; other domains bind \( \mathbf{P} \)-Ser and \( \mathbf{P} \)-Thr residues in various contexts.
- SH3 and PH domains bind the membrane phospholipid PIP3.
- Many signaling proteins are multivalent, with several different binding modules. By combining the substrate specificities of various protein kinases with the specificities of domains that bind phosphorylated Ser, Thr, or Tyr residues, and with phosphatases that can rapidly inactivate a signaling pathway, cells create a large number of multiprotein signaling complexes.
- Membrane rafts and caveolae sequester groups of signaling proteins in small regions of the plasma membrane, enhancing their interactions and making signaling more efficient.

**12.6 Gated Ion Channels**

**Ion Channels Underlie Electrical Signaling in Excitable Cells**

Certain cells in multicellular organisms are “excitable”: they can detect an external signal, convert it into an electrical signal (specifically, a change in membrane potential), and pass it on. Excitable cells play central roles in nerve conduction, muscle contraction, hormone secretion, sensory processes, and learning and memory. The excitability of sensory cells, neurons, and myocytes depends on ion channels, signal transducers that provide a regulated path for the movement of inorganic ions such as Na\(^+\), K\(^+\), Ca\(^{2+}\), and Cl\(^-\) across the plasma membrane in response to various stimuli. Recall from Chapter 11 that these ion channels are “gated”: they may be open or closed, depending on whether the associated receptor has been activated by the binding of its specific
FIGURE 12-24 Transmembrane electrical potential. (a) The electrogenic Na⁺K⁺ ATPase produces a transmembrane electrical potential of about −60 mV (inside negative). (b) Blue arrows show the direction in which ions tend to move spontaneously across the plasma membrane in an animal cell, driven by the combination of chemical and electrical gradients. The chemical gradient drives Na⁺ and Ca²⁺ inward (producing depolarization) and K⁺ outward (producing hyperpolarization). The electrical gradient drives Cl⁻ outward, against its concentration gradient (producing depolarization).

ligand (a neurotransmitter, for example) or by a change in the transmembrane electrical potential, $V_m$. The Na⁺K⁺ ATPase is electrogenic; it creates a charge imbalance across the plasma membrane by carrying 3 Na⁺ out of the cell for every 2 K⁺ carried in (Fig. 12-24a), making the inside negative relative to the outside. The membrane is said to be polarized.

**KEY CONVENTION:** $V_m$ is negative when the inside of the cell is negative relative to the outside. For a typical animal cell, $V_m = −50$ to $−70$ mV.

Because ion channels generally allow passage of either anions or cations but not both, ion flux through a channel causes a redistribution of charge on the two sides of the membrane, changing $V_m$. Influx of a positively charged ion such as Na⁺, or efflux of a negatively charged ion such as Cl⁻, depolarizes the membrane and brings $V_m$ closer to zero. Conversely, efflux of K⁺ hyperpolarizes the membrane and $V_m$ becomes more negative. These ion fluxes through channels are passive, in contrast to active transport by the Na⁺K⁺ ATPase.

The direction of spontaneous ion flow across a polarized membrane is dictated by the electrochemical potential of that ion across the membrane, which has two components: the difference in concentration ($C$) of the ion on the two sides of the membrane, and the difference in electrical potential, typically expressed in millivolts. The force (Δ$G$) that causes a cation (say, Na⁺) to pass spontaneously inward through an ion channel is a function of the ratio of its concentrations on the two sides of the membrane ($C_{in}/C_{out}$) and of the difference in electrical potential ($V_m$ or Δ$V$):

$$\Delta G = RT \ln \left(\frac{C_{in}}{C_{out}}\right) + ZFV_m$$ (12-1)

where $R$ is the gas constant, $T$ the absolute temperature, $Z$ the charge on the ion, and $F$ the Faraday constant. (Note that the sign of the charge on the ion determines the sign of the second term in Eqn 12-1.) In a typical neuron or myocyte, the concentrations of Na⁺, K⁺, Ca²⁺, and Cl⁻ in the cytosol are very different from those in the extracellular fluid (Table 12-6). Given these concentration differences, the resting $V_m$ of about −60 mV, and the relationship shown in Equation 12-1, the opening of a Na⁺ or Ca²⁺ channel will result in a spontaneous inward flow of Na⁺ or Ca²⁺ (and depolarization), whereas opening of a K⁺ channel will result in a spontaneous outward flux of K⁺ (and hyperpolarization) (Fig. 12-24b).

A given ionic species continues to flow through a channel only as long as the combination of concentration gradient and electrical potential provides a driving force. For example, as Na⁺ flows down its concentration gradient, it depolarizes the membrane. When the membrane potential reaches +70 mV, the effect of this membrane potential (resistance to further entry of Na⁺) exactly equals the effect of the [Na⁺] gradient (promotion of Na⁺ flow inward). At this equilibrium potential ($E$), the driving force (Δ$G$) tending to move a Na⁺ ion is zero. The equilibrium potential is different for each ionic species because the concentration gradients differ.

The number of ions that must flow to produce a physiologically significant change in the membrane potential is negligible relative to the concentrations of Na⁺, K⁺, and Cl⁻ in cells and extracellular fluid, so the ion fluxes that occur during signaling in excitable cells have essentially no effect on the concentrations of these ions. With Ca²⁺, the situation is different; because the intracellular [Ca²⁺] is generally very low (∼10⁻⁷ M), inward flow of Ca²⁺ can significantly alter the cytosolic [Ca²⁺].

The membrane potential of a cell at a given time is the result of the types and numbers of ion channels open at that instant. In most cells at rest, more K⁺ channels than Na⁺, Cl⁻, or Ca²⁺ channels are open and thus the resting potential is closer to the $E$ for K⁺ (−98 mV) than that for any other ion. When channels for Na⁺, Ca²⁺, or Cl⁻ open, the membrane potential moves toward the $E$ for that ion. The precisely timed opening and closing of ion channels and the resulting transient changes in
membrane potential underlie the electrical signaling by which the nervous system stimulates the skeletal muscles to contract, the heart to beat, or secretory cells to release their contents. Moreover, many hormones exert their effects by altering the membrane potential of their target cells. These mechanisms are not limited to animals; ion channels play important roles in the responses of bacteria, protists, and plants to environmental signals.

To illustrate the action of ion channels in cell-to-cell signaling, we describe the mechanisms by which a neuron passes a signal along its length and across a synapse to the next neuron (or to a myocyte) in a cellular circuit, using acetylcholine as the neurotransmitter.

**Voltage-Gated Ion Channels Produce Neuronal Action Potentials**

Signaling in the nervous system is accomplished by networks of neurons, specialized cells that carry an electrical impulse (action potential) from one end of the cell (the cell body) through an elongated cytoplasmic extension (the axon). The electrical signal triggers release of neurotransmitter molecules at the synapse, carrying the signal to the next cell in the circuit. Three types of **voltage-gated ion channels** are essential to this signaling mechanism. Along the entire length of the axon are **voltage-gated Na⁺ channels** (Fig. 12-25), which are closed when the membrane is at rest ($V_m = -60$ mV) but open briefly when the membrane is depolarized locally in response to acetylcholine (or some other neurotransmitter). Also distributed along the axon are **voltage-gated K⁺ channels**, which open, a second later, in response to the depolarization when nearby Na⁺ channels open. The depolarizing flow of Na⁺ into the axon (influx) is thus rapidly countered by a repolarizing flow of K⁺ out (efflux). At the distal end of the axon are **voltage-gated Ca²⁺ channels**, which open when the wave of depolarization and repolarization caused by the activity of Na⁺ and K⁺ channels arrives, triggering release of the neurotransmitter acetylcholine—which carries the signal to another neuron (fire an action potential) or to a muscle fiber: (contract!).

### FIGURE 12-25 Role of voltage-gated and ligand-gated ion channels in neural transmission

Initially, the plasma membrane of the presynaptic neuron is polarized (inside negative) through the action of the electrogenic Na⁺K⁺ ATPase, which pumps out 3 Na⁺ for every 2 K⁺ pumped in (see Fig. 12-24). 1 A stimulus to this neuron (not shown) causes an action potential to move along the axon (white arrow), away from the cell body. The opening of a voltage-gated Na⁺ channel allows Na⁺ entry, and the resulting local depolarization causes the adjacent Na⁺ channel to open, and so on. The directionality of movement of the action potential is ensured by the brief refractory period that follows the opening of each voltage-gated Na⁺ channel. 2 When the wave of depolarization reaches the axon tip, voltage-gated Ca²⁺ channels open, allowing Ca²⁺ entry. 3 The resulting increase in internal [Ca²⁺] triggers exocytic release of the neurotransmitter acetylcholine into the synaptic cleft. 4 Acetylcholine binds to a receptor on the postsynaptic neuron (or myocyte), causing its ligand-gated ion channel to open. 5 Extracellular Na⁺ and Ca²⁺ enter through this channel, depolarizing the postsynaptic cell. The electrical signal has thus passed to the cell body of the postsynaptic neuron (or myocyte) and will move along its axon to a third neuron (or a myocyte) by this same sequence of events.

The voltage-gated $\text{Na}^+$ channels are very selective for $\text{Na}^+$ over other cations (by a factor of 100 or more) and have a very high flux rate ($>10^7$ ions/s). After being opened—activated—by a reduction in transmembrane electrical potential, a $\text{Na}^+$ channel undergoes very rapid inactivation—within milliseconds, the channel closes and remains inactive for many milliseconds. As voltage-gated $\text{K}^+$ channels open in response to the depolarization induced by the opening of $\text{Na}^+$ channels, the resulting efflux of $\text{K}^+$ repolarizes the membrane locally. A brief pulse of depolarization thus traverses the axon as local depolarization triggers the brief opening of neighboring $\text{Na}^+$ channels, then $\text{K}^+$ channels (Fig. 12–25). The short refractory period that follows the opening of each $\text{Na}^+$ channel, during which it cannot open again, ensures that a unidirectional wave of depolarization—the action potential—sweeps from the nerve cell body toward the end of the axon (step 1 in Fig. 12–25).

When the wave of depolarization reaches the voltage-gated $\text{Ca}^{2+}$ channels, they open (step 2), and $\text{Ca}^{2+}$ enters from the extracellular space. The rise in cytoplasmic [Ca$^{2+}$] then triggers release of acetylcholine by exocytosis into the synaptic cleft (step 3). Acetylcholine diffuses to the postsynaptic cell (another neuron or a myocyte), where it binds to acetylcholine receptors and triggers depolarization. Thus the message is passed to the next cell in the circuit. We see, then, that gated ion channels convey signals in either of two ways: by changing the cytoplasmic concentration of an ion (such as Ca$^{2+}$), which then serves as an intracellular second messenger, or by changing $V_m$ and affecting other membrane proteins that are sensitive to $V_m$. The passage of an electrical signal through one neuron and on to the next illustrates both types of mechanism.

We discussed the structure and mechanism of voltage-gated $\text{K}^+$ channels in some detail in Section 11.3 (see Figs 11–48 through 11–50). Here we take a closer look at $\text{Na}^+$ channels. The essential component of a $\text{Na}^+$ channel is a single, large polypeptide (1,840 amino acid residues) organized into four domains clustered around a central channel (Fig. 12–26a, b), providing a path for $\text{Na}^+$ through the membrane. The path is made $\text{Na}^+$-specific by a “pore region” composed of the segments between transmembrane helices 5 and 6 of each domain, which fold into the channel. Helix 4 of each domain has a high density of positively charged Arg residues; this segment is believed to be the voltage sensor (Fig. 12–26). The voltage-sensing mechanism involves movement of helix 4 (blue) perpendicular to the plane of the membrane in response to a change in transmembrane potential. As shown at the top, the strong positive charge on helix 4 allows it to be pulled inward in response to the inside-negative membrane potential ($V_m$). Depolarization lessens this pull, and helix 4 relaxes by moving outward (bottom). This movement is communicated to the activation gate (orange), inducing conformational changes that open the channel in response to depolarization.

![Voltage-gated Na⁺ channels of neurons.](image)
to move within the membrane in response to changes in the transmembrane voltage, from the resting potential of about −60 mV to about +30 mV. The movement of helix 4 triggers opening of the channel, and this is the basis for the voltage gating (Fig. 12-26c).

Inactivation of the channel is thought to occur by a ball-and-chain mechanism. A protein domain on the cytoplasmic surface of the Na⁺ channel, the inactivation gate (the ball), is tethered to the channel by a short segment of the polypeptide (the chain; Fig. 12-26b). This domain is free to move about when the channel is closed, but when it opens, a site on the inner face of the channel becomes available for the tethered ball to bind, blocking the channel. The length of the tether seems to determine how long an ion channel stays open: the longer the tether, the longer the open period. Other gated ion channels may be inactivated by a similar mechanism.

**The Acetylcholine Receptor Is a Ligand-Gated Ion Channel**

The nicotinic acetylcholine receptor mediates the passage of an electrical signal at some types of synapses and at a neuromuscular junction (between motor neuron and muscle fiber), signaling the muscle to contract. (Nicotinic acetylcholine receptors were originally distinguished from muscarinic acetylcholine receptors by the sensitivity of the former to nicotine, the latter to the mushroom alkaloid muscarine. They are structurally and functionally different.) Acetylcholine released by the presynaptic neuron or motor neuron diffuses a few micrometers to the plasma membrane of the postsynaptic neuron or myocyte, where it binds to the acetylcholine receptor. This forces a conformational change in the receptor, causing its ion channel to open. The resulting inward movement of cations depolarizes the plasma membrane. In a muscle fiber, this triggers contraction. The acetylcholine receptor allows ready passage to Na⁺, Ca²⁺, and K⁺ ions, but other cations and all anions are unable to pass. Movement of Na⁺ through an acetylcholine receptor ion channel is unsaturable (its rate is linear with respect to extracellular [Na⁺]) and very fast—about 2 × 10⁹ ions/s under physiological conditions.

![Acetylcholine](image)

Like other gated ion channels, the acetylcholine receptor opens in response to stimulation by its signal molecule and has an intrinsic timing mechanism that closes the gate milliseconds later. Thus the acetylcholine signal is transient—as we have seen, an essential feature of electrical signal conduction. We understand the structural changes underlying gating in the acetylcholine re-

ceptor, but not the exact mechanism of “desensitization,” in which the gate remains closed even in the continued presence of acetylcholine.

The nicotinic acetylcholine receptor has five subunits: single copies of subunits β, γ, and δ, and two identical α subunits that each contain an acetylcholine-binding site. All five subunits are related in sequence and tertiary structure, each having four transmembrane helical segments (M1 to M4) (Fig. 12-27a). The five subunits surround a central pore, which is lined with their M2 helices (Fig. 12-27b, c). The pore is about 20 Å wide in the parts of the channel that protrude on the cytoplasmic and extracellular surfaces, but narrows as it passes through the lipid bilayer. Near the center of the bilayer is a ring of bulky hydrophobic side chains of Leu residues in the M2 helices, positioned so close together that they prevent ions from passing through the channel (Fig. 12-27d). Allosteric conformational changes induced by acetylcholine binding to the two α subunits include a slight twisting of the M2 helices, which draws these hydrophobic side chains away from the center of the channel, opening it to the passage of ions.

**Neurons Have Receptor Channels That Respond to Different Neurotransmitters**

Animal cells, especially those of the nervous system, contain a variety of ion channels gated by ligands, voltage, or both. We have so far focused on acetylcholine as neurotransmitter, but there are many others. 5-Hydroxytryptamine (serotonin), glutamate, and glycine all can act through receptor channels that are structurally related to the acetylcholine receptor. Serotonin and glutamate trigger the opening of cation (K⁺, Na⁺, Ca²⁺) channels, whereas glycine opens Cl⁻-specific channels. Cation and anion channels are distinguished by subtle differences in the amino acid residues that line the hydrophilic channel. Cation channels have negatively charged Glu and Asp side chains at crucial positions. When a few of these acidic residues are experimentally replaced with basic residues, the cation channel is converted to an anion channel.

![Serotonin](image)

![Glutamate](image)

Depending on which ion passes through a channel, binding of the ligand (neurotransmitter) for that channel results in either depolarization or hyperpolarization of the target cell. A single neuron normally receives input from many other neurons, each releasing its own characteristic neurotransmitter with its characteristic depolarizing or hyperpolarizing effect. The target cell's
FIGURE 12-27 The acetylcholine receptor ion channel. (a) Each of the five homologous subunits (α2βγδ) has four transmembrane helices, M1 to M4. The M2 helices are amphipathic; the others have mainly hydrophobic residues. (b) The five subunits are arranged around a central transmembrane channel, which is lined with the polar sides of the M2 helices. At the top and bottom of the channel are rings of negatively charged amino acid residues. (c) A model of the acetylcholine receptor, based on electron microscopy and x-ray structure determination of a related protein (the acetylcholine-binding protein from a mollusk). (d) This top view of a cross section through the center of the M2 helices shows five Leu side chains (yellow), one from each M2 helix, protruding into the channel and constricting it to a diameter too small to allow passage of Ca2+, Na+, or K+. When both acetylcholine receptor sites (one on each α subunit) are occupied, a conformational change occurs. As the M2 helices twist slightly, the five Leu residues rotate away from the channel and are replaced by smaller, polar residues (blue). This gating mechanism opens the channel, allowing the passage of Ca2+, Na+, or K+.

\[ V_m \] therefore reflects the integrated input (Fig. 12-1d) from multiple neurons. The cell responds with an action potential only if the integrated input adds up to a net depolarization of sufficient size.

The receptor channels for acetylcholine, glycine, glutamate, and γ-aminobutyric acid (GABA) are gated by extracellular ligands. Intracellular second messengers—such as cAMP, cGMP, IP3, Ca2+, and ATP—regulate ion channels of another class, which, as we shall see in Section 12.10, participate in the sensory transductions of vision, olfaction, and gustation.

Toxins Target Ion Channels

Many of the most potent toxins found in nature act on ion channels. As we noted in Section 11.3, for example, dendrotoxin (from the black mamba snake) blocks the action of voltage-gated K+ channels, tetrodotoxin (produced by puffer fish) acts on voltage-gated Na+ channels, and cobrotoxin disables acetylcholine receptor ion channels. Why, in the course of evolution, have ion channels become the preferred target of toxins, rather than some critical metabolic target such as an enzyme essential in energy metabolism?

Ion channels are extraordinary amplifiers; opening of a single channel can allow the flow of 10 million ions per second. Consequently, relatively few molecules of an ion channel protein are needed per neuron for signaling functions. This means that a relatively small number of toxin molecules with high affinity for ion channels, acting from outside the cell, can have a very pronounced effect on neurosignaling throughout the body. A comparable effect by way of a metabolic enzyme, typically present in cells at much higher concentrations than ion channels, would require far more copies of the toxin molecule.
12.7 Integrins: Bidirectional Cell Adhesion Receptors

**Integrins** are proteins of the plasma membrane that mediate the adhesion of cells to each other and to the extracellular matrix, and carry signals in both directions across the membrane (Fig. 12-28). The mammalian genome encodes 18 different α subunits and 8 different β subunits, which are found in a range of combinations with various ligand-binding specificities in various tissues. Each of the 24 different integrins found thus far seems to have a unique function. Because they can inform cells about the extracellular neighborhood, integrins play crucial roles in processes that require selective cell-cell interactions, such as embryonic development, blood clotting, immune cell function, and tumor growth and metastasis.

The extracellular ligands that interact with integrins include collagen, fibrinogen, fibronectin, and many other proteins that have the sequence recognized by integrins: Arg-Gly-Asp (RGD). The short, cytoplasmic extensions of the α and β subunits interact with cytoskeletal proteins just beneath the plasma membrane—talin, α-actinin, vinculin, paxillin, and others—modulating the assembly of actin-based cytoskeletal structures. The dual association of integrins with the extracellular matrix and the cytoskeleton allows the cell to integrate information about its extracellular and intracellular environments, and to coordinate cytoskeletal positioning with extracellular adhesion sites. In this capacity, integrins govern the shape, motility, polarity, and differentiation of many cell types. In “outside-in” signaling, the extracellular domains of an integrin undergo dramatic, global conformational changes when ligand binds at a site many angstroms from the transmembrane helices. These changes somehow alter the dispositions of the cytoplasmic tails of the α and β subunits, changing their interactions with intracellular proteins and thereby conducting the signal inward.

The conformation and adheriveness of integrin extracellular domains are also dramatically altered by signals from inside the cell. In one conformation, the extracellular domains have no affinity for the proteins of the extracellular matrix, but signals from the cell can favor another conformation in which integrins adhere tightly to extracellular proteins (Fig. 12-28).
Regulation of adhesiveness is central to leukocyte homing to the site of an infection (see Fig. 7–31), interactions between immune cells, and phagocytosis by macrophages. During an immune response, for example, leukocyte integrins are activated (exposing their extracellular ligand-binding sites) from inside the cell via a signaling pathway triggered by cytokines (extracellular developmental signals). Thus activated, the integrins can mediate the attachment of leukocytes to other immune cells or can target cells for phagocytosis. Mutation in an integrin gene encoding the β subunit known as CD18 is the cause of leukocyte adhesion deficiency, a rare human genetic disease in which leukocytes fail to pass out of blood vessels to reach sites of infection. Infants with a severe defect in CD18 commonly die of infections before the age of two.

An integrin specific to platelets (αIbb3) is involved in both normal and pathological blood clotting. Local damage to blood vessels at a site of injury exposes high-affinity binding sites (RGD sequences in thrombin and collagen, for example) for the integrins of platelets, which attach themselves to the lesion, to other platelets, and to the clotting protein fibrinogen, leading to clot formation that prevents further bleeding. Mutations in the α or β subunit of platelet integrin αIbb3 lead to a bleeding disorder known as Glanzmann thrombasthenia, in which individuals bleed excessively after a relatively minor injury. Overly effective blood coagulation is also undesirable. Dysregulation of platelet adhesion can lead to pathological blood clot formation, resulting in blockage of the arteries that supply blood to the heart and brain and increasing the risk of heart attack and stroke. Drugs such as tirofiban and epifibatide that block the external ligand-binding sites of platelet integrin reduce clot formation and are useful in treating and preventing heart attacks and strokes.

When tumors metastasize, tumor cells lose their adhesion to the originating tissue and invade new locations. Both the changes in tumor cell adhesion and the development of new blood vessels (angiogenesis) to support the tumor at a new location are modulated by specific integrins. These proteins are therefore potential targets for drugs that suppress the migration and relocation of tumor cells.

**SUMMARY 12.7 Integrins: Bidirectional Cell Adhesion Receptors**

- Integrins are a family of dimeric (αβ) plasma membrane receptors that interact with extracellular macromolecules and the cytoskeleton, carrying signals in and out of the cell.
- The active and inactive forms of an integrin differ in the conformation of their extracellular domains. Intracellular events and signals can interconvert the active and inactive forms.
- Integrins mediate various aspects of the immune response, blood clotting, and angiogenesis, and they play a role in tumor metastasis.

**12.8 Regulation of Transcription by Steroid Hormones**

The steroid, retinoic acid (retinoid), and thyroid hormones form a large group of hormones (receptor ligands) that exert at least part of their effects by a mechanism fundamentally different from that of other hormones: they act in the nucleus to alter gene expression. We discuss their mode of action in detail in Chapter 28, along with other mechanisms for regulating gene expression. Here we give a brief overview.

Steroid hormones (estrogen, progesterone, and cortisol, for example), too hydrophobic to dissolve readily in the blood, are transported on specific carrier proteins from their point of release to their target tissues. In target cells, these hormones pass through the plasma membrane by simple diffusion and bind to specific receptor proteins in the nucleus (Fig. 12–29). Steroid hormone receptors with no bound ligand (aporereceptors) often act to suppress the transcription of target genes. Hormone binding triggers changes in the conformation of a receptor protein so that it becomes capable of interacting with specific regulatory sequences in DNA called **hormone response elements (HREs)**, thus altering gene expression (see Fig. 28–34). The bound receptor-hormone complex enhances the expression of specific genes adjacent to HREs, with the help of several other proteins essential for transcription. Hours or days are required for these regulators to have their full effect—the time required for the changes in RNA synthesis and subsequent protein synthesis to become evident in altered metabolism.

The specificity of the steroid-receptor interaction is exploited in the use of the drug **tamoxifen** to treat breast cancer. In some types of breast cancer, division of the cancerous cells depends on the continued presence of estrogen. Tamoxifen is an estrogen antagonist; it competes with estrogen for binding to the estrogen receptor, but the tamoxifen-receptor complex has little or no effect on gene expression. Consequently, tamoxifen administered after surgery or during chemotherapy for hormone-dependent breast cancer slows or stops the growth of remaining cancerous cells. Another steroid analog, the drug mifepristone (RU486), binds to the progesterone receptor and blocks hormone actions essential to implantation of the fertilized ovum in the uterus.
Hormone (H), carried to the target tissue on serum binding proteins, diffuses across the plasma membrane and binds to its specific receptor protein (Rec) in the nucleus.

Hormone binding changes the conformation of Rec; it forms homo- or heterodimers with other hormone-receptor complexes and binds to specific regulatory regions called hormone response elements (HREs) in the DNA adjacent to specific genes.

Receptor attracts coactivator or corepressor protein(s) and, with them, regulates transcription of the adjacent gene(s), increasing or decreasing the rate of mRNA formation.

Altered levels of the hormone-regulated gene product produce the cellular response to the hormone.

**FIGURE 12-29** General mechanism by which steroid and thyroid hormones, retinoids, and vitamin D regulate gene expression. The details of transcription and protein synthesis are discussed in Chapters 26 and 27. Some steroids also act through plasma membrane receptors by a completely different mechanism.

Certain effects of steroids seem to occur too fast to be the result of altered protein synthesis via the classic mechanism of steroid hormone action through nuclear receptors. For example, the estrogen-mediated dilation of blood vessels is known to be independent of gene transcription or protein synthesis, as is the steroid-induced decrease in cellular [cAMP]. Another transduction mechanism involving plasma membrane receptors may be responsible for some of these effects.

**SUMMARY 12.8 Regulation of Transcription by Steroid Hormones**

- Steroid hormones enter cells and bind to specific receptor proteins.
- The hormone-receptor complex binds specific regions of DNA, the hormone response elements, and interacts with other proteins to regulate the expression of nearby genes.
- Certain effects of steroid hormones may occur through a different, faster, signaling pathway.

**12.9 Signaling in Microorganisms and Plants**

Much of what we have said here about signaling relates to mammalian tissues or cultured cells from such tissues. Bacteria, archaea, eukaryotic microorganisms, and vascular plants must also respond to a variety of external signals—O₂, nutrients, light, noxious chemicals, and so on. We turn here to a brief consideration of the kinds of signaling machinery used by microorganisms and plants.

**Bacterial Signaling Entails Phosphorylation in a Two-Component System**

*Escherichia coli* responds to nutrients in its environment, including sugars and amino acids, by swimming toward them, propelled by one or a few flagella. A family of membrane proteins have binding domains on the outside of the plasma membrane to which specific attractants (sugars or amino acids) bind (Fig. 12–30). Ligand binding causes another domain on the inside of the plasma membrane to autophosphorylate a His residue. This first component of the two-component system, the receptor histidine kinase, then catalyzes transfer of the phosphoryl group from the His residue to an Asp residue on a second, soluble protein,
FIGURE 12-30 The two-component signaling mechanism in bacterial chemotaxis. When an attractant ligand (A) binds to the receptor domain of the membrane-bound receptor, a protein His kinase in the cytosolic domain (component 1) is activated and autophosphorylates a His residue. This phosphoryl group is then transferred to an Asp residue on component 2 (in some cases, as shown here, a separate protein; in others, another domain of the receptor protein). After phosphorylation, component 2 moves to the base of the flagellum, where it reverses the direction of rotation of the flagellar motor.

The response regulator; this phosphoprotein moves to the base of the flagellum, carrying the signal from the membrane receptor. The flagellum is driven by a rotary motor that can propel the cell through its medium or cause it to stall, depending on the direction of motor rotation. Information from the receptor allows the cell to determine whether it is moving toward or away from the source of the attractant. If its motion is toward the attractant, the response regulator signals the cell to continue in a straight line; if away from it, the cell tumbles momentarily, acquiring a new direction. Repetition of this behavior results in a random path, biased toward movement in the direction of increasing attractant concentration.

*E. coli* detects not only sugars and amino acids but also *O*₂, extremes of temperature, and other environmental factors, using this basic two-component system. Two-component systems have been detected in many other bacteria, both gram-positive and gram-negative, and in archaea, as well as in protists and fungi. Clearly, this signaling mechanism developed early in the course of cellular evolution and has been conserved.

Various signaling systems used by animal cells also have analogs in bacteria. As the full genomic sequences of more, and more diverse, bacteria become known, researchers have discovered genes that encode proteins similar to protein Ser or Thr kinases, Ras-like proteins regulated by GTP binding, and proteins with SH3 domains. Receptor Tyr kinases have not been detected in bacteria, but Tyr residues do occur in some bacterial proteins, so there must be an enzyme that phosphorylates Tyr residues.

**Signaling Systems of Plants Have Some of the Same Components Used by Microbes and Mammals**

Like animals, vascular plants must have a means of communication between tissues to coordinate and direct growth and development; to adapt to conditions of *O*₂, nutrients, light, temperature, and water availability; and to warn of the presence of noxious chemicals and damaging pathogens (Fig. 12–31). At least a billion years of evolution have passed since the plant and animal branches of the eukaryotes diverged, which is reflected in the differences in signaling mechanisms: some plant mechanisms are conserved—that is, are similar to those in animals (protein kinases, adaptor proteins, cyclic nucleotides, electrogenic ion pumps, and gated ion channels); some are similar to bacterial two-component systems; and some are unique to plants (light-sensing mechanisms, for example) (Table 12–7). The genome of the plant *Arabidopsis thaliana*, for example, encodes about 1,000 protein Ser/Thr kinases, including about 60 MAPKs and nearly 400 membrane-associated receptor kinases that phosphorylate Ser or Thr residues; a variety of protein phosphatases; adaptor proteins that form scaffolds on which proteins assemble in signaling complexes;
enzymes for the synthesis and degradation of cyclic nucleotides; and 100 or more ion channels, including about 20 gated by cyclic nucleotides. Inositol phospholipids are present, as are kinases that interconvert them by phosphorylation of inositol head groups.

However, some types of signaling proteins common in animal tissues are not present in plants, or are represented by only a few genes. Cyclic nucleotide–dependent protein kinases (PKA and PKG) seem to be absent, for example. Heterotrimeric G proteins and protein Tyr kinase genes are much less prominent in the plant genome, and genes for GPCRs, the largest family of proteins in the human genome (~1,000 genes), are very sparsely represented in the plant genome. DNA-binding nuclear steroid receptors are certainly not prominent, and may be absent from plants. Although plants lack the most widely conserved light-sensing mechanism present in animals (rhodopsin, with retinal as pigment), they have a rich collection of other light-detecting mechanisms not found in animal tissues—phytochromes and cryptochromes, for example (Chapter 19).

The kinds of compounds that elicit signals in plants are similar to certain signaling molecules in mammals (Fig. 12–32). Instead of prostaglandins, plants have jasmonate; instead of steroid hormones, brassinosteroids. About 100 different small peptides serve as plant signals, and both plants and animals use compounds derived from aromatic amino acids as signals.

![Fig 12-32](image-url) Structural similarities between plant and animal signals.
Plants Detect Ethylene through a Two-Component System and a MAPK Cascade

The gaseous plant hormone ethylene ($CH_2=CH_2$), which stimulates the ripening of fruits (among other functions), acts through receptors that are related in primary sequence to the receptor His kinases of the bacterial two-component systems and probably evolved from them. In *Arabidopsis*, the two-component signaling system is contained within a single integral membrane protein of the endoplasmic reticulum (not the plasma membrane). Ethylene diffuses into the cell through the plasma membrane and into the ER. The first downstream component affected by ethylene signaling is a protein Ser/Thr kinase (CTR1; Fig. 12–33) with sequence homology to Raf, the protein kinase that begins the MAPK cascade in the mammalian response to insulin (see Fig. 12–15). In plants, in the absence of ethylene, the CTR1 kinase is active and inhibits the MAPK cascade, preventing transcription of ethylene-responsive genes. Exposure to ethylene inactivates the CTR1 kinase, thereby activating the MAPK cascade that leads to activation of the transcription factor EIN3. Active EIN3 stimulates the synthesis of a second transcription factor (ERF1), which in turn activates transcription of ethylene-responsive genes; the gene products affect processes ranging from seedling development to fruit ripening. Although apparently derived from the bacterial two-component signaling system, the ethylene system in *Arabidopsis* is different in that the His kinase activity that defines component 1 in bacteria is not essential to signal transduction in *Arabidopsis*.

Receptorlike Protein Kinases Transduce Signals from Peptides and brassinosteroids

One common motif in plant signaling involves receptorlike kinases (RLKs), which have a single helical segment in the plasma membrane that connects a receptor domain on the outside with a protein Ser/Thr kinase on the cytoplasmic side. This type of receptor participates in the defense mechanism triggered by infection with a bacterial pathogen (Fig. 12–34a). The signal to turn on the genes needed for defense against infection is a peptide (flg22) released by breakdown of flagellin, the major protein of the bacterial flagellum. Binding of flg22 to the FLS2 receptor of *Arabidopsis* induces receptor dimerization and autophosphorylation on Ser and Thr residues, and the downstream effect is activation of a MAPK cascade like that described above for insulin action (Fig. 12–15). The final kinase in this cascade activates a specific transcription factor, triggering synthesis of the proteins that defend against the bacterial infection. The steps between receptor phosphorylation and the MAPK cascade are not yet known. A phosphoprotein phosphatase (KAPP) associates with the active receptor protein and inactivates it by dephosphorylation to end the response.

The MAPK cascade in the plant’s defense against bacterial pathogens is remarkably similar to the innate immune response in mammals (Fig. 12–34b) that is triggered by bacterial lipopolysaccharide and mediated by the Toll-like receptors (TLRs, a name derived from a *Drosophila* mutant originally called Toll (German, “mad”); TLRs were subsequently found in many other organisms and were shown to function in embryonic development). Other membrane receptors use similar mechanisms to activate a MAPK cascade, ultimately activating transcription factors and turning on the genes essential to the defense response.

Most of the several hundred RLKs in plants are presumed to act in similar ways: ligand binding induces dimerization and autophosphorylation, and the activated receptor kinase triggers downstream responses by phosphorylating key proteins at Ser or Thr residues.
FIGURE 12-34 Similarities between the signaling pathways that trigger immune responses in plants and animals. (a) In Arabidopsis thaliana, the peptide flg22, derived from the flagella of a bacterial pathogen, binds to its receptor (FLS) in the plasma membrane, causing the receptor to form dimers and triggering autophosphorylation of the cytosolic protein kinase domain on a Ser or Thr residue (not a Tyr). Thus activated, the protein kinase phosphorylates downstream proteins (not shown). The activated receptor also activates (by means unknown) a MAPK cascade, which leads to phosphorylation of a nuclear protein that normally inhibits the transcription factors WRKY22 and 29; this phosphorylation triggers proteolytic degradation of the inhibitor and frees the transcription factors to stimulate gene expression related to the immune response. (b) In mammals, a toxic bacterial lipopolysaccharide (LPS; see Fig. 7-30) is detected by plasma membrane receptors, which then associate with and activate a soluble protein kinase (IRAK). The major flagellar protein of pathogenic bacteria acts through a similar receptor, also activating IRAK. The activated IRAK initiates two distinct MAPK cascades that end in the nucleus, causing the synthesis of proteins needed in the immune response. Jun, Fos, and NFκB are transcription factors.

SUMMARY 12.9 Signaling in Microorganisms and Plants

- Bacteria and eukaryotic microorganisms have a variety of sensory systems that allow them to sample and respond to their environment. In the two-component system, a receptor His kinase senses the signal and autophosphorylates a His residue, then phosphorylates an Asp residue of the response regulator.
- Plants respond to many environmental stimuli and employ hormones and growth factors to coordinate the development and metabolic activities of their tissues. Plant genomes encode hundreds of signaling proteins, including some very similar to those of mammals.
- Two-component signaling mechanisms common in bacteria are found in modified forms in plants, used in the detection of chemical signals and light.

- Plant receptorlike kinases (RLKs) participate in detecting a wide variety of stimuli, including brassinosteroids, peptides that originate from pathogens, and developmental signals. RLKs autophosphorylate Ser/Thr residues, then activate downstream proteins, which in some cases are MAPK cascades. The end result is increased transcription of specific genes.

12.10 Sensory Transduction in Vision, Olfaction, and Gustation

The detection of light, odors, and tastes (vision, olfaction, and gustation, respectively) in animals is accomplished by specialized sensory neurons that use signal-transduction mechanisms fundamentally similar to those that detect hormones, neurotransmitters, and growth factors. An initial sensory signal is amplified greatly by mechanisms that include gated ion channels and intracellular second
messengers; the system adapts to continued stimulation by changing its sensitivity to the stimulus (desensitization); and sensory input from several receptors is integrated before the final signal goes to the brain.

The Visual System Uses Classic GPCR Mechanisms

In the vertebrate eye, light entering through the pupil is focused on a highly organized collection of light-sensitive neurons (Fig. 12–35). The light-sensing cells are of two types: rods (about $10^9$ per retina), which sense low levels of light but cannot discriminate colors, and cones (about $3 \times 10^9$ per retina), which are less sensitive to light but can discriminate colors. Both cell types are long, narrow, specialized sensory neurons with two distinct cellular compartments: the outer segment contains dozens of membranous disks loaded with receptor proteins and their photosensitive chromophore retinal; the inner segment contains the nucleus and many mitochondria, which produce the ATP essential to phototransduction.

Like other neurons, rods and cones have a transmembrane electrical potential ($V_m$), produced by the electrogenic pumping of the Na\(^+\)K\(^+\) ATPase in the plasma membrane of the inner segment (Fig. 12–36).

**FIGURE 12–35 Light reception in the vertebrate eye.** The lens focuses light on the retina, which is composed of layers of neurons. The primary photosensory neurons are rod cells (yellow), which are responsible for high-resolution and night vision, and cone cells of three subtypes (pink), which initiate color vision. The rods and cones form synapses with several ranks of interconnecting neurons that convey and integrate the electrical signals. The signals eventually pass from ganglion neurons through the optic nerve to the brain.

**FIGURE 12–36 Light-induced hyperpolarization of rod cells.** The rod cell consists of an outer segment, filled with stacks of membranous disks (not shown) containing the photoreceptor rhodopsin, and an inner segment that contains the nucleus and other organelles (not shown). The inner segment synapses with interconnecting neurons (see Fig. 12–35). Cones have a similar structure. ATP in the inner segment powers the Na\(^+\)K\(^+\) ATPase, which creates a transmembrane electrical potential by pumping 3 Na\(^+\) out for every 2 K\(^+\) pumped in. The membrane potential is reduced by the inflow of Na\(^+\) and Ca\(^{2+}\) through cGMP-gated cation channels in the outer-segment plasma membrane. When rhodopsin absorbs light, it triggers degradation of cGMP (green dots) in the outer segment, causing closure of the ion channel. Without cation influx through this channel, the cell becomes hyperpolarized. This electrical signal is passed to the brain through the ranks of neurons shown in Figure 12–35.
Also contributing to the membrane potential is an ion channel in the outer segment that permits passage of either Na⁺ or Ca²⁺ and is gated (opened) by cGMP. In the dark, rod cells contain enough cGMP to keep this channel open. The membrane potential is therefore determined by the difference between the amount of Na⁺ and K⁺ pumped by the inner segment (which polarizes the membrane) and the influx of Na⁺ through the ion channels of the outer segment (which tends to depolarize the membrane).

The essence of signaling in the rod or cone cell is a light-induced decrease in [cGMP], which causes the cGMP-gated ion channel to close. The plasma membrane then becomes hyperpolarized by the Na⁺-K⁺ ATPase. Rod and cone cells synapse with interconnecting neurons (Fig. 12-35) that carry information about the electrical activity to ganglion neurons near the inner surface of the retina. The ganglion neurons integrate the output from many rod or cone cells and send the resulting signal through the optic nerve to the visual cortex of the brain.

Visual transduction begins when light falls on rhodopsin, many thousands of molecules of which are present in each disk of the outer segments of rod and cone cells. Rhodopsin (Mr 40,000) is an integral protein with seven membrane-spanning α helices (Fig. 12-37), the characteristic GPCR architecture. The light-absorbing pigment (chromophore) 11-cis-retinal is covalently attached to opsin, the protein component of rhodopsin, through a Schiff base to a Lys residue. The retinal molecule lies near the middle of the bilayer (Fig. 12-37), oriented with its long axis approximately in the plane of the membrane. When a photon is absorbed by the retinal component of rhodopsin, the energy causes a photochemical change; 11-cis-retinal is converted to all-trans-retinal (see Figs 1-18b and 10-21). This change in the structure of the chromophore forces conformational changes in the rhodopsin molecule—the first stage in visual transduction.

Retinal is derived from vitamin A₁ (retinol), which is produced from β-carotene (see Fig. 10-21). Dietary deficiency of vitamin A leads to night blindness (the inability to adapt to low light levels), which is relatively common in some developing countries. Vitamin A supplements or vegetables rich in carotene (such as carrots) supply the vitamin and reverse the night blindness.

Excited Rhodopsin Acts through the G Protein Transducin to Reduce the cGMP Concentration

In its excited conformation, rhodopsin interacts with a second protein, transducin, which hovers nearby on the cytoplasmic face of the disk membrane (Fig. 12-37). Transducin (T) belongs to the same family of heterotrimeric GTP-binding proteins as Gₛ and G₁. Although specialized for visual transduction, transducin shares many functional features with Gₛ and G₁. It can bind either GDP or GTP. In the dark, GDP is bound, all three subunits of the protein (Tα, Tβ, and Tγ) remain together, and no signal is sent. When rhodopsin is excited by light, it interacts with transducin, catalyzing the replacement of bound GDP by GTP from the cytosol (Fig. 12-38, steps 1 and 2). Transducin then dissociates into Tα and Tβγ, and the Tα-GTP carries the signal from the excited receptor to the next element in the transduction pathway, a cGMP phosphodiesterase; this enzyme converts cGMP to 5'-GMP (steps 3 and 4). Note that this is not the same cyclic nucleotide phosphodiesterase that hydrolyzes cAMP to terminate the β-adrenergic response. One isoform of the cGMP-specific PDE is unique to the visual cells of the retina.
Light absorption converts 11-cis-retinal to all-trans-retinal, activating rhodopsin (Rh).

Activated rhodopsin catalyzes replacement of GDP by GTP on transducin (T), which then dissociates into Tγ-GTP and Tβγ.

Tγ-GTP activates cGMP phosphodiesterase (PDE) by binding and removing its inhibitory subunit (I).

Active PDE reduces [cGMP] to below the level needed to keep cation channels open.

Activated cGMP phosphodiesterase (PDE) degrades the cGMP-gated ion channels.

Rhodopsin kinase (RK) phosphorylates "bleached" rhodopsin; low [Ca2+] and recoverin (Recover) stimulate this reaction. Arrestin (Arr) binds phosphorylated carboxyl terminus, inactivating rhodopsin.

Slowly, arrestin dissociates, rhodopsin is dephosphorylated, and all-trans-retinal is replaced with 11-cis-retinal. Rhodopsin is ready for another phototransduction cycle.

Cation channels close, preventing influx of Na+ and Ca2+; membrane is hyperpolarized. This signal passes to the brain.

Continued efflux of Ca2+ through the Na+-Ca2+ exchanger reduces cytosolic [Ca2+]i.

The top half of the figure (steps 1 to 5) describes excitation; the bottom (steps 6 to 9), recovery and adaptation after illumination.

The PDE of the retina is an integral protein with its active site on the cytoplasmic side of the disk membrane. In the dark, a tightly bound inhibitory subunit very effectively suppresses the PDE activity. When Tγ-GTP encounters the PDE, the inhibitory subunit leaves the enzyme and instead binds Tα, and the enzyme’s activity immediately increases by several orders of magnitude. Each molecule of the active PDE degrades many molecules of cGMP to the biologically inactive 5′-GMP, lowering [cGMP] in the outer segment within a fraction of a second. At the new, lower [cGMP], the cGMP-gated ion channels close, blocking reentry of Na+ and Ca2+ into the outer segment and hyperpolarizing the membrane of the rod or cone cell (step 5). Through this process, the initial stimulus—a photon—changes the Vm of the cell.

Several steps in the visual-transduction process result in a huge amplification of the signal. Each excited rhodopsin molecule activates at least 500 molecules of transducin, each of which can activate a molecule of the PDE. This phosphodiesterase has a remarkably high turnover number, each activated molecule hydrolyzing 4,200 molecules of cGMP per second. The binding of cGMP to cGMP-gated ion channels is cooperative, and a relatively small change in [cGMP] therefore registers as a large change in ion conductance. The result of these amplifications is exquisite sensitivity to light. Absorption of a single photon closes 1,000 or more ion channels and changes the cell’s membrane potential by about 1 mV.

The Visual Signal Is Quickly Terminated

As your eyes move across this line, the retinal images of the first words disappear rapidly—before you see the next series of words. In that short interval, a great deal of biochemistry has taken place. Very shortly after illumination of the rod or cone cells stops, the photosensory system shuts off. The α subunit of transducin (with bound GTP) has intrinsic GTPase activity. Within
millions of nanoseconds after the decrease in light intensity, GTP is hydrolyzed and \( T_\alpha \) reassociates with \( T_\beta \). The inhibitory subunit of the PDE, which had been bound to \( T_\alpha \)-GTP, is released and reassociates with the enzyme, strongly inhibiting its activity. To return \([\text{cGMP}]\) to its "dark" level, the enzyme guanylyl cyclase converts GTP to cGMP (step 7 in Fig. 12-38) in a reaction that is inhibited by high \([\text{Ca}^{2+}]\) (>100 nM). Calcium levels drop during illumination, because the steady-state \([\text{Ca}^{2+}]\) in the outer segment is the result of outward pumping of \( \text{Ca}^{2+} \) through the \( \text{Na}^+-\text{Ca}^{2+} \) exchanger of the plasma membrane (see Fig. 12-36) and influx of \( \text{Ca}^{2+} \) through open cGMP-gated channels. In the dark, this produces a \([\text{Ca}^{2+}]\) of about 500 nM—enough to inhibit cGMP synthesis. After brief illumination, \( \text{Ca}^{2+} \) entry slows and \([\text{Ca}^{2+}]\) declines (step 6). The inhibition of guanylyl cyclase by \( \text{Ca}^{2+} \) is relieved, and the cyclase converts GTP to cGMP to return the system to its prestimulus state (step 7).

Rhodopsin itself also undergoes changes in response to prolonged illumination. The conformational change induced by light absorption exposes several Thr and Ser residues in the carboxyl-terminal domain. These residues are quickly phosphorylated by rhodopsin kinase (step 8 in Fig. 12-38), which is functionally and structurally homologous to the \( \beta \)-adrenergic kinase (\( \beta \)-ARK) that desensitizes the \( \beta \)-adrenergic receptor (Fig. 12-8). The \( \text{Ca}^{2+} \)-binding protein recoverin inhibits rhodopsin kinase at high \([\text{Ca}^{2+}]\), but the inhibition is relieved when \([\text{Ca}^{2+}]\) drops after illumination, as described above. The phosphorylated carboxyl-terminal domain of rhodopsin is bound by the protein arrestin 1, preventing further interaction between activated rhodopsin and transducin. Arrestin 1 is a close homolog of arrestin 2 (\( \beta \)-AR; Fig. 12-8). On a relatively long time scale (seconds to minutes), the all-trans-retinal of an excited rhodopsin molecule is removed and replaced by 11-cis-retinal, to produce rhodopsin that is ready for another round of excitation (step 9 in Fig. 12-38).

**Cone Cells Specialize in Color Vision**

Color vision involves a path of sensory transduction in cone cells essentially identical to that described above, but triggered by slightly different light receptors. Three types of cone cells are specialized to detect light from different regions of the spectrum, using three related photoreceptor proteins (opsins). Each cone cell expresses only one kind of opsin, but each type is closely related to rhodopsin in size, amino acid sequence, and presumably three-dimensional structure. The differences among the opsins, however, are great enough to place the chromophore, 11-cis-retinal, in three slightly different environments, with the result that the three photoreceptors have different absorption spectra (Fig. 12-39). We discriminate colors and hues by integrating the output from the three types of cone cells, each containing one of the three photoreceptors.

**Vertebrate Olfaction and Gustation Use Mechanisms Similar to the Visual System**

The sensory cells that detect odors and tastes have much in common with the rod and cone cells. Olfactory neurons have long thin cilia extending from one end of the cell into a mucous layer that overlays the cell. These cilia present a large surface area for interaction with olfactory signals. The receptors for olfactory stimuli are ciliary membrane proteins with the familiar GPCR structure of seven transmembrane \( \alpha \) helices. The olfactory signal can be any one of the many volatile compounds for which there are specific receptor proteins. Our ability to discriminate odors stems from hundreds of different olfactory receptors in the tongue and nasal passages and from the brain's ability to integrate input from...
The chemist John Dalton (of atomic theory fame) was color-blind. He thought it probable that the vitreous humor of his eyes (the fluid that fills the eyeball behind the lens) was tinted blue, unlike the colorless fluid of normal eyes. He proposed that after his death, his eyes should be dissected and the color of the vitreous humor determined. His wish was honored. The day after Dalton’s death in July 1844, Joseph Ransome dissected his eyes and found the vitreous humor to be perfectly colorless. Ransome, like many scientists, was reluctant to throw samples away. He placed Dalton’s eyes in a jar of preservative, where they stayed for a century and a half.

Then, in the mid-1990s, molecular biologists in England took small samples of Dalton’s retinas and extracted DNA. Using the known gene sequences for the opsins of the red and green light receptors, they amplified the relevant sequences (using techniques described in Chapter 9) and determined that Dalton had the opsin gene for the red photopigment but lacked the opsin gene for the green photopigment. Dalton was a green dichromat. So, 150 years after his death, the experiment Dalton started—by hypothesizing about the cause of his color blindness—was finally finished.

**FIGURE 1** Dalton’s eyes.

**FIGURE 12-40** Molecular events of olfaction. These interactions occur in the cilia of olfactory receptor cells.
The activated Go11 then activates adenylyl cyclase of the ciliary membrane, which synthesizes cAMP from ATP, raising the local [cAMP]. The cAMP-gated Na⁺ and Ca²⁺ channels of the ciliary membrane open, and the influx of Na⁺ and Ca²⁺ produces a small depolarization called the receptor potential. If a sufficient number of odorant molecules encounter receptors, the receptor potential is strong enough to cause the neuron to fire an action potential. This is relayed to the brain in several stages and registers as a specific smell. All these events occur within 100 to 200 ms.

When the olfactory stimulus is no longer present, the transducing machinery shuts itself off in several ways. A cAMP phosphodiesterase returns [cAMP] to the prestimulus level. Go6 hydrolyzes its bound GTP to GDP, thereby inactivating itself. Phosphorylation of the receptor by a specific kinase prevents its interaction with Go11, by a mechanism analogous to that used to desensitize the β-adrenergic receptor and rhodopsin. And lastly, some odorants are enzymatically destroyed by oxidases.

The sense of taste in vertebrates reflects the activity of gustatory neurons clustered in taste buds on the surface of the tongue. In these sensory neurons, GPCRs are coupled to the heterotrimeric G protein gustducin (very similar to the transducin of rod and cone cells). Sweet-tasting molecules are those that bind receptors in “sweet” taste buds. When the molecule (tastant) binds, gustducin is activated by replacement of bound GDP with GTP and then stimulates cAMP production by adenylyl cyclase. The resulting elevation of [cAMP] activates PKA, which phosphorylates K⁺ channels in the plasma membrane, causing them to close. Reduced efflux of K⁺ depolarizes the cell (Fig. 12-41). Other taste buds specialize in detecting bitter, sour, salty, or umami (savory) tastants, using various combinations of second messengers and ion channels in the transduction mechanisms.

**GPCRs of the Sensory Systems Share Several Features with GPCRs of Hormone Signaling Systems**

We have now looked at several types of signaling systems (hormone signaling, vision, olfaction, and gustation) in which membrane receptors are coupled to second messenger-generating enzymes through G proteins. As we have intimated, signaling mechanisms must have arisen early in evolution; genomic studies have revealed hundreds of genes encoding GPCRs in vertebrates, arthropods (Drosophila and mosquito), and the roundworm Caenorhabditis elegans. Even the common baker’s yeast Saccharomyces uses GPCRs and G proteins to detect the opposite mating type. Overall patterns have been conserved, and the introduction of variety has given modern organisms the ability to respond to a wide range of stimuli (Table 12-8). Of the approximately 30,000 genes in the human genome, as many as 1,000 encode GPCRs, including hundreds for olfactory stimuli and many “orphan receptors” for which the natural ligand is not yet known.

All well-studied transducing systems that act through heterotrimeric G proteins share some common features, which reflect their evolutionary relatedness (Fig. 12-42). The receptors have seven transmembrane segments, a domain (generally the loop between transmembrane helices 6 and 7) that interacts with a G protein, and a carboxyl-terminal cytoplasmic domain that undergoes reversible phosphorylation on several Ser or Thr residues.

The ligand-binding site (or, in the case of light reception, the light receptor) is buried deep in the membrane and includes residues from several of the transmembrane segments. Ligand binding (or light) induces a conformational change in the receptor, exposing a domain that can interact with a G protein. Heterotrimeric G proteins activate or inhibit effector enzymes (adenylyl cyclase, PDE, or PLC), which change the concentration of a second messenger (cAMP, cGMP, IP3, or Ca2+). In the hormone-detecting systems, the final output is an activated protein kinase that regulates some cellular process by phosphorylating a protein critical to that process. In sensory neurons, the output is a change in membrane potential and a consequent electrical signal that passes to another neuron in the pathway connecting the sensory cell to the brain.

All these systems self-inactivate. Bound GTP is converted to GDP by the intrinsic GTPase activity of G proteins, often augmented by GTPase-activating proteins (GAPs) or RGS proteins (regulators of G-protein signaling; see Fig. 12–5). In some cases, the effectors that are the targets of modulation by G proteins also serve as GAPs. The desensitization mechanism involving phosphorylation of the carboxyl-terminal region followed by arrestin binding is widespread, and may be universal.

![FIGURE 12-42 Common features of signaling systems that detect hormones, light, smells, and tastes.](image)

GPCRs provide signal specificity, and their interaction with G proteins provides signal amplification. Heterotrimeric G proteins activate effector enzymes: adenylyl cyclase (AC), phospholipase C (PLC), and phosphodiesterases (PDEs) that degrade cAMP or cGMP. Changes in concentration of the second messengers (cAMP, cGMP, IP3) result in alterations of enzymatic activities by phosphorylation or alterations in the permeability (p) of surface membranes to Ca2+, Na+, and K+. The resulting depolarization or hyperpolarization of the sensory cell (the signal) passes through relay neurons to sensory centers in the brain. In the best-studied cases, desensitization includes phosphorylation of the receptor and binding of a protein (arrestin) that interrupts receptor–G protein interactions. VR is the vasopressin receptor; β-AR is the β-adrenergic receptor. Other receptor and G-protein abbreviations are as used in earlier illustrations.
SUMMARY 12.10 Sensory Transduction in Vision, Olfaction, and Gustation

- Vision, olfaction, and gustation in vertebrates employ GPCRs, which act through heterotrimeric G proteins to change the $V_m$ of a sensory neuron.
- In rod and cone cells of the retina, light activates rhodopsin, which activates the G protein transducin. The freed $\alpha$ subunit of transducin activates a cGMP phosphodiesterase, which lowers [cGMP] and thus closes cGMP-dependent ion channels in the outer segment of the neuron. The resulting hyperpolarization of the rod or cone cell carries the signal to the next neuron in the pathway, and eventually to the brain.
- In olfactory neurons, olfactory stimuli, acting through GPCRs and G proteins, trigger either an increase in [cAMP] (by activating adenylyl cyclase) or an increase in [Ca$^{2+}$] (by activating PLC). These second messengers affect ion channels and thus the $V_m$.
- Gustatory neurons have GPCRs that respond to tastants by altering levels of cAMP, which changes $V_m$ by gating ion channels.
- There is a high degree of conservation of signaling proteins and transduction mechanisms across signaling systems and across species.

12.11 Regulation of the Cell Cycle by Protein Kinases

One of the most dramatic manifestations of signaling pathways is the regulation of the eukaryotic cell cycle. During embryonic growth and later development, cell division occurs in virtually every tissue. In the adult organism most tissues become quiescent. A cell's "decision" to divide or not is of crucial importance to the organism. When the regulatory mechanisms that limit cell division are defective and cells undergo unregulated division, the result is catastrophic—cancer. Proper cell division requires a precisely ordered sequence of biochemical events that assures every daughter cell a full complement of the molecules required for life. Investigations into the control of cell division in diverse eukaryotic cells have revealed universal regulatory mechanisms. Signaling mechanisms much like those discussed above are central in determining whether and when a cell undergoes cell division, and they also ensure orderly passage through the stages of the cell cycle.

The Cell Cycle Has Four Stages

Cell division accompanying mitosis in eukaryotes occurs in four well-defined stages (Fig. 12–43). In the S (synthesis) phase, the DNA is replicated to produce copies for both daughter cells. In the G2 phase (G indicates the gap between divisions), new proteins are synthesized and the cell approximately doubles in size. In the M phase (mitosis), the maternal nuclear envelope breaks down, paired chromosomes are pulled to opposite poles of the cell, each set of daughter chromosomes is surrounded by a newly formed nuclear envelope, and cytokinesis pinches the cell in half, producing two daughter cells (see Fig. 24–25). In embryonic or rapidly proliferating tissue, each daughter cell divides again, but only after a waiting period (G1). In cultured animal cells the entire process takes about 24 hours.

After passing through mitosis and into G1, a cell either continues through another division or ceases to divide, entering a quiescent phase (G0) that may last hours, days, or the lifetime of the cell. When a cell in G0 begins to divide again, it reenters the division cycle through the G1 phase. Differentiated cells such as hepatocytes or adipocytes have acquired their specialized function and form; they remain in the G0 phase. Stem cells retain their potential to divide and to differentiate into any of a number of cell types.

Levels of Cyclin-Dependent Protein Kinases Oscillate

The timing of the cell cycle is controlled by a family of protein kinases with activities that change in response to cellular signals. By phosphorylating specific proteins at precisely timed intervals, these protein kinases orchestrate the metabolic activities of the cell to produce orderly cell division. The kinases are heterodimers with a regulatory subunit, cyclin, and a catalytic subunit, cyclin-dependent protein kinase (CDK). In the absence of
cyclin, the catalytic subunit is virtually inactive. When cyclin binds, the catalytic site opens up, a residue essential to catalysis becomes accessible (Fig. 12–44), and the activity of the catalytic subunit increases 10,000-fold. Animal cells have at least 10 different cyclins (designated A, B, and so forth) and at least 8 CDKs (CDK1 through CDK8), which act in various combinations at specific points in the cell cycle. Plants also use a family of CDKs to regulate their cell division in root and shoot meristems, the principal tissues in which division occurs.

In a population of animal cells undergoing synchronous division, some CDK activities show striking oscillations (Fig. 12–45). These oscillations are the result of four mechanisms for regulating CDK activity: phosphorylation or dephosphorylation of the CDK, controlled degradation of the cyclin subunit, periodic synthesis of CDKs and cyclins, and the action of specific CDK-inhibiting proteins. In general, active CDKs enable a cell to enter a stage of cell division.

**Regulation of CDKs by Phosphorylation** The activity of a CDK is strikingly affected by phosphorylation and dephosphorylation of two critical residues in the protein (Fig. 12–46a). Phosphorylation of Tyr\(^{16}\) near the amino terminus renders CDK2 inactive; the \(\text{P}^-\text{Y}^-\text{Y}^-\text{r}\) residue is in the ATP-binding site of the kinase, and the negatively charged phosphate group blocks the entry of ATP. A specific phosphatase (a PTPase) dephosphorylates this \(\text{P}^-\text{Y}^-\text{Y}^-\text{r}\) residue, permitting the binding of ATP. Phosphorylation of Thr\(^{16}\) in the “T loop” of CDK, catalyzed by the CDK-activating kinase, forces the T loop out of the substrate-binding cleft, permitting substrate binding and catalytic activity (see Fig. 12–44c).
12.11 Regulation of the Cell Cycle by Protein Kinases

Cyclin synthesis leads to its accumulation.

No cyclin present; CDK is inactive.

Cyclin-CDK complex forms, but phosphorylation on Tyr^{15} blocks ATP-binding site; still inactive.

Phosphorylation of Thr^{160} in T loop and removal of Tyr^{15} phosphoryl group activates cyclin-CDK manyfold.

CDK phosphorylates phosphatase, which activates more CDK.

CDK phosphorylates DBRP, activating it.

DBRP triggers addition of ubiquitin molecules to cyclin by ubiquitin ligase.

Cyclin is degraded by proteasome, leaving CDK inactive.

CDK activates more CDK.

Phosphorylation of Thr^{160} in T loop activates cyclin-CDK manyfold.

Controlled Degradation of Cyclin

Highly specific and precisely timed proteolytic breakdown of mitotic cyclins regulates CDK activity throughout the cell cycle. Progress through mitosis requires first the activation of the catalytic subunit of the M-phase CDK. These cyclins contain near their amino terminus the sequence -Arg-Thr-Ala-Leu-Gly-Asp-Ile-Gly-Asn-, the “destruction box,” which targets them for degradation. This usage of “box” derives from the common practice, in diagramming the sequence of a nucleic acid or protein, of enclosing within a box a short sequence of nucleotide or amino acid residues with some specific function. It does not imply any three-dimensional structure.) The protein DBRP (destruction box recognizing protein) recognizes this sequence and initiates the process of cyclin degradation by bringing together the cyclin and another protein, ubiquitin. Cyclin and activated ubiquitin are covalently joined by the enzyme ubiquitin ligase (Fig. 12-46b). Several more ubiquitin molecules are then appended, providing the signal for a proteolytic enzyme complex, or proteasome, to degrade cyclin.

What controls the timing of cyclin breakdown? A feedback loop occurs in the overall process shown in Figure 12-46. Increased CDK activity activates cyclin proteolysis. Newly synthesized cyclin associates with and activates CDK, which phosphorylates and activates DBRP. Active DBRP then causes proteolysis of cyclin. The lowered cyclin level causes a decline in CDK activity, and the activity of DBRP also drops through slow,

One circumstance that triggers this control mechanism is the presence of single-strand breaks in DNA, which leads to arrest of the cell cycle in G2. A specific protein kinase (called Rad3 in yeast), which is activated by single-strand breaks, triggers a cascade leading to the inactivation of the PTPase that dephosphorylates Thr^{160} of CDK. The CDK remains inactive and the cell is arrested in G2. The cell cannot divide until the DNA is repaired and the effects of the cascade are reversed.

FIGURE 12-46 Regulation of CDK by phosphorylation and proteolysis. (a) The cyclin-dependent protein kinase activated at the time of mitosis (the M-phase CDK) has a “T loop” that can fold into the substrate-binding site. When Thr^{160} in the T loop is phosphorylated, the loop moves out of the substrate-binding site, activating the CDK.

(b) The active cyclin-CDK complex triggers its own inactivation by phosphorylation of DBRP (destruction box recognizing protein; step 5). DBRP and ubiquitin ligase then attach several molecules of ubiquitin (U) to cyclin (step 7), targeting it for destruction by proteasomes, proteolytic enzyme complexes (step 8).
constant dephosphorylation and inactivation by a DBRP phosphatase. The cyclin level is ultimately restored by synthesis of new cyclin molecules.

The role of ubiquitin and proteasomes is not limited to the regulation of cyclin; as we shall see in Chapter 27, both also take part in the turnover of cellular proteins, a process fundamental to cellular housekeeping.

**Regulated Synthesis of CDKs and Cyclins** The third mechanism for changing CDK activity is regulation of the rate of synthesis of cyclin or CDK or both. For example, cyclin D, cyclin E, CDK2, and CDK4 are synthesized only when a specific transcription factor, E2F, is present in the nucleus to activate transcription of their genes. Synthesis of E2F is in turn regulated by extracellular signals such as growth factors and cytokines (developmental signals that induce cell division), compounds found to be essential for the division of mammalian cells in culture. They induce the synthesis of specific nuclear transcription factors essential to the production of the enzymes of DNA synthesis. Growth factors trigger phosphorylation of the nuclear proteins Jun and Fos, transcription factors that promote the synthesis of a variety of gene products, including cyclins, CDKs, and E2F. In turn, E2F controls production of several enzymes essential for the synthesis of deoxynucleotides and DNA, enabling cells to enter the S phase (Fig. 12-47).

**Inhibition of CDKs** Finally, specific protein inhibitors bind to and inactivate specific CDKs. One such protein is p21, which we discuss below.

These four control mechanisms modulate the activity of specific CDKs that, in turn, control whether a cell will divide, differentiate, become permanently quiescent, or begin a new cycle of division after a period of quiescence. The details of cell cycle regulation, such as the number of different cyclins and kinases and the combinations in which they act, differ from species to species, but the basic mechanism has been conserved in the evolution of all eukaryotic cells.

**CDKs Regulate Cell Division by Phosphorylating Critical Proteins**

We have examined how cells maintain close control of CDK activity, but how does the activity of CDK control the cell cycle? The list of target proteins that CDKs are known to act upon continues to grow, and much remains to be learned. But we can see a general pattern behind CDK regulation by inspecting the effect of CDKs on the structures of lamin and myosin and on the activity of retinoblastoma protein.

The structure of the nuclear envelope is maintained in part by highly organized meshworks of intermediate filaments composed of the protein lamin. Breakdown of the nuclear envelope before segregation of the sister chromatids in mitosis is partly due to the phosphorylation of lamin by a CDK, which causes lamin filaments to depolymerize.

A second kinase target is the ATP-driven contractile machinery (actin and myosin) that pinches a dividing cell into two equal parts during cytokinesis. After the division, CDK phosphorylates a small regulatory subunit of myosin, causing dissociation of myosin from actin filaments and inactivating the contractile machinery. Subsequent dephosphorylation allows reassembly of the contractile apparatus for the next round of cytokinesis.

A third and very important CDK substrate is the retinoblastoma protein, pRb; when DNA damage is detected, this protein participates in a mechanism that arrests cell division in G1 (Fig. 12-48). Named for the retinal tumor cell line in which it was discovered, pRb functions in most, perhaps all, cell types to regulate cell division in response to a variety of stimuli. Unphosphorylated pRb binds the transcription factor E2F; while bound to pRb, E2F cannot promote transcription of a group of genes necessary for DNA synthesis (the genes for DNA polymerase α, ribonucleotide reductase, and other proteins; see Chapter 25). In this state, the cell cycle cannot proceed from the G1 to the S phase, the step that commits a cell to mitosis and cell division. The pRb-E2F blocking mechanism is relieved when pRb is phosphorylated by cyclin E-CDK2, which occurs in response to a signal for cell division to proceed.

When the protein kinases ATM and ATR detect damage to DNA (signaled by the presence of the protein MRN
cells. When the damage is too severe to allow effective repair, this same machinery triggers a process (apoptosis, described below) that leads to the death of the cell, preventing the possible development of a cancer.

**SUMMARY 12.11 Regulation of the Cell Cycle by Protein Kinases**

- Progression through the cell cycle is regulated by the cyclin-dependent protein kinases (CDKs), which act at specific points in the cycle, phosphorylating key proteins and modulating their activities. The catalytic subunit of CDKs is inactive unless associated with the regulatory cyclin subunit.

- The activity of a cyclin-CDK complex changes during the cell cycle through differential synthesis of CDKs, specific degradation of cyclin, phosphorylation and dephosphorylation of critical residues in CDKs, and binding of inhibitory proteins to specific cyclin-CDKs.

**12.12 Oncogenes, Tumor Suppressor Genes, and Programmed Cell Death**

Tumors and cancer are the result of uncontrolled cell division. Normally, cell division is regulated by a family of extracellular growth factors, proteins that cause resting cells to divide and, in some cases, differentiate. The result is a precise balance between the formation of new cells (such as skin cells that die and are replaced every few weeks, or white blood cells that are replaced every few days) and cell destruction. When this balance is disturbed by defects in regulatory proteins, the result is sometimes the formation of a clone of cells that divide repeatedly and without regulation (a tumor) until their presence interferes with the function of normal tissues—cancer. The direct cause is almost always a genetic defect in one or more of the proteins that regulate cell division. In some cases, a defective gene is inherited from one parent; in other cases, the mutation occurs when a toxic compound from the environment (a mutagen or carcinogen) or high-energy radiation interacts with the DNA of a single cell to damage it and introduce a mutation. In most cases there is both an inherited and an environmental contribution, and in most cases, more than one mutation is required to cause completely unregulated division and full-blown cancer.

**Oncogenes Are Mutant Forms of the Genes for Proteins That Regulate the Cell Cycle**

Oncogenes were originally discovered in tumor-causing viruses, then later found to be derived from genes in the animal host cells, proto-oncogenes, which encode growth-regulating proteins. During a viral infection, the host DNA sequence of a proto-oncogene is sometimes copied into the viral genome, where
it proliferates with the virus. In subsequent viral infection cycles, the proto-oncogenes can become defective by truncation or mutation. Viruses, unlike animal cells, do not have effective mechanisms for correcting mistakes during DNA replication, so they accumulate mutations rapidly. When a virus carrying an oncogene infects a new host cell, the viral DNA (and oncogene) can be incorporated into the host cell's DNA, where it can now interfere with the regulation of cell division in the host cell. In an alternative, nonviral mechanism, a single cell in a tissue exposed to carcinogens may suffer DNA damage that renders one of its regulatory proteins defective, with the same effect as the oncogenic mechanism: failed regulation of cell division.

The mutations that produce oncogenes are genetically dominant; if either of a pair of chromosomes contains a defective gene, that gene product sends the signal "divide" and a tumor will result. The oncogenic defect can be in any of the proteins involved in communicating the "divide" signal. Oncogenes discovered thus far include those that encode secreted proteins, growth factors, transmembrane proteins (receptors), cytoplasmic proteins (G proteins and protein kinases), and the nuclear transcription factors that control the expression of genes essential for cell division (Jun, Fos).

Some oncogenes encode surface receptors with defective or missing signal-binding sites, such that their intrinsic Tyr kinase activity is unregulated. For example, the oncoprotein ErbB is essentially identical to the normal receptor for epidermal growth factor, except that ErbB lacks the amino-terminal domain that normally binds EGF (Fig. 12–49) and as a result sends the "divide" signal whether EGF is present or not. Mutations in erbB2, the gene for a receptor Tyr kinase related to ErbB, are commonly associated with cancers of the glandular epithelium in breast, stomach, and ovary. (For an explanation of the use of abbreviations in naming genes and their products, see Chapter 25.)

The prominent role played by protein kinases in signaling processes related to normal and abnormal cell division has made them a prime target in the development of drugs for the treatment of cancer (Box 12–5). Mutant forms of the G protein Ras are common in tumor cells. The ras oncogene encodes a protein with normal GTP binding but no GTPase activity. The mutant Ras protein is therefore always in its activated (GTP-bound) form, regardless of the signals arriving through normal receptors. The result can be unregulated growth. Mutations in ras are associated with 30% to 50% of lung and colon carcinomas and more than 90% of pancreatic carcinomas.

Defects in Certain Genes Remove Normal Restraints on Cell Division

Tumor suppressor genes encode proteins that normally restrain cell division. Mutation in one or more of these genes can lead to tumor formation. Unregulated growth due to defective tumor suppressor genes, unlike that due to oncogenes, is genetically recessive; tumors form only if both chromosomes of a pair contain a defective gene. This is because the function of these genes is to prevent cell division, and if either copy of the gene for such a protein is normal, the normal inhibition of division will take place. In a person who inherits one correct copy and one defective copy, every cell begins with one defective copy of the gene. If any one of those $10^{12}$ somatic cells undergoes mutation in the one good copy, a tumor may grow from that doubly mutant cell. Mutations in both copies of the genes for pRb, p53, or p21 yield cells in which the normal restraint on cell division is lost and a tumor forms.

Retinoblastoma occurs in children and causes blindness if not surgically treated. The cells of a retinoblastoma have two defective versions of the Rb gene (two defective alleles). Very young children who develop retinoblastoma commonly have multiple tumors in both eyes. These children have inherited one defective copy of the Rb gene, which is present in every cell; each tumor is derived from a single retinal cell that has undergone a mutation in its one good copy of the Rb gene. (A fetus with two mutant alleles in every cell is nonviable.) People with retinoblastoma who survive childhood also have a high incidence of cancers of the lung, prostate, and breast later in life.

A far less likely event is that a person born with two good copies of the Rb gene will have independent mutations in both copies in the same cell. Some individuals do develop retinoblastomas later in childhood, usually with only one tumor in one eye. These individuals were presumably born with two good copies (alleles) of Rb in
When a single cell divides without any regulatory limitation, it eventually gives rise to a clone of cells so large that it interferes with normal physiological functions (Fig. 1). This is cancer, a leading cause of death in the developed world, and increasingly so in the developing world. In all types of cancer, the normal regulation of cell division has become dysfunctional due to defects in one or more genes. For example, genes encoding proteins that normally send intermittent signals for cell division become oncogenes, producing constitutively active signaling proteins; or genes encoding proteins that normally restrain cell division (tumor suppressor genes) mutate to produce proteins that lack this braking function. In many tumors, both kinds of mutation have occurred.

Many oncogenes and tumor suppressor genes encode protein kinases or proteins that act in pathways upstream from protein kinases. It is therefore reasonable to hope that specific inhibitors of protein kinases could prove valuable in the treatment of cancer. For example, a mutant form of the EGF receptor is a constantly active receptor tyrosine kinase (RTK), signaling cell division whether EGF is present or not (see Fig. 12-49). In about 30% of all women with invasive breast cancer, a mutation in the receptor gene HER2/neu yields an RTK with activity increased up to 100-fold. Another RTK, vascular endothelial growth factor receptor (VEGF-R), must be activated for the formation of new blood vessels (angiogenesis) to produce a solid tumor with its own blood supply, and inhibition of VEGF-R might starve a tumor of essential nutrients. Nonreceptor Tyr kinases can also mutate, resulting in constant signaling and unregulated cell division. For example, the oncogene Abl (from the Abelson leukemia virus) is associated with acute myeloid leukemia, a relatively rare blood disease (~5,000 cases a year in the United States). Another group of oncogenes encode unregulated cyclin-dependent protein kinases. In each of these cases, specific protein kinase inhibitors might be valuable chemotherapeutic agents in the treatment of disease. Not surprisingly, huge efforts are under way to develop such inhibitors. How should one approach this challenge?

Protein kinases of all types show striking conservation of structure at the active site. All share with the prototypical PKA structure the features shown in Figure 2: two lobes that enclose the active site, with a P loop that helps to align and bind the phosphoryl groups of ATP, an activation loop that moves to open the active site to the protein substrate, and a C helix that changes position as the enzyme is activated, bringing the residues in the substrate-binding cleft into their binding positions.

The simplest protein kinase inhibitors are ATP analogs that occupy the ATP-binding site but cannot serve as phosphoryl group donors. Many such compounds are known, but their clinical usefulness is limited by their lack of selectivity—they inhibit virtually all protein kinases and would produce unacceptable side effects. (continued on next page)
effects. More selectivity is seen with compounds that fill part of the ATP-binding site but also interact outside this site, with parts of the protein unique to the target protein kinase. A third possible strategy is based on the fact that although the active conformations of all protein kinases are similar, their inactive conformations are not. Drugs that target the inactive conformation of a specific protein kinase and prevent its conversion to the active form may have a higher specificity of action. A fourth approach employs the great specificity of antibodies. For example, monoclonal antibodies (p. 173) that bind the extracellular portions of specific RTKs could eliminate the receptors' kinase activity by preventing dimerization or by causing their removal from the cell surface. In some cases, an antibody selectively binding to the surface of cancer cells could cause the immune system to attack those cells.

Between 1998 and mid-2006, only eight new drugs were approved in the United States for use in cancer therapy: five small molecules and three monoclonal antibodies, each having shown efficacy in clinical trials. For example, imatinib mesylate (Gleevec; Fig. 3a), one of the small molecule inhibitors, has proved nearly 100% effective in bringing about remission in patients with early-stage chronic myeloid leukemia. Erlotinib (Tarceva; Fig. 3b), which targets EGF-R, is effective against advanced non-small-cell lung cancer (NSCLC). Because many cell-division signaling systems involve more than one protein kinase, inhibitors that act on several protein kinases may be useful in the treatment of cancer. Sunitinib (Sutent) and sorafenib (Nexavar) target several protein kinases, including VEGF-R and PDGF-R. These two drugs are in clinical use for patients with gastrointestinal stromal tumors and advanced renal cell carcinoma, respectively. Trastuzumab (Herceptin), cetuximab (Erbitux), and bevacizumab (Avastin) are monoclonal antibodies that target HER2/neu, EGF-R, and VEGF-R, respectively; all three drugs are in clinical use for certain types of cancer.

At least a hundred more compounds are in preclinical trials. Among the drugs being evaluated are some obtained from natural sources and some produced by synthetic chemistry. Indirubin is a component of a Chinese herbal preparation traditionally used to treat certain leukemias; it inhibits CDK2 and CDK5. Flavopiridol (Fig. 3d), a synthetic analog of an alkaloid extracted from the stem bark of the Indian plant Ampelopsis rohituka, is a general CDK inhibitor. With several hundred potential anticancer drugs heading toward clinical testing, it is realistic to hope that some will prove more effective or more target-specific than those now in use.
every cell, but both Rb alleles in a single retinal cell have undergone mutation, leading to a tumor. After about age three, retinal cells stop dividing, and retinoblastomas at later ages are quite rare.

Stability genes (also called caretaker genes) encode proteins that function in the repair of major genetic defects that result from aberrant DNA replication, ionizing radiation, or environmental carcinogens. Mutations in these genes lead to a high frequency of unrepaired damage (mutations) in other genes, including proto-oncogenes and tumor suppressor genes, and thus to cancer. Among the stability genes are ATM (see Fig. 12–48); the XP gene family, in which mutations lead to xeroderma pigmentosum; and the BRCAI genes associated with some types of breast cancer (see Box 25–1).

Mutations in the gene for p53 also cause tumors; in more than 90% of human cutaneous squamous cell carcinomas (skin cancers) and in about 50% of all other human cancers, p53 is defective. Those very rare individuals who inherit one defective copy of p53 commonly have the Li-Fraumeni cancer syndrome, with multiple cancers (of the breast, brain, bone, blood, lung, and skin) occurring at high frequency and at an early age. The explanation for multiple tumors in this case is the same as that for Rb mutations: an individual born with one defective copy of p53 in every somatic cell is likely to suffer a second p53 mutation in more than one cell during his or her lifetime.

In summary, then, three classes of defects can contribute to the development of cancer: oncogenes, in which the defect is the equivalent of a car's accelerator pedal being stuck down, with the engine racing; mutated tumor suppressor genes, in which the defect leads to the equivalent of brake failure; and mutated stability genes, with the defect leading to unrepaired damage to the cell's replication machinery, the equivalent of an unskilled car mechanic.

Mutations in oncogenes and tumor suppressor genes do not have an all-or-none effect. In some cancers, perhaps in all, the progression from a normal cell to a malignant tumor requires an accumulation of mutations (sometimes over several decades), none of which, alone, is responsible for the end effect. For example, the development of colorectal cancer has several recognizable stages, each associated with a mutation (Fig. 12–50). If an epithelial cell in the colon undergoes mutation of both copies of the tumor suppressor gene APC (adenomatous polyposis coli), it begins to divide faster than normal and produces a clone of itself, a benign polyp (early adenoma). For reasons not yet known, the APC mutation results in chromosomal instability, and whole regions of a chromosome are lost or rearranged during cell division. This instability can lead to another mutation, commonly in ras, that converts the clone into an intermediate adenoma. A third mutation (often in the tumor suppressor gene DCC) leads to a late adenoma. Only when both copies of p53 become defective does this cell mass become a carcinoma—a malignant, life-threatening tumor. The full sequence therefore requires at least seven genetic “hits”: two on each of three tumor suppressor genes (APC, DCC, and p53) and one on the proto-oncogene ras. There are probably several other routes to colorectal cancer as well, but the principle that full malignancy results only from multiple mutations is likely to hold true for all of them. When a polyp is detected in the early adenoma stage and the cells containing the first mutations are removed surgically, late adenomas and carcinomas will not develop; hence the importance of early detection. Cells and organisms, too, have their early detection systems. For example, the ATM and ATR proteins described in Section 12.11 can detect DNA damage too extensive to be repaired effectively. They then trigger, through a pathway that includes p53, the process of apoptosis, in which a cell that has become dangerous to the organism kills itself.

**Apoptosis Is Programmed Cell Suicide**

Many cells can precisely control the time of their own death by the process of programmed cell death, or apoptosis (app'-a-toe'-sis; from the Greek for “dropping off,” as in leaves dropping in the fall). One trigger for apoptosis is irreparable damage to DNA. Programmed cell death also occurs during the development of an
embryo, when some cells must die to give a tissue or organ its final shape. Carving fingers from stubby limb buds requires the precisely timed death of cells between developing finger bones. During development of the nematode *C. elegans* from a fertilized egg, exactly 131 cells (of a total of 1,090 somatic cells in the embryo) must undergo programmed death in order to construct the adult body.

Apoptosis also has roles in processes other than development. If a developing antibody-producing cell generates antibodies against a protein or glycoprotein normally present in the body, that cell undergoes programmed death in the thymus gland—an essential mechanism for eliminating anti-self antibodies. The monthly sloughing of cells of the uterine wall (menstruation) is another case of apoptosis mediating normal cell death. The dropping of leaves in the fall is the result of apoptosis in specific cells of the stem. Sometimes cell suicide is not programmed but occurs in response to biological circumstances that threaten the rest of the organism. For example, a virus-infected cell that dies before completion of the infection cycle prevents spread of the virus to nearby cells. Severe stresses such as heat, hyperosmolarity, UV light, and gamma irradiation also trigger cell suicide; presumably the organism is better off with any aberrant, potentially mutated cells dead.

The regulatory mechanisms that trigger apoptosis involve some of the same proteins that regulate the cell cycle. The signal for suicide often comes from outside, through a surface receptor. Tumor necrosis factor (TNF), produced by cells of the immune system, interacts with cells through specific TNF receptors. These receptors have TNF-binding sites on the outer face of the plasma membrane and a "death domain" (~80 amino acid residues) that carries the self-destruct signal through the membrane to cytosolic proteins such as TRADD (TNF receptor-associated death domain) (Fig. 12–51). Another receptor, Fas, has a similar death domain that allows it to interact with the cytosolic protein FADD (Fas-associated death domain), which activates the cytosolic protease caspase 8. This enzyme belongs to a family of proteases that participate in apoptosis; all are synthesized as inactive proenzymes, all have a critical Cys residue at the active site, and all hydrolyze their target proteins on the carboxyl-terminal side of specific Asp residues (hence the name caspase, from Cys and Asp).

When caspase 8, an "initiator" caspase, is activated by an apoptotic signal carried through FADD, it further self-activates by cleaving its own proenzyme form. Mitochondria are one target of active caspase 8. The protease causes the release of certain proteins contained between the inner and outer mitochondrial membranes: cytochrome *c* (Chapter 19) and several "effector" caspases. Cytochrome *c* binds to the proenzyme form of the effector enzyme caspase 9 and stimulates its proteolytic activation. The activated caspase 9 in turn catalyzes wholesale destruction of cellular proteins—a major cause of apoptotic cell death. One specific target of caspase action is a caspase-activated deoxyribonuclease.

In apoptosis, the monomeric products of protein and DNA degradation (amino acids and nucleotides) are released in a controlled process that allows them to be taken up and reused by neighboring cells. Apoptosis thus allows the organism to eliminate a cell that is unneeded or potentially dangerous without wasting its components.

**SUMMARY 12.12 Oncogenes, Tumor Suppressor Genes, and Programmed Cell Death**

- Oncogenes encode defective signaling proteins. By continually giving the signal for cell division, they lead to tumor formation. Oncogenes are genetically dominant and may encode defective growth factors, receptors, G proteins, protein kinases, or nuclear regulators of transcription.
- Tumor suppressor genes encode regulatory proteins that normally inhibit cell division; mutations in these genes are genetically recessive but can lead to tumor formation.
Cancer is generally the result of an accumulation of mutations in oncogenes and tumor suppressor genes.

When stability genes, which encode proteins necessary for the repair of genetic damage, are mutated, other mutations go unrepaired, including mutations in proto-oncogenes and tumor suppressor genes that can lead to cancer.

Apoptosis can be triggered by extracellular signals such as TNF, acting through plasma membrane receptors.

Cell Cycle and Cancer

Problems

1. Hormone Experiments in Cell-Free Systems In the 1950s, Earl W. Sutherland, Jr., and his colleagues carried out pioneering experiments to elucidate the mechanism of action of epinephrine and glucagon. Given what you have learned in this chapter about hormone action, interpret each of the experiments described below. Identify substance X and indicate the significance of the results.

(a) Addition of epinephrine to a homogenate of normal liver resulted in an increase in the activity of glycogen phosphorylase. However, when the homogenate was centrifuged at a high speed and epinephrine or glucagon was added to the clear supernatant fraction that contains phosphorylase, no increase in the phosphorylase activity occurred.

(b) When the particulate fraction from the centrifugation in (a) was treated with epinephrine, substance X was produced. The substance was isolated and purified. Unlike epinephrine, substance X activated glycogen phosphorylase when added to the clear supernatant fraction of the centrifuged homogenate.

(c) Substance X was heat-stable; that is, heat treatment did not affect its capacity to activate phosphorylase. (Hint: Would this be the case if substance X were a protein?) Substance X was nearly identical to a compound obtained when pure ATP was treated with barium hydroxide. (Fig. 8-6 will be helpful.)

2. Effect of Dibutyryl cAMP versus cAMP on Intact Cells The physiological effects of epinephrine should in principle be mimicked by addition of cAMP to the target cells. In practice, addition of cAMP to intact target cells elicits only a minimal physiological response. Why? When the structurally related derivative dibutyryl cAMP (shown below) is added to intact cells, the expected physiological response is readily apparent. Explain the basis for the difference in cellular response to these two substances. Dibutyryl cAMP is widely used in studies of cAMP function.

![Dibutyryl cAMP](image)

3. Effect of Cholera Toxin on Adenylyl Cyclase

The gram-negative bacterium Vibrio cholerae produces a protein, cholera toxin (Mr, 90,000), that is responsible for the characteristic symptoms of cholera: extensive loss of body water and Na⁺ through continuous, debilitating diarrhea. If body fluids and Na⁺ are not replaced, severe dehydration results; untreated, the disease is often fatal. When the cholera toxin gains access to the human intestinal tract it binds tightly to specific sites in the plasma membrane of the epithelial cells lining the small intestine,
causing adenyl cyclase to undergo prolonged activation (hours or days).

(a) What is the effect of cholera toxin on [cAMP] in the intestinal cells?

(b) Based on the information above, suggest how cAMP normally functions in intestinal epithelial cells.

(c) Suggest a possible treatment for cholera.

4. Mutations in PKA Explain how mutations in the R or C subunit of cAMP-dependent protein kinase (PKA) might lead to (a) a constantly active PKA or (b) a constantly inactive PKA.

5. Therapeutic Effects of Albuterol The respiratory symptoms of asthma result from constriction of the bronchi and bronchioles of the lungs, caused by contraction of the smooth muscle of their walls. This constriction can be reversed by raising [cAMP] in the smooth muscle. Explain the therapeutic effects of albuterol, a β-adrenergic agonist taken (by inhalation) for asthma. Would you expect this drug to have any side effects? How might one design a better drug that did not have these effects?

6. Termination of Hormonal Signals Signals carried by hormones must eventually be terminated. Describe several different mechanisms for signal termination.

7. Using FRET to Explore Protein-Protein Interactions in Vivo Figure 12–8 shows the interaction between β-arrestin and the β-adrenergic receptor. How would you use FRET (see Box 12–3) to demonstrate this interaction in living cells? Which proteins would you fuse? Which wavelengths would you use to illuminate the cells, and which would you monitor? What would you expect to observe if the interaction occurred? If it did not occur? How might you explain the failure of this approach to demonstrate this interaction?

8. EGTA Injection EGTA (ethylene glycol-bis(β-aminoethyl ether)-N,N,N',N'-tetraacetic acid) is a chelating agent with high affinity and specificity for Ca2+. By microinjecting a cell with an appropriate Ca2+–EGTA solution, an experimenter can prevent cytosolic [Ca2+] from rising above 10−7 M. How would EGTA microinjection affect a cell’s response to vasopressin (see Table 12–4)? To glucagon?

9. Amplification of Hormonal Signals Describe all the sources of amplification in the insulin receptor system.

10. Mutations in ras How would a mutation in ras that leads to formation of a Ras protein with no GTPase activity affect a cell’s response to insulin?

11. Differences among G Proteins Compare the G proteins Gα, which acts in transducing the signal from β-adrenergic receptors, and Ras. What properties do they share? How do they differ? What is the functional difference between Gα and Gβ?

12. Mechanisms for Regulating Protein Kinases Identify eight general types of protein kinases found in eukaryotic cells, and explain what factor is directly responsible for activating each type.

13. Nonhydrolyzable GTP Analogs Many enzymes can hydrolyze GTP between the β and γ phosphates. The GTP analog β,γ-imidoguanosine 5’-triphosphate (Gpp(NH)p), shown below, cannot be hydrolyzed between the β and γ phosphates.

![Gpp(NH)p](image)

Predict the effect of microinjection of Gpp(NH)p into a myocyte on the cell’s response to β-adrenergic stimulation.

14. Use of Toxin Binding to Purify a Channel Protein α-Bungarotoxin is a powerful neurotoxin found in the venom of a poisonous snake (Bungarus multicinctus). It binds with high specificity to the nicotinic acetylcholine receptor (AChR) protein and prevents the ion channel from opening. This interaction was used to purify AChR from the electric organ of the electric fish.

(a) Outline a strategy for using α-bungarotoxin covalently bound to chromatography beads to purify the AChR protein. (Hint: See Fig. 3–17c.)

(b) Outline a strategy for the use of [125I]α-bungarotoxin to purify the AChR protein.

15. Resting Membrane Potential A variety of unusual invertebrates, including giant clams, mussels, and polychaete worms, live on the fringes of deep-sea hydrothermal vents, where the temperature is 60 °C.

(a) The adductor muscle of a giant clam has a resting membrane potential of −95 mV. Given the intracellular and extracellular ionic compositions shown below, would you have predicted this membrane potential? Why or why not?

(b) Assume that the adductor muscle membrane is permeable to only one of the ions listed above. Which ion could determine the \( V_m \)?

16. Membrane Potentials in Frog Eggs Fertilization of a frog oocyte by a sperm cell triggers ionic changes similar to those observed in neurons (during movement of the action potential) and initiates the events that result in cell division and development of the embryo. Oocytes can be stimulated to divide
without fertilization, by suspending them in 80 mM KCl (normal pond water contains 9 mM KCl).

(a) Calculate how much the change in extracellular [KCl] changes the resting membrane potential of the oocyte. (Hint: Assume the oocyte contains 120 mM K⁺ and is permeable only to K⁺.) Assume a temperature of 20 °C.

(b) When the experiment is repeated in Ca²⁺-free water, elevated [KCl] has no effect. What does this suggest about the mechanism of the KCl effect?

17. Excitation Triggered by Hyperpolarization In most neurons, membrane depolarization leads to the opening of voltage-dependent ion channels, generation of an action potential, and ultimately an influx of Ca²⁺, which causes release of neurotransmitter at the axon terminus. Devise a cellular strategy by which hyperpolarization in rod cells could produce excitation of the visual pathway and passage of visual signals to the brain. (Hint: The neuronal signaling pathway in higher organisms consists of a series of neurons that relay information to the brain (see Fig. 12-35). The signal released by one neuron can be either excitatory or inhibitory to the following, postsynaptic neuron.)

18. Genetic “Channelopathies” There are many genetic diseases that result from defects in ion channels. For each of the following, explain how the molecular defect might lead to the symptoms described.

(a) A loss-of-function mutation in the gene encoding the α subunit of the cGMP-gated cation channel of retinal cone cells leads to a complete inability to distinguish colors.

(b) Loss-of-function alleles of the gene encoding the α subunit of the ATP-gated K⁺ channel shown in Figure 23–29 lead to a condition known as congenital hyperinsulinism—persistently high levels of insulin in the blood.

(c) Mutations affecting the β subunit of the ATP-gated K⁺ channel that prevent ATP binding lead to neonatal diabetes—persistently low levels of insulin in the blood in newborn babies.

19. Visual Desensitization Oguchi’s disease is an inherited form of night blindness. Affected individuals are slow to recover vision after a flash of bright light against a dark background, such as the headlights of a car on the freeway. Suggest what the molecular defect(s) might be in Oguchi’s disease. Explain in molecular terms how this defect would account for night blindness.

20. Effect of a Permeant cGMP Analog on Rod Cells An analog of cGMP, 8-Br-cGMP, will permeate cellular membranes, is only slowly degraded by a rod cell’s PDE activity, and is as effective as cGMP in opening the gated channel in the cell’s outer segment. If you suspended rod cells in a buffer containing a relatively high [8-Br-cGMP], then illuminated the cells while measuring their membrane potential, what would you observe?

21. Hot and Cool Taste Sensations The sensations of heat and cold are transduced by a group of temperature-gated cation channels. For example, TRPV1, TRPV3, and TRPM8 are usually closed, but open under the following conditions: TRPV1 at ≥43 °C; TRPV3 at ≥33 °C; and TRPM8 at <25 °C. These channels are expressed in sensory neurons known to be responsible for temperature sensation.

(a) Propose a reasonable model to explain how exposing a sensory neuron containing TRPV1 to high temperature leads to a sensation of heat.

(b) Capsaicin, one of the active ingredients in “hot” peppers, is an agonist of TRPV1. Capsaicin shows 50% activation of the TRPV1 response at a concentration (i.e., it has an EC₅₀) of 32 nM. Explain why even a very few drops of hot pepper sauce can taste very “hot” without actually burning you.

(c) Menthol, one of the active ingredients in mint, is an agonist of TRPM8 (EC₅₀ = 30 μM) and TRPV3 (EC₅₀ = 20 μM). What sensation would you expect from contact with low levels of menthol? With high levels?

22. Oncogenes, Tumor-Suppressor Genes, and Tumors For each of the following situations, provide a plausible explanation for how it could lead to unrestricted cell division.

(a) Colon cancer cells often contain mutations in the gene encoding the prostaglandin E₂ receptor. PGE₂ is a growth factor required for the division of cells in the gastrointestinal tract.

(b) Kaposi sarcoma, a common tumor in people with untreated AIDS, is caused by a virus carrying a gene for a protein similar to the chemokine receptors CXCR1 and CXCR2. Chemokines are cell-specific growth factors.

(c) Adenovirus, a tumor virus, carries a gene for the protein E1A, which binds to the retinoblastoma protein, pRb. (Hint: See Fig. 12–48.)

An important feature of many oncogenes and tumor suppressor genes is their cell-type specificity. For example, mutations in the PGE₂ receptor are not typically found in lung tumors.

(d) Explain this observation. (Note that PGE₂ acts through a GPCR in the plasma membrane.)

23. Mutations in Tumor Suppressor Genes and Oncogenes Explain why mutations in tumor suppressor genes are recessive (both copies of the gene must be defective for the regulation of cell division to be defective) whereas mutations in oncogenes are dominant.

24. Retinoblastoma in Children Explain why some children with retinoblastoma develop multiple tumors of the retina in both eyes, whereas others have a single tumor in only one eye.

25. Specificity of a Signal for a Single Cell Type Discuss the validity of the following proposition. A signaling molecule (hormone, growth factor, or neurotransmitter) elicits identical responses in different types of target cells if they contain identical receptors.
26. Exploring Taste Sensation in Mice Figure 12–41 shows the signal-transduction pathway for sweet taste in mammals. Pleasing tastes are an evolutionary adaptation to encourage animals to consume nutritious foods. Zhao and coauthors (2003) examined the two major pleasurable taste sensations: sweet and umami. Umami is a “distinct savory taste” triggered by amino acids, especially aspartate and glutamate, and probably encourages animals to consume protein-rich foods. Monosodium glutamate (MSG) is a flavor enhancer that exploits this sensitivity.

At the time the article was published, specific taste receptor proteins (labeled SR in Fig. 12–41) for sweet and umami had been tentatively characterized. Three such proteins were known—T1R1, T1R2, and T1R3—which function as heterodimeric receptor complexes: T1R1–T1R3 was tentatively identified as the umami receptor, and T1R2–T1R3 as the sweet receptor. It was not clear how taste sensation was encoded and sent to the brain, and two possible models had been suggested. In the cell-based model, individual taste-sensing cells express only one kind of receptor; that is, there are “sweet cells,” “bitter cells,” “umami cells,” and so on, and each type of cell sends its information to the brain via a different nerve. The brain “knows” which taste is detected by the identity of the nerve fiber that transmits the message. In the receptor-based model, individual taste-sensing cells have several kinds of receptors and send different messages along the same nerve fiber to the brain, the message depending on which receptor is activated. Also unclear at the time was whether there was any interaction between the different taste sensations, or whether parts of one taste-sensing system were required for other taste sensations.

(a) Previous work had shown that different taste receptor proteins are expressed in nonoverlapping sets of taste receptor cells. Which model does this support? Explain your reasoning.

Zhao and colleagues constructed a set of “knockout mice”—mice homozygous for loss-of-function alleles for one of the three receptor proteins, T1R1, T1R2, or T1R3—and double-knockout mice with nonfunctioning T1R2 and T1R3. The researchers measured the taste perception of these mice by measuring their “lick rate” of solutions containing different taste molecules. Mice will lick the spout of a feeding bottle with a pleasant-tasting solution more often than one with an unpleasant-tasting solution. The researchers measured relative lick rates: how often the mice licked a sample solution compared with water. A relative lick rate of 1 indicated no preference; <1, an aversion; and >1, a preference.

(b) All four types of knockout strains had the same responses to salt and bitter tastes as did wild-type mice. Which of the above issues did this experiment address? What do you conclude from these results?

The researchers then studied umami taste reception by measuring the relative lick rates of the different mouse strains with different quantities of MSG in the feeding solution. Note that the solutions also contained inosine monophosphate (IMP), a strong potentiator of umami taste reception (and a common ingredient in ramen soups, along with MSG), and ameloride, which suppresses the pleasant salty taste imparted by the sodium of MSG. The results are shown in the graph.

(c) Are these data consistent with the umami taste receptor consisting of a heterodimer of T1R1 and T1R3? Why or why not?

(d) Which model(s) of taste encoding does this result support? Explain your reasoning.

Zhao and coworkers then performed a series of similar experiments using sucrose as a sweet taste. These results are shown below.

(e) Are these data consistent with the sweet taste receptor consisting of a heterodimer of T1R2 and T1R3? Why or why not?

(f) There were some unexpected responses at very high sucrose concentrations. How do these complicate the idea of a heterodimeric system as presented above?

In addition to sugars, humans also taste other compounds (e.g., the peptides monellin and aspartame) as sweet; mice do not taste these as sweet. Zhao and coworkers inserted into TIR2 knockout mice a copy of the human T1R2 gene under the control of the mouse T1R2 promoter. These modified mice now tasted monellin and saccharin as sweet. The researchers then went further, adding to T1R1 knockout mice the RASSL protein—a G protein-linked receptor for the synthetic opiate spiradoline; the RASSL gene was under the control of the mouse T1R2 promoter. These modified mice now tasted monellin and saccharin as sweet. The researchers then went further, adding to T1R1 knockout mice the RASSL protein—a G protein-linked receptor for the synthetic opiate spiradoline; the RASSL gene was under the control of the promoter that could be induced by feeding the mice tetracycline. These mice did not prefer spiradoline in the absence of tetracycline; in the presence of tetracycline, they showed a strong preference for nanomolar concentrations of spiradoline.

(g) How do these results strengthen Zhao and coauthors’ conclusions about the mechanism of taste sensation?

Reference
Metabolism is a highly coordinated cellular activity in which many multienzyme systems (metabolic pathways) cooperate to (1) obtain chemical energy by capturing solar energy or degrading energy-rich nutrients from the environment; (2) convert nutrient molecules into the cell’s own characteristic molecules, including precursors of macromolecules; (3) polymerize monomeric precursors into macromolecules: proteins, nucleic acids, and polysaccharides; and (4) synthesize and degrade biomolecules required for specialized cellular functions, such as membrane lipids, intracellular messengers, and pigments.

Although metabolism embraces hundreds of different enzyme-catalyzed reactions, our major concern in Part II is the central metabolic pathways, which are few in number and remarkably similar in all forms of life. Living organisms can be divided into two large groups according to the chemical form in which they obtain carbon from the environment. Autotrophs (such as photosynthetic bacteria, green algae, and vascular plants) can use carbon dioxide from the atmosphere as their sole source of carbon, from which they construct all their carbon-containing biomolecules (see Fig. 1-5). Some autotrophic organisms, such as cyanobacteria, can also use atmospheric nitrogen to generate all their nitrogenous components. Heterotrophs cannot use atmospheric carbon dioxide and must obtain carbon from their environment in the form of relatively complex
organic molecules such as glucose. Multicellular animals and most microorganisms are heterotrophic. Autotrophic cells and organisms are relatively self-sufficient, whereas heterotrophic cells and organisms, with their requirements for carbon in more complex forms, must subsist on the products of other organisms.

Many autotrophic organisms are photosynthetic and obtain their energy from sunlight, whereas heterotrophic organisms obtain their energy from the degradation of organic nutrients produced by autotrophs. In our biosphere, autotrophs and heterotrophs live together in a vast, interdependent cycle in which autotrophic organisms use atmospheric carbon dioxide to build their organic biomolecules, some of them generating oxygen from water in the process. Heterotrophs in turn use the organic products of autotrophs as nutrients and return carbon dioxide to the atmosphere. Some of the oxidation reactions that produce carbon dioxide also consume oxygen, converting it to water. Thus carbon, oxygen, and water are constantly cycled between the heterotrophic and autotrophic worlds, with solar energy as the driving force for this global process (Fig. 1).

All living organisms also require a source of nitrogen, which is necessary for the synthesis of amino acids, nucleotides, and other compounds. Bacteria and plants can generally use either ammonia or nitrate as their sole source of nitrogen, but vertebrates must obtain nitrogen in the form of amino acids or other organic compounds. Only a few organisms—the cyanobacteria and many species of soil bacteria that live symbiotically on the roots of some plants—are capable of converting (“fixing”) atmospheric nitrogen (N₂) into ammonia. Other bacteria (the nitrifying bacteria) oxidize ammonia to nitrites and nitrates; yet others convert nitrate to N₂. The anammox bacteria convert ammonia and nitrite to N₂. Thus, in addition to the global carbon and oxygen cycle, a nitrogen cycle operates in the biosphere, turning over huge amounts of nitrogen (Fig. 2). The cycling of carbon, oxygen, and nitrogen, which ultimately involves all species, depends on a proper balance between the activities of the producers (autotrophs) and consumers (heterotrophs) in our biosphere.

These cycles of matter are driven by an enormous flow of energy into and through the biosphere, beginning with the capture of solar energy by photosynthetic organisms and use of this energy to generate energy-rich carbohydrates and other organic nutrients; these nutrients are then used as energy sources by heterotrophic organisms. In metabolic processes, and in all energy transformations, there is a loss of useful energy (free energy) and an inevitable increase in the amount of unusable energy (heat and entropy). In contrast to the cycling of matter, therefore, energy flows one way through the biosphere; organisms cannot regenerate useful energy from energy dissipated as heat and entropy. Carbon, oxygen, and nitrogen recycle continuously, but energy is constantly transformed into unusable forms such as heat.

**Metabolism**, the sum of all the chemical transformations taking place in a cell or organism, occurs through a series of enzyme-catalyzed reactions that constitute **metabolic pathways**. Each of the consecutive steps in a metabolic pathway brings about a specific, small chemical change, usually the removal, transfer, or addition of a particular atom or functional group. The precursor is converted into a product through a series of metabolic intermediates called **metabolites**. The term **intermediary metabolism** is often applied to the combined activities of all the metabolic pathways that interconvert precursors, metabolites, and products of low molecular weight (generally, $M_r < 1,000$).
Catabolism is the degradative phase of metabolism in which organic nutrient molecules (carbohydrates, fats, and proteins) are converted into smaller, simpler end products (such as lactic acid, CO₂, NH₃). Catabolic pathways release energy, some of which is conserved in the formation of ATP and reduced electron carriers (NADH, NADPH, and FADH₂); the rest is lost as heat. In anabolism, also called biosynthesis, small, simple precursors are built up into larger and more complex molecules, including lipids, polysaccharides, proteins, and nucleic acids. Anabolic reactions require an input of energy, generally in the form of the phosphoryl group transfer potential of ATP and the reducing power of NADH, NADPH, and FADH₂ (Fig. 3).

Some metabolic pathways are linear, and some are branched, yielding multiple useful end products from a single precursor or converting several starting materials into a single product. In general, catabolic pathways are convergent and anabolic pathways divergent (Fig. 4). Some pathways are cyclic: one starting component of the pathway is regenerated in a series of reactions that converts another starting component into a product. We shall see examples of each type of pathway in the following chapters.

Most cells have the enzymes to carry out both the degradation and the synthesis of the important categories of biomolecules—fatty acids, for example. The simultaneous synthesis and degradation of fatty acids would be wasteful, however, and this is prevented by reciprocally regulating the anabolic and catabolic reaction sequences: when one sequence is active, the other is suppressed. Such regulation could not occur if anabolic and catabolic pathways were catalyzed by exactly the same set of enzymes, operating in one direction for anabolism, the opposite direction for catabolism: inhibition of an enzyme involved in catabolism would also inhibit the reaction sequence in the anabolic direction. Catabolic and anabolic pathways that connect the same two end points (glucose → pyruvate, and pyruvate → glucose, for example) may employ many of the same enzymes, but invariably at least one of the steps is catalyzed by different enzymes in the catabolic and anabolic directions, and these enzymes are the sites of separate regulation. Moreover, for both anabolic and catabolic pathways to be essentially irreversible, the reactions unique to each direction must include at least one that is thermodynamically very favorable—in other words, a reaction for which the reverse reaction is very unfavorable. As a further contribution to the separate regulation of catabolic and anabolic reaction sequences, paired catabolic and anabolic pathways commonly take place in different cellular compartments: for example, fatty acid catabolism in mitochondria, fatty acid synthesis in the cytosol. The concentrations of intermediates, enzymes, and regulators can be maintained at different levels in these different compartments. Because metabolic pathways are subject to kinetic control by substrate concentration, separate pools of anabolic and catabolic intermediates also contribute to the control of metabolic rates. Devices that separate anabolic and catabolic processes will be of particular interest in our discussions of metabolism.

Metabolic pathways are regulated at several levels, from within the cell and from outside. The most immediate regulation is by the availability of substrate; when the intracellular concentration of an enzyme's substrate is near or below $K_m$ (as is commonly the case), the rate of the reaction depends strongly upon substrate concentration (see Fig. 6–11). A second type of rapid control from within is allosteric regulation (p. 220) by a metabolic intermediate or coenzyme—an amino acid or ATP, for example—that signals the cell's internal metabolic state.
When the cell contains an amount of, say, aspartate sufficient for its immediate needs, or when the cellular level of ATP indicates that further fuel consumption is unnecessary at the moment, these signals allosterically inhibit the activity of one or more enzymes in the relevant pathway. In multicellular organisms the metabolic activities of different tissues are regulated and integrated by growth factors and hormones that act from outside the cell. In some cases this regulation occurs virtually instantaneously (sometimes in less than a millisecond) through changes in the levels of intracellular messengers that modify the activity of existing enzyme molecules by allosteric mechanisms or by covalent modification such as phosphorylation. In other cases, the extracellular signal changes the cellular concentration of an enzyme by altering the rate of its synthesis or degradation, so the effect is seen only after minutes or hours.

We begin Part II with a discussion of the basic energetic principles that govern all metabolism (Chapter 13). We then consider the major catabolic pathways by which cells obtain energy from the oxidation of various fuels (Chapters 14 through 19). Chapter 19 is the pivotal point of our discussion of metabolism; it concerns chemiosmotic energy coupling, a universal mechanism in which a transmembrane electrochemical potential, produced either by substrate oxidation or by light absorption, drives the synthesis of ATP.

Chapters 20 through 22 describe the major anabolic pathways by which cells use the energy in ATP to produce carbohydrates, lipids, amino acids, and nucleotides from simpler precursors. In Chapter 23 we step back from our detailed look at the metabolic pathways—as they occur in all organisms, from Escherichia coli to humans—and consider how they are regulated and integrated in mammals by hormonal mechanisms.

As we undertake our study of intermediary metabolism, a final word. Keep in mind that the myriad reactions described in these pages take place in, and play crucial roles in, living organisms. As you encounter each reaction and each pathway ask, What does this chemical transformation do for the organism? How does this pathway interconnect with the other pathways operating simultaneously in the same cell to produce the energy and products required for cell maintenance and growth? How do the multilayered regulatory mechanisms cooperate to balance metabolic and energy inputs and outputs, achieving the dynamic steady state of life? Studied with this perspective, metabolism provides fascinating and revealing insights into life, with countless applications in medicine, agriculture, and biotechnology.
Life cells and organisms must perform work to stay alive, to grow, and to reproduce. The ability to harness energy and to channel it into biological work is a fundamental property of all living organisms; it must have been acquired very early in cellular evolution. Modern organisms carry out a remarkable variety of energy transductions, conversions of one form of energy to another. They use the chemical energy in fuels to bring about the synthesis of complex, highly ordered macromolecules from simple precursors. They also convert the chemical energy of fuels into concentration gradients and electrical gradients, into motion and heat, and, in a few organisms such as fireflies and deep-sea fish, into light. Photosynthetic organisms transduce light energy into all these other forms of energy.

The chemical mechanisms that underlie biological energy transductions have fascinated and challenged biologists for centuries. The French chemist Antoine Lavoisier recognized that animals somehow transform chemical fuels (foods) into heat and that this process of respiration is essential to life. He observed that

\[ \ldots \text{in general, respiration is nothing but a slow combustion of carbon and hydrogen, which is entirely similar to that which occurs in a lighted lamp or candle, and that, from this point of view, animals that respire are true combustible bodies that burn and consume themselves \ldots} \]

One may say that this analogy between combustion and respiration has not escaped the notice of the poets, or rather the philosophers of antiquity, and which they had expounded and interpreted. This fire stolen from heaven, this torch of Prometheus, does not only represent an ingenious and poetic idea, it is a faithful picture of the operations of nature, at least for animals that breathe; one may therefore say, with the ancients, that the torch of life lights itself at the moment the infant breathes for the first time, and it does not extinguish itself except at death.*

In the twentieth century, we began to understand much of the chemistry underlying that "torch of life." Biological energy transductions obey the same chemical and physical laws that govern all other natural processes. It is therefore essential for a student of biochemistry to understand these laws and how they apply to the flow of energy in the biosphere.

In this chapter we first review the laws of thermodynamics and the quantitative relationships among free energy, enthalpy, and entropy. We then review the common types of biochemical reactions that occur in living cells, reactions that harness, store, transfer, and release the

energy taken up by organisms from their surroundings. Our focus then shifts to reactions that have special roles in biological energy exchanges, particularly those involving ATP. We finish by considering the importance of oxidation-reduction reactions in living cells, the energetics of biological electron transfers, and the electron carriers commonly employed as cofactors in these processes.

### 13.1 Bioenergetics and Thermodynamics

Bioenergetics is the quantitative study of energy transductions—changes of one form of energy into another—that occur in living cells, and of the nature and function of the chemical processes underlying these transductions. Although many of the principles of thermodynamics have been introduced in earlier chapters and may be familiar to you, a review of the quantitative aspects of these principles is useful here.

#### Biological Energy Transformations Obey the Laws of Thermodynamics

Many quantitative observations made by physicists and chemists on the interconversion of different forms of energy led, in the nineteenth century, to the formulation of two fundamental laws of thermodynamics. The first law is the principle of the conservation of energy: for any physical or chemical change, the total amount of energy in the universe remains constant; energy may change form or it may be transported from one region to another; but it cannot be created or destroyed. The second law of thermodynamics, which can be stated in several forms, says that the universe always tends toward increasing disorder: in all natural processes, the entropy of the universe increases.

Living organisms consist of collections of molecules much more highly organized than the surrounding materials from which they are constructed, and organisms maintain and produce order, seemingly oblivious to the second law of thermodynamics. But living organisms do not violate the second law; they operate strictly within it. To discuss the application of the second law to biological systems, we must first define those systems and their surroundings.

The reacting system is the collection of matter that is undergoing a particular chemical or physical process; it may be an organism, a cell, or two reacting compounds. The reacting system and its surroundings together constitute the universe. In the laboratory, some chemical or physical processes can be carried out in isolated or closed systems, in which no material or energy is exchanged with the surroundings. Living cells and organisms, however, are open systems, exchanging both material and energy with their surroundings; living systems are never at equilibrium with their surroundings, and the constant transactions between system and surroundings explain how organisms can create order within themselves while operating within the second law of thermodynamics.

In Chapter 1 (p. 22) we defined three thermodynamic quantities that describe the energy changes occurring in a chemical reaction:

- **Gibbs Free Energy**, \( G \), expresses the amount of energy capable of doing work during a reaction at constant temperature and pressure. When a reaction proceeds with the release of free energy (that is, when the system changes so as to possess less free energy), the free-energy change, \( \Delta G \), has a negative value and the reaction is said to be exergonic. In endergonic reactions, the system gains free energy and \( \Delta G \) is positive.

- **Enthalpy**, \( H \), is the heat content of the reacting system. It reflects the number and kinds of chemical bonds in the reactants and products. When a chemical reaction releases heat, it is said to be exothermic; the heat content of the products is less than that of the reactants and \( \Delta H \) has, by convention, a negative value. Reacting systems that take up heat from their surroundings are endothermic and have positive values of \( \Delta H \).

- **Entropy**, \( S \), is a quantitative expression for the randomness or disorder in a system (see Box 1–3). When the products of a reaction are less complex and more disordered than the reactants, the reaction is said to proceed with a gain in entropy.

The units of \( \Delta G \) and \( \Delta H \) are joules/mole or calories/mole (recall that 1 cal = 4.184 J); units of entropy are joules/mole · Kelvin (J/mol · K) (Table 13–1).

Under the conditions existing in biological systems (including constant temperature and pressure), changes in free energy, enthalpy, and entropy are related to each other quantitatively by the equation

\[
\Delta G = \Delta H - T\Delta S
\]  

(13–1)
in which ΔG is the change in Gibbs free energy of the reacting system, ΔH is the change in enthalpy of the system, T is the absolute temperature, and ΔS is the change in entropy of the system. By convention, ΔS has a positive sign when entropy increases and ΔH, as noted above, has a negative sign when heat is released by the system to its surroundings. Either of these conditions, which are typical of energetically favorable processes, tend to make ΔG negative. In fact, ΔG of a spontaneously reacting system is always negative.

The second law of thermodynamics states that the entropy of the universe increases during all chemical and physical processes, but it does not require that the entropy increase take place in the reacting system itself. The order produced within cells as they grow and divide is more than compensated for by the disorder they create in their surroundings in the course of growth and division (see Box 1-3, case 2). In short, living organisms preserve their internal order by taking from the surroundings free energy in the form of nutrients or sunlight, and returning to their surroundings an equal amount of energy as heat and entropy.

### Cells Require Sources of Free Energy

Cells are isothermal systems—they function at essentially constant temperature (and also function at constant pressure). Heat flow is not a source of energy for cells, because heat can do work only as it passes to a zone or object at a lower temperature. The energy that cells can and must use is free energy, described by the Gibbs free-energy function G, which allows prediction of the direction of chemical reactions, their exact equilibrium position, and the amount of work they can (in theory) perform at constant temperature and pressure. Heterotrophic cells acquire free energy from nutrient molecules, and photosynthetic cells acquire it from absorbed solar radiation. Both kinds of cells transform this free energy into ATP and other energy-rich compounds capable of providing energy for biological work at constant temperature.

### Standard Free-Energy Change Is Directly Related to the Equilibrium Constant

The composition of a reacting system (a mixture of chemical reactants and products) tends to continue changing until equilibrium is reached. At the equilibrium concentration of reactants and products, the rates of the forward and reverse reactions are exactly equal and no further net change occurs in the system. The concentrations of reactants and products at equilibrium define the equilibrium constant, K_{eq} (p. 24). In the general reaction aA + bB ⇌ cC + dD, where a, b, c, and d are the number of molecules of A, B, C, and D participating, the equilibrium constant is given by

$$K_{eq} = \frac{[C]^c[D]^d}{[A]^a[B]^b}$$

where [A], [B], [C], and [D] are the molar concentrations of the reaction components at the point of equilibrium.

When a reacting system is not at equilibrium, the tendency to move toward equilibrium represents a driving force, the magnitude of which can be expressed as the free-energy change for the reaction, ΔG. Under standard conditions (298 K = 25°C), when reactants and products are initially present at 1 M concentrations or, for gases, at partial pressures of 101.3 kilopascals (kPa), or 1 atm, the force driving the system toward equilibrium is defined as the standard free-energy change, ΔG°. By this definition, the standard state for reactions that involve hydrogen ions is [H^+] = 1 M, or pH 0. Most biochemical reactions, however, occur in well-buffered aqueous solutions near pH 7; both the pH and the concentration of water (55.5 M) are essentially constant.

**KEY CONVENTION:** For convenience of calculations, biochemists define a standard state different from that used in chemistry and physics: in the biochemical standard state, [H^+] is 10^{-7} M (pH 7) and [H_2O] is 55.5 M. For reactions that involve Mg^{2+} (which include most of those with ATP as a reactant), [Mg^{2+}] in solution is commonly taken to be constant at 1 mM.

Physical constants based on this biochemical standard state are called **standard transformed constants** and are written with a prime (such as ΔG°' and K_{eq}') to distinguish them from the untransformed constants used by chemists and physicists. (Note that most other textbooks use the symbol ΔG°" rather than ΔG°'. Our use of ΔG°', recommended by an international committee of chemists and biochemists, is intended to emphasize that the transformed free energy, G', is the criterion for equilibrium.) For simplicity, we will hereafter refer to these transformed constants as **standard free-energy changes**.

KEY CONVENTION: In another simplifying convention used by biochemists, when $H_2O$, $H^+$, and/or $Mg^{2+}$ are reactants or products, their concentrations are not included in equations such as Equation 13-2 but are instead incorporated into the constants $K'_{eq}$ and $\Delta G'^o$. 

Just as $K'_{eq}$ is a physical constant characteristic for each reaction, so too is $\Delta G'^o$ a constant. As we noted in Chapter 6, there is a simple relationship between $K'_{eq}$ and $\Delta G'^o$:

$$\Delta G'^o = -RT \ln K'_ {eq} \quad (13-3)$$

The standard free-energy change of a chemical reaction is simply an alternative mathematical way of expressing its equilibrium constant. Table 13-2 shows the relationship between $\Delta G'^o$ and $K'_ {eq}$. If the equilibrium constant for a given chemical reaction is 1.0, the standard free-energy change of that reaction is 0.0 (the natural logarithm of 1.0 is zero). If $K'_ {eq}$ of a reaction is greater than 1.0, its $\Delta G'^o$ is negative. If $K'_ {eq}$ is less than 1.0, $\Delta G'^o$ is positive. Because the relationship between $\Delta G'^o$ and $K'_ {eq}$ is exponential, relatively small changes in $\Delta G'^o$ correspond to large changes in $K'_ {eq}$.

It may be helpful to think of the standard free-energy change in another way. $\Delta G'^o$ is the difference between the free-energy content of the products and the free-energy content of the reactants, under standard conditions. When $\Delta G'^o$ is negative, the products contain less free energy than the reactants and the reaction will proceed spontaneously under standard conditions; all chemical reactions tend to go in the direction that results in a decrease in the free energy of the system. A positive value of $\Delta G'^o$ means that the products of the reaction contain more free energy than the reactants, and this reaction will tend to go in the reverse direction if we start with 1.0 m concentrations of all components (standard conditions). Table 13-3 summarizes these points.

WORKED EXAMPLE 13-1 Calculation of $\Delta G'^o$

Calculate the standard free-energy change of the reaction catalyzed by the enzyme phosphoglucomutase

$$\text{Glucose 1-phosphate} \rightleftharpoons \text{glucose 6-phosphate}$$

given that, starting with 20 mM glucose 1-phosphate and no glucose 6-phosphate, the final equilibrium mixture at 25 °C and pH 7.0 contains 1.0 mM glucose 1-phosphate and 19 mM glucose 6-phosphate. Does the reaction in the direction of glucose 6-phosphate formation proceed with a loss or a gain of free energy?

Solution: First we calculate the equilibrium constant:

$$K'_ {eq} = \frac{[\text{glucose 6-phosphate}]}{[\text{glucose 1-phosphate}]} = \frac{19 \text{ mM}}{1.0 \text{ mM}} = 19$$

We can now calculate the standard free-energy change:

$$\Delta G'^o = -RT \ln K'_ {eq} = -[8.315 \text{ J/mol} \cdot \text{K} / 298 \text{ K} \ln 19] = -7.3 \text{ kJ/mol}$$

Because the standard free-energy change is negative, the conversion of glucose 1-phosphate to glucose 6-phosphate proceeds with a loss (release) of free energy. (For the reverse reaction, $\Delta G'^o$ has the same magnitude but the opposite sign.)

Table 13-4 gives the standard free-energy changes for some representative chemical reactions. Note that hydrolysis of simple esters, amides, peptides, and glycosides, as well as rearrangements and eliminations, proceed with relatively small standard free-energy changes, whereas hydrolysis of acid anhydrides is accompanied by relatively large decreases in standard free energy. The complete oxidation of organic compounds such as glucose or palmitate to CO$_2$ and H$_2$O, which in cells requires many steps, results in very large decreases in standard free energy. However, standard free-energy

*Although joules and kilojoules are the standard units of energy and are used throughout this text, biochemists and nutritionists sometimes express $\Delta G'^o$ values in kilocalories per mole. We have therefore included values in both kilojoules and kilocalories in this table and in Tables 13-4 and 13-6. To convert kilojoules to kilocalories, divide the number of kilojoules by 4.184.
changes such as those in Table 13-4 indicate how much free energy is available from a reaction under standard conditions. To describe the energy released under the conditions existing in cells, an expression for the actual free-energy change is essential.

Actual Free-Energy Changes Depend on Reactant and Product Concentrations

We must be careful to distinguish between two different quantities: the actual free-energy change, $\Delta G$, and the standard free-energy change, $\Delta G^\circ$. Each chemical reaction has a characteristic standard free-energy change, which may be positive, negative, or zero, depending on the equilibrium constant of the reaction. The standard free-energy change tells us in which direction and how far a given reaction must go to reach equilibrium when the initial concentration of each component is 1.0 M, the pH is 7.0, the temperature is 25 °C, and the pressure is 101.3 kPa (1 atm). Thus $\Delta G^\circ$ is a constant: it has a characteristic, unchanging value for a given reaction. But the actual free-energy change, $\Delta G$, is a function of reactant and product concentrations and of the temperature prevailing during the reaction, none of which will necessarily match the standard conditions as defined above. Moreover, the $\Delta G$ of any reaction proceeding spontaneously toward its equilibrium is always negative, becomes less negative as the reaction proceeds, and is zero at the point of equilibrium, indicating that no more work can be done by the reaction.

$\Delta G$ and $\Delta G^\circ$ for any reaction $aA + bB \rightarrow cC + dD$ are related by the equation

$$\Delta G = \Delta G^\circ + RT \ln \frac{[C][D]^{d}}{[A]^{a}[B]^{b}}$$

in which the terms in red are those actually prevailing in the system under observation. The concentration terms in this equation express the effects commonly called mass action, and the term $[C][D]^{d}/[A]^{a}[B]^{b}$ is called the mass-action ratio, $Q$. Thus Equation 13-4 can be expressed as $\Delta G = \Delta G^\circ + RT \ln Q$. As an example, let us suppose that the reaction $A + B \rightarrow C + D$ is taking place under the standard conditions of temperature (25 °C) and pressure (101.3 kPa) but that the concentrations of A, B, C, and D are not equal and none of the components is present at the standard concentration of 1.0 M. To determine the actual free-energy change, $\Delta G$, under these nonstandard conditions of concentration as the

</table>
reaction proceeds from left to right, we simply enter the actual concentrations of A, B, C, and D in Equation 13-4; the values of \( R, \frac{T}{RT} \), and \( \Delta G'\circ \) are the standard values. \( \Delta G \) is negative and approaches zero as the reaction proceeds, because the actual concentrations of A and B decrease and the concentrations of C and D increase. Notice that when a reaction is at equilibrium—when there is no force driving the reaction in either direction and \( \Delta G \) is zero—Equation 13-4 reduces to

\[
0 = \Delta G = \Delta G'\circ + \frac{RT}{K_{eq}} \ln \left( \frac{[C]_{eq}[D]_{eq}}{[A]_{eq}[B]_{eq}} \right)
\]

or

\[
\Delta G'\circ = -RT \ln K_{eq}
\]

which is the equation relating the standard free-energy change and equilibrium constant (Eqn 13-3).

The criterion for spontaneity of a reaction is the value of \( \Delta G \), not \( \Delta G'\circ \). A reaction with a positive \( \Delta G'\circ \) can go in the forward direction if \( \Delta G \) is negative. It is possible if the term \( RT \ln ([\text{products}]/[\text{reactants}] \right) \) in Equation 13-4 is negative and has a larger absolute value than \( \Delta G'\circ \). For example, the immediate removal of the products of a reaction can keep the ratio \([\text{products}]/[\text{reactants}] \) well below 1, such that the term \( RT \ln ([\text{products}]/[\text{reactants}] \right) \) has a large, negative value. \( \Delta G'\circ \) and \( \Delta G \) are expressions of the maximum amount of free energy that a given reaction can theoretically deliver—an amount of energy that could be realized only if a perfectly efficient device were available to trap or harness it. Given that no such device is possible (some energy is always lost to entropy during any process), the amount of work done by the reaction at constant temperature and pressure is always less than the theoretical amount.

Another important point is that some thermodynamically favorable reactions (that is, reactions for which \( \Delta G'\circ \) is large and negative) do not occur at measurable rates. For example, combustion of firewood to CO\(_2\) and H\(_2\)O is very favorable thermodynamically, but firewood remains stable for years because the activation energy (see Figs 6-2 and 6-3) for the combustion reaction is higher than the energy available at room temperature. If the necessary activation energy is provided (with a lighted match, for example), combustion will begin, converting the wood to the more stable products CO\(_2\) and H\(_2\)O and releasing energy as heat and light. The heat released by this exothermic reaction provides the activation energy for combustion of neighboring regions of the firewood; the process is self-perpetuating.

In living cells, reactions that would be extremely slow if uncataylized are caused to proceed not by supplying additional heat but by lowering the activation energy through use of an enzyme. An enzyme provides an alternative reaction pathway with a lower activation energy than the uncatalyzed reaction, so that at room temperature a large fraction of the substrate molecules have enough thermal energy to overcome the activation barrier, and the reaction rate increases dramatically. The free-energy change for a reaction is independent of the pathway by which the reaction occurs; it depends only on the nature and concentration of the initial reactants and the final products. Enzymes cannot, therefore, change equilibrium constants; but they can and do increase the rate at which a reaction proceeds in the direction dictated by thermodynamics (see Section 6.2).

### Standard Free-Energy Changes Are Additive

In the case of two sequential chemical reactions, \( A \rightleftharpoons B \) and \( B \rightleftharpoons C \), each reaction has its own equilibrium constant and each has its characteristic standard free-energy change, \( \Delta G'\circ1 \) and \( \Delta G'\circ2 \). As the two reactions are sequential, B cancels out to give the overall reaction \( A \rightleftharpoons C \), which has its own equilibrium constant and thus its own standard free-energy change, \( \Delta G'\circ\text{total} \). The \( \Delta G'\circ \) values of sequential chemical reactions are additive. For the overall reaction \( A \rightleftharpoons C \), \( \Delta G'\circ\text{total} \) is the sum of the individual standard free-energy changes, \( \Delta G'\circ1 \) and \( \Delta G'\circ2 \), of the two reactions:

\[
\Delta G'\circ\text{total} = \Delta G'\circ1 + \Delta G'\circ2.
\]

This principle of bioenergetics explains how a thermodynamically unfavorable (endergonic) reaction can be driven in the forward direction by coupling it to a highly exergonic reaction through a common intermediate. For example, the synthesis of glucose 6-phosphate is the first step in the utilization of glucose by many organisms:

\[
\text{Glucose} + \text{P}_i \rightarrow \text{glucose 6-phosphate} + \text{H}_2\text{O} \\
\Delta G'\circ = 13.8 \text{ kJ/mol}
\]

The positive value of \( \Delta G'\circ \) predicts that under standard conditions the reaction will tend not to proceed spontaneously in the direction written. Another cellular reaction, the hydrolysis of ATP to ADP and P\(_i\), is very exergonic:

\[
\text{ATP} + \text{H}_2\text{O} \rightarrow \text{ADP} + \text{P}_i \\
\Delta G'\circ = -30.5 \text{ kJ/mol}
\]

These two reactions share the common intermediates P\(_i\) and H\(_2\)O and may be expressed as sequential reactions:

\[
\begin{align*}
\text{(1) } \text{Glucose} + \text{P}_i & \rightarrow \text{glucose 6-phosphate} + \text{H}_2\text{O} \\
\text{(2) } \text{ATP} + \text{H}_2\text{O} & \rightarrow \text{ADP} + \text{P}_i
\end{align*}
\]

**Sum:** \( \text{ATP} + \text{glucose} \rightarrow \text{ADP} + \text{glucose 6-phosphate} \)

The overall standard free-energy change is obtained by adding the \( \Delta G'\circ \) values for individual reactions:

\[
\Delta G' = 13.8 \text{ kJ/mol} + (-30.5 \text{ kJ/mol}) = -16.7 \text{ kJ/mol}
\]

The overall reaction is exergonic. In this case, energy stored in ATP is used to drive the synthesis of glucose 6-phosphate, even though its formation from glucose and inorganic phosphate (P\(_i\)) is endergonic. The pathway of glucose 6-phosphate formation from glucose by phosphoryl transfer from ATP is different from reactions
(1) and (2) above, but the net result is the same as the sum of the two reactions. In thermodynamic calculations, all that matters is the state of the system at the beginning of the process and its state at the end; the route between the initial and final states is immaterial.

We have said that $\Delta G^\circ$ is a way of expressing the equilibrium constant for a reaction. For reaction (1) above,

$$K_{eq}^1 = \frac{[\text{glucose 6-phosphate}]}{[\text{glucose}][\text{P}]} = 3.9 \times 10^{-3} \text{M}^{-1}$$

Notice that H$_2$O is not included in this expression, as its concentration (55.5 M) is assumed to remain unchanged by the reaction. The equilibrium constant for the hydrolysis of ATP is

$$K_{eq}^2 = \frac{[\text{ADP}][\text{P}]}{[\text{ATP}]} = 2.0 \times 10^5 \text{M}$$

The equilibrium constant for the two coupled reactions is

$$K_{eq} = \frac{[\text{glucose 6-phosphate}][\text{ADP}][\text{P}]}{[\text{glucose}][\text{P}][\text{ATP}]} = (3.9 \times 10^{-3} \text{M}^{-1})(2.0 \times 10^5 \text{M})$$

$$= 7.8 \times 10^2$$

This calculation illustrates an important point about equilibrium constants: although the $\Delta G^\circ$ values for two reactions that sum to a third, overall reaction are additive, the $K_{eq}$ for the overall reaction is the product of the individual $K_{eq}$ values for the two reactions. Equilibrium constants are multiplicative. By coupling ATP hydrolysis to glucose 6-phosphate synthesis, the $K_{eq}$ for formation of glucose 6-phosphate from glucose has been raised by a factor of about $2 \times 10^5$.

This common-intermediate strategy is employed by all living cells in the synthesis of metabolic intermediates and cellular components. Obviously, the strategy works only if compounds such as ATP are continuously available. In the following chapters we consider several of the most important cellular pathways for producing ATP.

**SUMMARY 13.1 Bioenergetics and Thermodynamics**

- Living cells constantly perform work. They require energy for maintaining their highly organized structures, synthesizing cellular components, generating electric currents, and many other processes.
- Bioenergetics is the quantitative study of energy relationships and energy conversions in biological systems. Biological energy transformations obey the laws of thermodynamics.
- All chemical reactions are influenced by two forces: the tendency to achieve the most stable bonding state (for which enthalpy, $H$, is a useful expression) and the tendency to achieve the highest degree of randomness, expressed as entropy, $S$. The net driving force in a reaction is $\Delta G$, the free-energy change, which represents the net effect of these two factors: $\Delta G = \Delta H - T\Delta S$.
- The standard transformed free-energy change, $\Delta G^\circ$, is a physical constant that is characteristic for a given reaction and can be calculated from the equilibrium constant for the reaction: $\Delta G^\circ = -RT \ln K_{eq}$.
- The actual free-energy change, $\Delta G$, is a variable that depends on $\Delta G^\circ$ and on the concentrations of reactants and products: $\Delta G = \Delta G^\circ + RT \ln ([\text{products}]/[\text{reactants}])$.
- When $\Delta G$ is large and negative, the reaction tends to go in the forward direction; when $\Delta G$ is large and positive, the reaction tends to go in the reverse direction; and when $\Delta G = 0$, the system is at equilibrium.
- The free-energy change for a reaction is independent of the pathway by which the reaction occurs. Free-energy changes are additive; the net chemical reaction that results from successive reactions sharing a common intermediate has an overall free-energy change that is the sum of the $\Delta G$ values for the individual reactions.

**13.2 Chemical Logic and Common Biochemical Reactions**

The biological energy transductions we are concerned with in this book are chemical reactions. Cellular chemistry does not encompass every kind of reaction learned in a typical organic chemistry course. Which reactions take place in biological systems and which do not is determined by (1) their relevance to that particular metabolic system and (2) their rates. Both considerations play major roles in shaping the metabolic pathways we consider throughout the rest of the book. A relevant reaction is one that makes use of an available substrate and converts it to a useful product. However, even a potentially relevant reaction may not occur. Some chemical transformations are too slow (have activation energies that are too high) to contribute to living systems even with the aid of powerful enzyme catalysts. The reactions that do occur in cells represent a toolbox that evolution has used to construct metabolic pathways that circumvent the "impossible" reactions. Learning to recognize the plausible reactions can be a great aid in developing a command of biochemistry.

Even so, the number of metabolic transformations taking place in a typical cell can seem overwhelming. Most cells have the capacity to carry out thousands of specific, enzyme-catalyzed reactions: for example, transformation of a simple nutrient such as glucose into amino acids, nucleotides, or lipids; extraction of energy from fuels by oxidation; and polymerization of monomeric subunits into macromolecules.
To study these reactions, some organization is essential. There are patterns within the chemistry of life; you do not need to learn every individual reaction to comprehend the molecular logic of biochemistry. Most of the reactions in living cells fall into one of five general categories: (1) reactions that make or break carbon–carbon bonds; (2) internal rearrangements, isomerizations, and eliminations; (3) free-radical reactions; (4) group transfers; and (5) oxidation-reductions. We discuss each of these in more detail below and refer to some examples of each type in later chapters. Note that the five reaction types are not mutually exclusive; for example, an isomerization reaction may involve a free-radical intermediate.

Before proceeding, however, we should review two basic chemical principles. First, a covalent bond consists of a shared pair of electrons, and the bond can be broken in two general ways (Fig. 13-1). In homolytic cleavage, each atom leaves the bond as a radical, carrying one unpaired electron. In heterolytic cleavage, which is more common, one atom retains both bonding electrons. The species most often generated when C—C and C—H bonds are cleaved are illustrated in Figure 13-1. Carbanions, carbocations, and hydride ions are highly unstable; this instability shapes the chemistry of these ions, as we shall see.

The second basic principle is that many biochemical reactions involve interactions between nucleophiles (functional groups rich in and capable of donating electrons) and electrophiles (electron-deficient functional groups that seek electrons). Nucleophiles combine with and give up electrons to electrophiles. Common biological nucleophiles and electrophiles are shown in Figure 13-2. Note that a carbon atom can act as either a nucleophile or an electrophile, depending on which bonds and functional groups surround it.

Reactions That Make or Break Carbon–Carbon Bonds Heterolytic cleavage of a C—C bond yields a carbanion and a carbocation (Fig. 13-1). Conversely, the formation of a C—C bond involves the combination of a nucleophilic carbanion and an electrophilic carbocation. Carbanions and carbocations are generally so unstable that their formation as reaction intermediates can be energetically inaccessible even with enzyme catalysts. For the purpose of cellular biochemistry they are impossible reactions—unless chemical assistance is provided in the form of functional groups containing electronegative atoms (O and

---

\[ \text{C—C} \rightarrow \text{C}^- \cdot \cdot \text{C}^- \]

Carbanion Carbanion

**Nucleophiles**

- \( \text{O}^- \)
  - Negatively charged oxygen (as in an unprotonated hydroxyl group or an ionized carboxylic acid)
- \( \text{Si}^- \)
  - Negatively charged sulfhydryl
- \( \text{C}^- \)
  - Carbanion
- \( \text{N}^- \)
  - Uncharged amine group
- \( \text{Imidazole} \)
  - Imidazole
- \( \text{H—O}^- \)
  - Hydroxide ion

**Electrophiles**

- \( \text{R—C}^+ \)
  - Carbon atom of a carbonyl group (the more electronegative oxygen of the carbonyl group pulls electrons away from the carbon)
- \( \text{R—C—N}^- \)
  - Pronated imine group (activated for nucleophilic attack at the carbon by protonation of the imine)
- \( \text{O—P—O}^- \)
  - Phosphorus of a phosphate group
- \( \text{H}^+ \)
  - Proton

**FIGURE 13-1** Two mechanisms for cleavage of a C—C or C—H bond.

In a homolytic cleavage, each atom keeps one of the bonding electrons, resulting in the formation of carbon radicals (carbons having unpaired electrons) or uncharged hydrogen atoms. In a heterolytic cleavage, one of the atoms retains both bonding electrons. This can result in the formation of carbanions, carbocations, protons, or hydride ions.
N) that can alter the electronic structure of adjacent carbon atoms so as to stabilize and facilitate the formation of carbanion and carbocation intermediates.

Carbonyl groups are particularly important in the chemical transformations of metabolic pathways. The carbon of a carbonyl group has a partial positive charge due to the electron-withdrawing property of the carbonyl oxygen, and thus is an electrophilic carbon (Fig. 13-3a). A carbonyl group can thus facilitate the formation of a carbanion on an adjoining carbon by delocalizing the carbanion’s negative charge (Fig. 13-3b). An imine (C=NH₂) group can serve a similar function (Fig. 13-3c). The capacity of carbonyl and imine groups to delocalize electrons can be further enhanced by a general acid catalyst or by a metal ion such as Mg²⁺ (Fig. 13-3d; see also Figs 6–21 and 6–23).

The importance of a carbonyl group is evident in three major classes of reactions in which C—C bonds are formed or broken (Fig. 13-4): aldol condensations, Claisen ester condensations, and decarboxylations. In each type of reaction, a carbanion intermediate is stabilized by a carbonyl group, and in many cases another carbonyl provides the electrophile with which the nucleophilic carbanion reacts.

An **aldol condensation** is a common route to the formation of a C—C bond; the aldolase reaction, which converts a six-carbon compound to two three-carbon compounds in glycolysis, is an aldol condensation in reverse (see Fig. 14–5). In a **Claisen condensation**, the carbanion is stabilized by the carbonyl of an adjacent thioester; an example is the synthesis of citrate in the citric acid cycle (see Fig. 16–9). Decarboxylation also commonly involves the formation of a carbanion stabilized by a carbonyl group; the acetoacetate decarboxylase reaction that occurs in the formation of ketone bodies during fatty acid catabolism provides an example (see Fig. 17–18). Entire metabolic pathways are organized around the introduction of a carbonyl group in a particular location so that a nearby carbon–carbon bond can be formed or cleaved. In some reactions, an imine or a specialized cofactor such as pyridoxal phosphate plays the electron-withdrawing role of the carbonyl group.

The carbocation intermediate occurring in some reactions that form or cleave C—C bonds is generated by the elimination of a very good leaving group, such as pyrophosphate (see Group Transfer Reactions below). An example is the prenyltransferase reaction (Fig. 13-5), an early step in the pathway of cholesterol biosynthesis.

**Internal Rearrangements, Isomerizations, and Eliminations** Another common type of cellular reaction is an intramolecular rearrangement in which redistribution of electrons results in alterations of many different types without a change in the overall oxidation state of the molecule. For example, different groups in a molecule may undergo oxidation-reduction, with no net change in oxidation state of the molecule; groups at a double bond may undergo a cis-trans rearrangement; or the positions of double bonds may be transposed. An example of an isomerization entailing oxidation-reduction is the formation of fructose 6-phosphate from glucose.
6-phosphate in glycolysis (Fig. 13–6; this reaction is discussed in detail in Chapter 14): C-1 is reduced (aldehyde to alcohol) and C-2 is oxidized (alcohol to ketone). Figure 13–6b shows the details of the electron movements in this type of isomerization. A cis-trans rearrangement is illustrated by the prolyl cis-trans isomerase reaction in the folding of certain proteins (see Fig. 4–7b). A simple transposition of a C≡C bond occurs during metabolism of oleic acid, a common fatty acid (see Fig. 17–9). Some spectacular examples of double-bond repositioning occur in the biosynthesis of cholesterol (see Fig. 21–33).

An example of an elimination reaction that does not affect overall oxidation state is the loss of water from an alcohol, resulting in the introduction of a C≡C bond:

\[
\begin{align*}
\text{R}-\text{C}≡\text{C}-\text{R}_1 & \xrightarrow{\text{H}_2\text{O}} \text{R}-\text{C}≡\text{C}-\text{H} \\
\text{R}_2 & \quad \text{H} \\
\end{align*}
\]

Similar reactions can result from eliminations in amines.

**Free-Radical Reactions** Once thought to be rare, the homolytic cleavage of covalent bonds to generate free radicals has now been found in a wide range of biochemical processes. These include: isomerizations that make use of adenosylcobalamin (vitamin B₁₂) or S-adenosylmethionine, which are initiated with a 5'-deoxyadenosyl radical (see the methylmalonyl-CoA mutase reaction in Box 17–2); certain radical-initiated decarboxylation reactions (Fig. 13–7); some reductase reactions, such as that catalyzed by ribonucleotide reductase (see Fig. 22–41); and some rearrangement reactions, such as that catalyzed by DNA photolyase (see Fig. 25–27).

---

**FIGURE 13–5 Carbocations in carbon–carbon bond formation.** In one of the early steps in cholesterol biosynthesis, the enzyme prenyl transferase catalyzes condensation of isopentenyl pyrophosphate and dimethylallyl pyrophosphate to form geranyl pyrophosphate (see Fig. 21–36). The reaction is initiated by elimination of pyrophosphate from the dimethylallyl pyrophosphate to generate a carbocation, stabilized by resonance with the adjacent C≡C bond.

**FIGURE 13–6 Isomerization and elimination reactions.** (a) The conversion of glucose 6-phosphate to fructose 6-phosphate, a reaction of sugar metabolism catalyzed by phosphohexose isomerase. (b) This reaction proceeds through an enediol intermediate. The curved blue arrows represent movement of bonding electron pairs. Pink screens indicate nucleophilic groups; blue, electrophilic.
FIGURE 13-7 A free radical-initiated decarboxylation reaction. The biosynthesis of heme (see Fig. 22–24) in Escherichia coli includes a decarboxylation step in which propionyl side chains on the coproporphyrinogen III intermediate are converted to the vinyl side chains of protoporphyrinogen IX. When the bacteria are grown anaerobically, the enzyme oxygen-independent coproporphyrinogen III oxidase, also called HemN protein, promotes decarboxylation via the free-radical mechanism shown here. The acceptor of the released electron is not known. For simplicity, only the relevant portions of the large coproporphyrinogen III and protoporphyrinogen molecules are shown; the entire structures are given in Figure 22–24. When E. coli are grown in the presence of oxygen, this reaction is an oxidative decarboxylation and is catalyzed by a different enzyme.

Group Transfer Reactions The transfer of acyl, glycosyl, and phosphoryl groups from one nucleophile to another is common in living cells. Acyl group transfer generally involves the addition of a nucleophile to the carbonyl carbon of an acyl group to form a tetrahedral intermediate:

The chymotrypsin reaction is one example of acyl group transfer (see Fig. 6–21). Glycosyl group transfers involve nucleophilic substitution at C-1 of a sugar ring, which is the central atom of an acetal. In principle, the substitution could proceed by an S_N 1 or S_N 2 pathway, as described in Figure 6–25 for the enzyme lysozyme.

Phosphoryl group transfers play a special role in metabolic pathways, and these transfer reactions are discussed in detail in Section 13.3. A general theme in metabolism is the attachment of a good leaving group to a metabolic intermediate to “activate” the intermediate for subsequent reaction. Among the better leaving groups in nucleophilic substitution reactions are inorganic orthophosphate (the ionized form of H_3PO_4 at neutral pH, a mixture of H_2PO_4^- and HPO_4^{2-}, commonly abbreviated P) and inorganic pyrophosphate (P_2O_7^{4-}, abbreviated PP); esters and anhydrides of phosphoric acid are effectively activated for reaction. Nucleophilic substitution is made more favorable by the attachment of a phosphoryl group to an otherwise poor leaving group such as —OH. Nucleophilic substitutions in which the phosphoryl group (—PO_3^{3-}) serves as a leaving group occur in hundreds of metabolic reactions.

Phosphorus can form five covalent bonds. The conventional representation of P, (Fig. 13–8a), with three P—O bonds and one P==O bond, is a convenient but

FIGURE 13-8 Alternative ways of showing the structure of inorganic orthophosphate. (a) In one (inadequate) representation, three oxygens are single-bonded to phosphorus, and the fourth is double-bonded, allowing the four different resonance structures shown here. (b) The resonance structures can be represented more accurately by showing all four phosphorus—oxygen bonds with some double-bond character; the hybrid orbitals so represented are arranged in a tetrahedron with P at its center. (c) When a nucleophile Z (in this case, the —OH on C-6 of glucose) attacks ATP, it displaces ADP (W). In this S_N 2 reaction, a pentacovalent intermediate (d) forms transiently.
inaccurate picture. In P₄, four equivalent phosphorus–oxygen bonds share some double-bond character, and the anion has a tetrahedral structure (Fig. 13–8b). Because oxygen is more electronegative than phosphorus, the sharing of electrons is unequal: the central phosphorus bears a partial positive charge and can therefore act as an electrophile. In a great many metabolic reactions, a phosphoryl group (—PO₄³⁻) is transferred from ATP to an alcohol, forming a phosphate ester (Fig. 13–8c), or to a carboxylic acid, forming a mixed anhydride. When a nucleophile attacks the electrophilic phosphoryl atom in ATP, a relatively stable pentacoordinate structure forms as a reaction intermediate (Fig. 13–8d). With departure of the leaving group (ADP), the transfer of a phosphoryl group is complete. The large family of enzymes that catalyze phosphoryl group transfers with ATP as donor are called kinases (Greek kinein, “to move”). Hexokinase, for example, “moves” a phosphoryl group from ATP to glucose.

Phosphoryl groups are not the only groups that activate molecules for reaction. Thioalcohols (thiols), in which the oxygen atom of an alcohol is replaced with a sulfur atom, are also good leaving groups. Thiols activate carboxylic acids by forming thioesters (thioesters). In later chapters we discuss several reactions, including those catalyzed by the fatty acyl synthases in lipid synthesis (Fig. 21–2), in which nucleophilic substitution at the carbonyl carbon of a thioester results in transfer of the acyl group to another moiety.

Oxidation-Reduction Reactions

Carbon atoms can exist in five oxidation states, depending on the elements with which they share electrons (Fig. 13–9), and transitions between these states are of crucial importance in metabolism (oxidation-reduction reactions are the topic of Section 13.4). In many biological oxidations, a compound loses two electrons and two hydrogen ions (that is, two hydrogen atoms); these reactions are commonly called dehydrogenations and the enzymes that catalyze them are called dehydrogenases (Fig. 13–10). In some, but not all, biological oxidations, a carbon atom becomes covalently bonded to an oxygen atom. The enzymes that catalyze these oxidations are generally called oxidases or, if the oxygen atom is derived directly from molecular oxygen (O₂), oxygenases.

Every oxidation must be accompanied by a reduction, in which an electron acceptor acquires the electrons removed by oxidation. Oxidation reactions generally release energy (think of camp fires: the compounds in wood are oxidized by oxygen molecules in the air). Most living cells obtain the energy needed for cellular work by oxidizing metabolic fuels such as carbohydrates or fat (photosynthetic organisms can also trap and use the energy of sunlight). The catabolic (energy-yielding) pathways described in Chapters 14 through 19 are oxidative reaction sequences that result in the transfer of electrons from fuel molecules, through a series of electron carriers, to oxygen. The high affinity of O₂ for electrons makes the overall electron-transfer process highly exergonic, providing the energy that drives ATP synthesis—the central goal of catabolism.

Many of the reactions within these five classes are facilitated by cofactors, in the form of coenzymes and metals (vitamin B₁₂, S-adenosylmethionine, folate, nicotinamide, and iron are some examples). Cofactors bind to enzymes—in some cases reversibly, in other cases almost irreversibly—and confer on them the capacity to promote a particular kind of chemistry (p. 184). Most cofactors participate in a narrow range of closely related reactions. In the following chapters, we will introduce and discuss each important cofactor at the point where we first encounter it. The cofactors provide another way to organize the study of biochemical processes, since the reactions facilitated by a given cofactor generally are mechanistically related.

Biochemical and Chemical Equations Are Not Identical

Biochemists write metabolic equations in a simplified way, and this is particularly evident for reactions involving ATP. Phosphorylated compounds can exist in several
ionization states and, as we have noted, the different species can bind Mg$^{2+}$. For example, at pH 7 and 2 mM Mg$^{2+}$, ATP exists in the forms ATP$^4^-$, HATP$^3^-$, H$_2$ATP$^2^-$, MgHATP$^-$, and Mg$_2$ATP. In thinking about the biological role of ATP, however, we are not always interested in all this detail, and so we consider ATP as an entity made up of a sum of species, and we write its hydrolysis as the biochemical equation

$$ATP + H_2O \rightarrow ADP + P_i$$

where ATP, ADP, and P$_i$ are sums of species. The corresponding standard transformed equilibrium constant, $K'_e = [ADP][P_i]/[ATP]$, depends on the pH and the concentration of free Mg$^{2+}$. Note that H$^+$ and Mg$^{2+}$ do not appear in the biochemical equation because they are held constant. Thus a biochemical equation does not necessarily balance H, Mg, or charge, although it does balance all other elements involved in the reaction (C, N, O, and P in the equation above).

We can write a chemical equation that does balance for all elements and for charge. For example, when ATP is hydrolyzed at a pH above 8.5 in the absence of Mg$^{2+}$, the chemical reaction is represented by

$$ATP^4^- + H_2O \rightarrow ADP^3^- + HPO_4^{2-} + H^+$$

The corresponding equilibrium constant, $K'_e = [ADP^3^-][HPO_4^{2-}]/[ATP^4^-]$, depends only on temperature, pressure, and ionic strength.

Both ways of writing a metabolic reaction have value in biochemistry. Chemical equations are needed when we want to account for all atoms and charges in a reaction, as when we are considering the mechanism of a chemical reaction. Biochemical equations are used to determine in which direction a reaction will proceed spontaneously, given a specified pH and [Mg$^{2+}$], or to calculate the equilibrium constant of such a reaction.

Throughout this book we use biochemical equations, unless the focus is on chemical mechanism, and we use values of $\Delta G^\circ$ and $K'_e$, as determined at pH 7 and 1 mM Mg$^{2+}$.

**SUMMARY 13.2 Chemical Logic and Common Biochemical Reactions**

- Living systems make use of a large number of chemical reactions that can be classified into five general types.
- Carbonyl groups play a special role in reactions that form or cleave C–C bonds. Carbanion intermediates are common and are stabilized by adjacent carbonyl groups or, less often, by imines or certain cofactors.
- A redistribution of electrons can produce internal rearrangements, isomerizations, and eliminations.
- Such reactions include intramolecular oxidation-reduction, change in cis-trans arrangement at a double bond, and transposition of double bonds.
- Homolytic cleavage of covalent bonds to generate free radicals occurs in some pathways, such as in certain isomerization, decarboxylation, reductase, and rearrangement reactions.
- Phosphoryl transfer reactions are an especially important type of group transfer in cells, required for the activation of molecules for reactions that would otherwise be highly unfavorable.
- Oxidation-reduction reactions involve the loss or gain of electrons: one reactant gains electrons and is reduced, while the other loses electrons and is oxidized. Oxidation reactions generally release energy and are important in catabolism.

### 13.3 Phosphoryl Group Transfers and ATP

Having developed some fundamental principles of energy changes in chemical systems and reviewed the common classes of reactions, we can now examine the energy cycle in cells and the special role of ATP as the energy currency that links catabolism and anabolism (see Fig. 1-28). Heterotrophic cells obtain free energy in a chemical form by the catabolism of nutrient molecules, and they use that energy to make ATP from ADP and P$_i$. ATP then donates some of its chemical energy to endergonic processes such as the synthesis of metabolic intermediates and macromolecules from smaller precursors, the transport of substances across membranes against concentration gradients, and mechanical motion. This donation of energy from ATP generally involves the covalent participation of ATP in the reaction that is to be driven, with the eventual result that ATP is converted to ADP and P$_i$ or, in some reactions, to AMP and 2 P$_i$. We discuss here the chemical basis for the large free-energy changes that accompany hydrolysis of ATP and other high-energy phosphate compounds, and we show that most cases of energy donation by ATP involve group transfer, not simple hydrolysis of ATP. To illustrate the range of energy transductions in which ATP provides the energy, we consider the synthesis of information-rich macromolecules, the transport of solutes across membranes, and motion produced by muscle contraction.

The Free-Energy Change for ATP Hydrolysis Is Large and Negative

Figure 13-11 summarizes the chemical basis for the relatively large, negative, standard free energy of hydrolysis of ATP. The hydrolytic cleavage of the terminal
Bioenergetics and Biochemical Reaction Types

ATP$^4-$ + $H_2O$ $\rightarrow$ ADP$^{3-}$ + P$_r$ + H$^+$

$\Delta G^\circ$ = -30.5 kJ/mol

The charge separation that results from hydrolysis relieves electrostatic repulsion among the four negative charges on ATP. The product inorganic phosphate (P$_r$) is stabilized by formation of a resonance hybrid, in which each of the four phosphorus-oxygen bonds has the same degree of double-bond character and the hydrogen ion is not permanently associated with any one of the oxygens. Some degree of resonance stabilization also occurs in phosphates involved in ester or anhydride linkages, but fewer resonance forms are possible than for P$_r$.

The product ADP$^{2-}$ immediately ionizes, releasing a proton into a medium of very low [H$^+$] (pH 7). A fourth factor (not shown) that favors ATP hydrolysis is the greater degree of solvation (hydration) of the products P$_r$ and ADP relative to ATP, which further stabilizes the products relative to the reactants immediately ionizes, releasing H$^+$ into a medium of very low [H$^+$] ($\sim$10$^{-7}$ M). Because the concentrations of the direct products of ATP hydrolysis are, in the cell, far below the concentrations at equilibrium (Table 13–5), mass action favors the hydrolysis reaction in the cell.

The free-energy change for ATP hydrolysis is $-30.5$ kJ/mol under standard conditions, but the actual free energy of hydrolysis ($\Delta G$) of ATP in living cells is very different: the cellular concentrations of ATP, ADP, and P$_r$ are not identical and are much lower than the 1.0 M of standard conditions (Table 13–5). Furthermore, Mg$^{2+}$ in the cytosol binds to ATP and ADP (Fig. 13–12), and for most enzymatic reactions that involve ATP as phosphoryl group donor, the true substrate is MgATP$^{2-}$. The relevant $\Delta G^\circ$ is therefore that for MgATP$^{2-}$ hydrolysis. We can calculate $\Delta G$ for ATP hydrolysis using data such as those in Table 13–5. The actual free energy of hydrolysis of ATP under intracellular conditions is often called its phosphorylation potential, $\Delta G_p$.

*For erythrocytes the concentrations are those of the cytosol (human erythrocytes lack a nucleus and mitochondria). In the other types of cells the data are for the entire cell contents, although the cytosol and the mitochondria have very different concentrations of ADP, PCR is phosphocreatine, discussed on p. 510.

This value reflects total concentration; the true value for free ADP may be much lower (p. 503).

**FIGURE 13–11** Chemical basis for the large free-energy change associated with ATP hydrolysis. 1. The charge separation that results from hydrolysis relieves electrostatic repulsion among the four negative charges on ATP. 2. The product inorganic phosphate (P$_r$) is stabilized by formation of a resonance hybrid, in which each of the four phosphorus-oxygen bonds has the same degree of double-bond character and the hydrogen ion is not permanently associated with any one of the oxygens. Some degree of resonance stabilization also occurs in phosphates involved in ester or anhydride linkages, but fewer resonance forms are possible than for P$_r$. 3. The product ADP$^{2-}$ immediately ionizes, releasing H$^+$ into a medium of very low [H$^+$] (pH 7). A fourth factor (not shown) that favors ATP hydrolysis is the greater degree of solvation (hydration) of the products P$_r$ and ADP relative to ATP, which further stabilizes the products relative to the reactants.

**FIGURE 13–12** Mg$^{2+}$ and ATP. Formation of Mg$^{2+}$ complexes partially shields the negative charges and influences the conformation of the phosphate groups in nucleotides such as ATP and ADP.
**WORKED EXAMPLE 13-2  Calculation of $\Delta G_p$**

Calculate the actual free energy of hydrolysis of ATP, $\Delta G_p$, in human erythrocytes. The standard free energy of hydrolysis of ATP is $-30.5 \text{ kJ/mol}$, and the concentrations of ATP, ADP, and P$_i$ in erythrocytes are as shown in Table 13-5. Assume that the pH is 7.0 and the temperature is 37°C (body temperature). What does this reveal about the amount of energy required to synthesize ATP under the same cellular conditions?

**Solution:** The concentrations of ATP, ADP, and P$_i$ in human erythrocytes are 2.25, 0.25, and 1.65 mM, respectively. The actual free energy of hydrolysis of ATP under these conditions is given by the relationship (see Eqn 13-4)

$$\Delta G_p = \Delta G^\circ + RT \ln \left( \frac{[\text{ADP}][\text{P}_i]}{[\text{ATP}]} \right)$$

Substituting the appropriate values we get

$$\Delta G_p = -30.5 \text{ kJ/mol} + \left[ (8.315 \text{ J/mol} \cdot \text{K})(310 \text{ K}) \ln \left( \frac{0.25 \times 10^{-3})(1.65 \times 10^{-3})}{(2.25 \times 10^{-3})} \right) \right]$$

$$= -30.5 \text{ kJ/mol} + (2.58 \text{ kJ/mol}) \ln 1.8 \times 10^{-4}$$

$$= -30.5 \text{ kJ/mol} + (2.58 \text{ kJ/mol})(-8.6)$$

$$= -30.5 \text{ kJ/mol} - 22 \text{ kJ/mol}$$

$$= -52 \text{ kJ/mol}$$

(Note that the final answer has been rounded to the correct number of significant figures (52.5 rounded to 52), following rules for rounding 5 down to the nearest even number to avoid the bias inherent in rounding “up.”) Thus $\Delta G_p$, the actual free-energy change for ATP hydrolysis in the intact erythrocyte ($-52 \text{ kJ/mol}$), is much larger than the standard free-energy change ($-30.5 \text{ kJ/mol}$). By the same token, the free energy required to synthesize ATP from ADP and P$_i$ under the conditions prevailing in the erythrocyte would be 52 kJ/mol.

Because the concentrations of ATP, ADP, and P$_i$ differ from one cell type to another, $\Delta G_p$ for ATP likewise differs among cells. Moreover, in any given cell, $\Delta G_p$ can vary from time to time, depending on the metabolic conditions and how they influence the concentrations of ATP, ADP, P$_i$, and H$^+$ (pH). We can calculate the actual free-energy change for any given metabolic reaction as it occurs in a cell, providing we know the concentrations of all the reactants and products and other factors (such as pH, temperature, and [Mg$^{2+}$]) that may affect the actual free-energy change.

To further complicate the issue, the total concentrations of ATP, ADP, P$_i$, and H$^+$ in a cell may be substantially higher than the free concentrations, which are the thermodynamically relevant values. The difference is due to tight binding of ATP, ADP, and P$_i$ to cellular proteins. For example, the free [ADP] in resting muscle has been variously estimated at between 1 and 37 $\mu$M. Using the value 25 $\mu$M in Worked Example 13-2, we would get a $\Delta G_p$ of $-64 \text{ kJ/mol}$. Calculation of the exact value of $\Delta G_p$, however, is perhaps less instructive than the generalization we can make about actual free-energy changes: in vivo, the energy released by ATP hydrolysis is greater than the standard free-energy change, $\Delta G^\circ$.

In the following discussions we use the $\Delta G^\circ$ value for ATP hydrolysis because this allows comparison, on the same basis, with the energetics of other cellular reactions. Always keep in mind, however, that in living cells $\Delta G$ is the relevant quantity—for ATP hydrolysis and all other reactions—and may be quite different from $\Delta G^\circ$.

Here we must make an important point about cellular ATP levels. We have shown (and will discuss further) how the chemical properties of ATP make it a suitable form of energy currency in cells. But it is not merely the molecule's intrinsic chemical properties that give it this ability to drive metabolic reactions and other energy-requiring processes. Even more important is that, in the course of evolution, there has been a very strong selective pressure for regulatory mechanisms that hold cellular ATP concentrations far above the equilibrium concentrations for the hydrolysis reaction. When the ATP level drops, not only does the amount of fuel decrease, but the fuel itself loses its potency: $\Delta G$ for its hydrolysis (that is, its phosphorylation potential, $\Delta G_p$) is diminished. As our discussions of the metabolic pathways that produce and consume ATP will show, living cells have developed elaborate mechanisms—often at what might seem to us the expense of efficiency and common sense—to maintain high concentrations of ATP.
FIGURE 13–13 Hydrolysis of phosphoenolpyruvate (PEP). Catalyzed by pyruvate kinase, this reaction is followed by spontaneous tautomerization of the product, pyruvate. Tautomerization is not possible in PEP and thus the products of hydrolysis are stabilized relative to the reactants. Resonance stabilization of P\textsubscript{i} also occurs, as shown in Figure 13–11.

Other Phosphorylated Compounds and Thioesters Also Have Large Free Energies of Hydrolysis

Phosphoenolpyruvate (PEP, Fig. 13–13) contains a phosphate ester bond that undergoes hydrolysis to yield the enol form of pyruvate, and this direct product can immediately tautomerize to the more stable keto form. Because the reactant (PEP) has only one form (enol) and the product (pyruvate) has two possible forms, the product is stabilized relative to the reactant. This is the greatest contributing factor to the high standard free energy of hydrolysis of phosphoenolpyruvate: ΔG° = -61.9 kJ/mol.

Another three-carbon compound, 1,3-bisphosphoglycerate (Fig. 13–14), contains an anhydride bond between the C-1 carboxyl group and phosphoric acid. Hydrolysis of this acyl phosphate is accompanied by a large, negative, standard free-energy change (ΔG° = -49.3 kJ/mol), which can, again, be explained in terms of the structure of reactant and products. When H\textsubscript{2}O is added across the anhydride bond of 1,3-bisphosphoglycerate, one of the direct products, 3-phosphoglyceric acid, can immediately lose a proton to give the carboxylate ion, 3-phosphoglycerate, which has two equally probable resonance forms (Fig. 13–14). Removal of the direct product (3-phosphoglyceric acid) and formation of the resonance-stabilized ion favor the forward reaction.

In phosphocreatine (Fig. 13–15), the P–N bond can be hydrolyzed to generate free creatine and P\textsubscript{i}. The release of P\textsubscript{i} and the resonance stabilization of creatine favor the forward reaction. The standard free-energy change of phosphocreatine hydrolysis is again large, -43.0 kJ/mol.

In all these phosphate-releasing reactions, the several resonance forms available to P\textsubscript{i} (Fig. 13–11) stabilize this product relative to the reactant, contributing to an already negative free-energy change. Table 13–6 lists

FIGURE 13–14 Hydrolysis of 1,3-bisphosphoglycerate. The direct product of hydrolysis is 3-phosphoglyceric acid, with an undissociated carboxylic acid group, but dissociation occurs immediately. This ionization and the resonance structures it makes possible stabilize the product relative to the reactants. Resonance stabilization of P\textsubscript{i} further contributes to the negative free-energy change.

FIGURE 13–15 Hydrolysis of phosphocreatine. Breakage of the P–N bond in phosphocreatine produces creatine, which is stabilized by formation of a resonance hybrid. The other product, P\textsubscript{i}, is also resonance stabilized.

The standard free energies of hydrolysis for some biologically important phosphorylated compounds.

**Thioesters**, in which a sulfur atom replaces the usual oxygen in the ester bond, also have large, negative, standard free energies of hydrolysis. Acetyl-coenzyme A, or acetyl-CoA (Fig. 13–16), is one of many thioesters important in metabolism. The acyl group in these compounds is activated for transacylation, condensation, or oxidation-reduction reactions. Thioesters undergo much less resonance stabilization than do oxygen esters; consequently, the difference in free energy between the reactant and its hydrolysis products, which

**FIGURE 13–16 Hydrolysis of acetyl-coenzyme A.** Acetyl-CoA is a thioester with a large, negative, standard free energy of hydrolysis. Thioesters contain a sulfur atom in the position occupied by an oxygen atom in oxygen esters. The complete structure of coenzyme A (CoA, or CoASH) is shown in Figure 8–38.

are resonance-stabilized, is greater for thioesters than for comparable oxygen esters (Fig. 13–17). In both cases, hydrolysis of the ester generates a carboxylic acid, which can ionize and assume several resonance forms. Together, these factors result in the large, negative $\Delta G^{\circ}$ ($\sim$31.4 kJ/mol) for acetyl-CoA hydrolysis.

To summarize, for hydrolysis reactions with large, negative, standard free-energy changes, the products are more stable than the reactants for one or more of the following reasons: (1) the bond strain in reactants due to electrostatic repulsion is relieved by charge separation, as for ATP; (2) the products are stabilized by ionization, as for ATP, acyl phosphates, and thioesters; (3) the products are stabilized by isomerization (tautomerization), as

**FIGURE 13–17 Free energy of hydrolysis for thioesters and oxygen esters.** The products of both types of hydrolysis reaction have about the same free-energy content (G), but the thioester has a higher free-energy content than the oxygen ester. Orbital overlap between the O and C atoms allows resonance stabilization in oxygen esters; orbital overlap between S and C atoms is poorer and provides little resonance stabilization.
for PEP; and/or (4) the products are stabilized by resonance, as for creatine released from phosphocreatine, carboxylate ion released from acyl phosphates and thioesters, and phosphate (P_i) released from anhydride or ester linkages.

**ATP Provides Energy by Group Transfers, Not by Simple Hydrolysis**

Throughout this book you will encounter reactions or processes for which ATP supplies energy, and the contribution of ATP to these reactions is commonly indicated as in Figure 13–18a, with a single arrow showing the conversion of ATP to ADP and P_i (or, in some cases, ATP to AMP and pyrophosphate, PP_i). When written this way, these reactions of ATP seem to be simple hydrolysis reactions in which water displaces P_i (or PP_i), and one is tempted to say that an ATP-dependent reaction is “driven by the hydrolysis of ATP.” This is not the case; ATP hydrolysis per se usually accomplishes nothing but the liberation of heat, which cannot drive a chemical process in an isothermal system. A single reaction arrow such as that in Figure 13–18a almost invariably represents a two-step process (Fig. 13–18b) in which part of the ATP molecule, a phosphoryl or pyrophosphoryl group or the adenylate moiety (AMP), is first transferred to a substrate molecule or to an amino acid residue in an enzyme, becoming covalently attached to the substrate or the enzyme and raising its free-energy content. Then, in a second step, the phosphate-containing moiety transferred in the first step is displaced, generating P_i, PP_i, or AMP. Thus ATP participates *covalently* in the enzyme-catalyzed reaction to which it contributes free energy.

Some processes do involve direct hydrolysis of ATP (or GTP), however. For example, noncovalent binding of ATP (or GTP), followed by its hydrolysis to ADP (or GDP) and P_i, can provide the energy to cycle some proteins between two conformations, producing mechanical motion. This occurs in muscle contraction (see Fig. 5–31), and in the movement of enzymes along DNA (see Fig. 25–35) or of ribosomes along messenger RNA (see Fig. 27–30). The energy-dependent reactions catalyzed by helicases, RecA protein, and some topoisomerases (Chapter 25) also involve direct hydrolysis of phosphoanhydride bonds. The AAA+ ATPases involved in DNA replication and other processes described in Chapter 25 use ATP hydrolysis to cycle associated proteins between active and inactive forms. GTP-binding proteins that act in signaling pathways directly hydrolyze GTP to drive conformational changes that terminate signals triggered by hormones or by other extracellular factors (Chapter 12).

The phosphate compounds found in living organisms can be divided somewhat arbitrarily into two groups, based on their standard free energies of hydrolysis (Fig. 13–19). “High-energy” compounds have a ΔG° of hydrolysis more negative than -25 kJ/mol; “low-energy” compounds have a less negative ΔG°. Based on this criterion, ATP, with a ΔG° of hydrolysis of -30.5 kJ/mol (-7.3 kcal/mol), is a high-energy compound; glucose 6-phosphate, with a ΔG° of hydrolysis of -13.8 kJ/mol (-3.3 kcal/mol), is a low-energy compound.

The term “high-energy phosphate bond,” long used by biochemists to describe the P—O bond broken in hydrolysis reactions, is incorrect and misleading as it wrongly suggests that the bond itself contains the energy. In fact, the breaking of all chemical bonds requires an input of energy. The free energy released by hydrolysis of phosphate compounds does not come from the specific bond that is broken; it results from the products of the reaction having a lower free-energy content than the reactants. For simplicity, we will sometimes use the term “high-energy phosphate compound” when referring to ATP or other phosphate compounds with a large, negative, standard free energy of hydrolysis.

As is evident from the additivity of free-energy changes of sequential reactions (see Section 13.1), any phosphorylated compound can be synthesized by coupling the synthesis to the breakdown of another phosphorylated compound with a more negative free energy of hydrolysis. For example, because cleavage of P_i from

---

**FIGURE 13–18 ATP hydrolysis in two steps.** (a) The contribution of ATP to a reaction is often shown as a single step, but is almost always a two-step process. (b) Shown here is the reaction catalyzed by ATP-dependent glutamine synthetase. 1. A phosphoryl group is transferred from ATP to glutamate, then 2. the phosphoryl group is displaced by NH3 and released as P_i.
phosphoenolpyruvate releases more energy than is needed to drive the condensation of $P_i$ with ADP, the direct donation of a phosphoryl group from PEP to ADP is thermodynamically feasible:

$$
\Delta G^\circ = -31.4 \text{ kJ/mol}
$$

Notice that while the overall reaction is represented as the algebraic sum of the first two reactions, the overall reaction is actually a third, distinct reaction that does not involve $P_i$; PEP donates a phosphoryl group directly to ADP. We can describe phosphorylated compounds as having a high or low phosphoryl group transfer potential, on the basis of their standard free energies of hydrolysis (as listed in Table 13-6). The phosphoryl group transfer potential of PEP is very high, that of ATP is high, and that of glucose 6-phosphate is low (Fig. 13-19).

Much of catabolism is directed toward the synthesis of high-energy phosphate compounds, but their formation is not an end in itself; they are the means of activating a very wide variety of compounds for further chemical transformation. The transfer of a phosphoryl group to a compound effectively puts free energy into that compound, so that it has more free energy to give up during subsequent metabolic transformations. We described above how the synthesis of glucose 6-phosphate is accomplished by phosphoryl group transfer from ATP. In the next chapter we see how this phosphorylation of glucose activates, or "primes," the glucose for catabolic reactions that occur in nearly every living cell. Because of its intermediate position on the scale of group transfer potential, ATP can carry energy from high-energy phosphate compounds produced by catabolism to compounds such as glucose, converging them into more reactive species. ATP thus serves as the universal energy currency in all living cells.

One more chemical feature of ATP is crucial to its role in metabolism: although in aqueous solution ATP is thermodynamically unstable and is therefore a good phosphoryl group donor, it is kinetically stable. Because of the huge activation energies (200 to 400 kJ/mol) required for uncatalyzed cleavage of its phosphoanhydride bonds, ATP does not spontaneously donate phosphoryl groups to water or to the hundreds of other potential acceptors in the cell. Only when specific enzymes are present to lower the energy of activation does phosphoryl group transfer from ATP proceed. The cell is therefore able to regulate the disposition of the energy carried by ATP by regulating the various enzymes that act on it.

**ATP Donates Phosphoryl, Pyrophosphoryl, and Adenylyl Groups**

The reactions of ATP are generally $S_N2$ nucleophilic displacements (see Section 13.2) in which the nucleophile may be, for example, the oxygen of an alcohol or carboxylate, or a nitrogen of creatine or of the side chain of arginine or histidine. Each of the three phosphates of ATP is susceptible to nucleophilic attack (Fig. 13-20), and each position of attack yields a different type of product.

Nucleophilic attack by an alcohol on the $\gamma$ phosphate (Fig. 13-20a) displaces ADP and produces a new phosphate ester. Studies with $^{18}O$-labeled reactants have shown that the bridge oxygen in the new compound is...
FIGURE 13–20 Nucleophilic displacement reactions of ATP. Any of the three P atoms (α, β, or γ) may serve as the electrophilic target for nucleophilic attack—in this case, by the labeled nucleophile R\textsuperscript{18}O\textsuperscript{−}. The nucleophile may be an alcohol (ROH), a carboxyl group (RCOO\textsuperscript{−}), or a phosphoanhydride (a nucleoside mono- or diphosphate, for example). (a) When the oxygen of the nucleophile attacks the γ position, the bridge oxygen of the product is labeled, indicating that the group transferred from ATP is a phosphoryl (−PO\textsuperscript{2}−), not a phosphate (−PO\textsuperscript{3}−). Phosphoryl group transfer from ATP to glutamate (Fig. 13–18) or to glucose (p. 212) involves attack at the γ position of the ATP molecule.

Attack at the β phosphate of ATP displaces AMP and transfers a pyrophosphoryl (not pyrophosphate) group to the attacking nucleophile (Fig. 13–20b). For example, the formation of 5-phosphoribosyl-1-pyrophosphate (p. 861), a key intermediate in nucleotide synthesis, results from attack of an −OH of the ribose on the β phosphate.

Nucleophilic attack at the α position of ATP displaces PP\textsubscript{i} and transfers adenylate (5′-AMP) as an adenyllyl group (Fig. 13–20c); the reaction is an adenylylation (a-den′-i-lā′-shun, one of the most ungainly words in the biochemical language). Notice that hydrolysis of the α-β phosphoanhydride bond releases considerably more energy (~46 kJ/mol) than hydrolysis of the β-γ bond (~31 kJ/mol) (Table 13–6). Furthermore, the PP\textsubscript{i} formed as a byproduct of the adenylylation is hydrolyzed to two P\textsubscript{i} by the ubiquitous enzyme inorganic pyrophosphatase, releasing 19 kJ/mol and thereby providing a further energy “push” for the adenylylation reaction. In effect, both phosphoanhydride bonds of ATP are split in the overall reaction. Adenylylation reactions are therefore thermodynamically very favorable. When the energy of ATP is used to drive a particularly unfavorable metabolic reaction, adenylylation is often the mechanism of energy coupling. Fatty acid activation is a good example of this energy-coupling strategy.

The first step in the activation of a fatty acid—either for energy-yielding oxidation or for use in the synthesis of more complex lipids—is the formation of its thiol ester (see Fig. 17–5). The direct condensation of a fatty acid with coenzyme A is endergonic, but the formation of fatty acyl-CoA is made exergonic by stepwise removal of two phosphoryl groups from ATP. First, adenylate (AMP) is transferred from ATP to the carboxyl group of the fatty acid, forming a mixed anhydride (fatty acyl adenylate) and liberating PP\textsubscript{i}. The thiol group of coenzyme A then displaces the adenyl group and forms a thioester with the fatty acid. The sum of these two reactions is energetically equivalent to the exergonic hydrolysis of ATP to AMP and PP\textsubscript{i} (ΔG° = −45.6 kJ/mol) and the endergonic formation of fatty acyl-CoA (ΔG° = 31.4 kJ/mol). The formation of fatty acyl-CoA is made energetically favorable by hydrolysis of the PP\textsubscript{i} by inorganic pyrophosphatase. Thus, in the activation of a fatty acid, both phosphoanhydride bonds of ATP are broken. The resulting ΔG° is the sum of the ΔG° values for the breakdown of these bonds, or −45.6 kJ/mol + (−19.2) kJ/mol:

\[
\text{ATP} + 2\text{H}_2\text{O} \rightarrow \text{AMP} + 2\text{PP}_i \quad \Delta G^\circ = -64.8 \text{kJ/mol}
\]

The activation of amino acids before their polymerization into proteins (see Fig. 27–19) is accomplished by an analogous set of reactions in which a transfer RNA molecule takes the place of coenzyme A. An interesting use of the cleavage of ATP to AMP and PP\textsubscript{i} occurs in the firefly, which uses ATP as an energy source to produce light flashes (Box 13–1).

Assembly of Informational Macromolecules Requires Energy

When simple precursors are assembled into high molecular weight polymers with defined sequences (DNA, RNA, proteins), as described in detail in Part III, energy is required both for the condensation of monomeric units and for the creation of ordered sequences. The precursors for DNA and RNA synthesis are nucleoside triphosphates, and polymerization is accompanied by cleavage of the phosphoanhydride linkage between the α and β phosphates, with the release of PP\textsubscript{i} (Fig. 13–20). The moieties transferred to the growing polymer in these reactions are adenylate (AMP), guanylate (GMP), cytidylate (CMP), or uridylate (UMP) for RNA synthesis, and their deoxy analogs (with TMP in place of UMP).
13.3 Phosphoryl Group Transfers and ATP

Bioluminescence requires considerable amounts of energy. In the firefly, ATP is used in a set of reactions that converts chemical energy into light energy. In the 1950s, from many thousands of fireflies collected by children in and around Baltimore, William McElroy and his colleagues at The Johns Hopkins University isolated the principal biochemical components: luciferin, a complex carboxylic acid, and luciferase, an enzyme. The generation of a light flash requires activation of luciferin by an enzymatic reaction involving pyrophosphate cleavage of ATP to form luciferyl adenylate (Fig. 1). In the presence of molecular oxygen and luciferase, the luciferin undergoes a multistep oxidative decarboxylation to oxyluciferin. This process is accompanied by emission of light. The color of the light flash differs with the firefly species and seems to be determined by differences in the structure of the luciferase. Luciferin is regenerated from oxyluciferin in a subsequent series of reactions.

In the laboratory, pure firefly luciferin and luciferase are used to measure minute quantities of ATP by the intensity of the light flash produced. As little as a few picomoles (10⁻¹² mol) of ATP can be measured in this way. An enlightening extension of the studies in luciferase was the cloning of the luciferase gene into tobacco plants. When watered with a solution containing luciferin, the plants glowed in the dark (see Fig. 9–29).

**FIGURE 1** Important components in the firefly bioluminescence cycle.

for DNA synthesis. As noted above, the activation of amino acids for protein synthesis involves the donation of adenylyl groups from ATP, and we shall see in Chapter 27 that several steps of protein synthesis on the ribosome are also accompanied by GTP hydrolysis. In all these cases, the exergonic breakdown of a nucleoside triphosphate is coupled to the endergonic process of synthesizing a polymer of a specific sequence.

**ATP Energizes Active Transport and Muscle Contraction**

ATP can supply the energy for transporting an ion or a molecule across a membrane into another aqueous compartment where its concentration is higher (see Fig. 11–38). Transport processes are major consumers of energy; in human kidney and brain, for example, as much as two-thirds of the energy consumed at rest is used to pump Na⁺ and K⁺ across plasma membranes via the Na⁺K⁺ ATPase. The transport of Na⁺ and K⁺ is driven by cyclic phosphorylation and dephosphorylation of the transporter protein, with ATP as the phosphoryl group donor (see Fig. 11–37). Na⁺-dependent phosphorylation of the Na⁺K⁺ ATPase forces a change in the protein’s conformation, and K⁺-dependent dephosphorylation favors return to the original conformation. Each cycle in the transport process results in the conversion of ATP to ADP and Pᵢ, and it is the free-energy change of ATP hydrolysis that drives the cyclic changes in protein conformation that result in the electrogenic pumping of Na⁺ and K⁺. Note that in this case ATP interacts covalently by phosphoryl group transfer to the enzyme, not the substrate.

In the contractile system of skeletal muscle cells, myosin and actin are specialized to transduce the chemical energy of ATP into motion (see Fig. 5–31). ATP binds tightly but noncovalently to one conformation of...
myosin, holding the protein in that conformation. When myosin catalyzes the hydrolysis of its bound ATP, the ADP and P_i dissociate from the protein, allowing it to relax into a second conformation until another molecule of ATP binds. The binding and subsequent hydrolysis of ATP (by myosin ATPase) provide the energy that forces cyclic changes in the conformation of the myosin head. The change in conformation of many individual myosin molecules results in the sliding of myosin fibrils along actin filaments (see Fig. 5–30), which translates into macroscopic contraction of the muscle fiber. As we noted earlier, this production of mechanical motion at the expense of ATP is one of the few cases in which ATP hydrolysis per se, rather than group transfer from ATP, is the source of the chemical energy in a coupled process.

Transphosphorylations between Nucleotides Occur in All Cell Types

Although we have focused on ATP as the cell's energy currency and donor of phosphoryl groups, all other nucleoside triphosphates (GTP, UTP, and CTP) and all deoxynucleoside triphosphates (dATP, dGTP, dTTP, and dCTP) are energetically equivalent to ATP. The standard free-energy changes associated with hydrolysis of their phosphoanhydride linkages are very nearly identical with those shown in Table 13–6 for ATP. In preparation for their various biological roles, these other nucleotides are generated and maintained as the nucleoside triphosphate (NTP) forms by phosphoryl group transfer from the corresponding nucleoside diphosphates (NDPs) and monophosphates (NMPs).

ATP is the primary high-energy phosphate compound produced by catabolism, in the processes of glycolysis, oxidative phosphorylation, and, in photosynthetic cells, photophosphorylation. Several enzymes then carry phosphoryl groups from ATP to the other nucleotides. Nucleoside diphosphate kinase, found in all cells, catalyzes the reaction

\[
\text{ATP} + \text{NDP (or dNDP)} \rightarrow \text{ADP} + \text{NTP (or dNTP)} \quad \Delta G^\circ = 0
\]

Although this reaction is fully reversible, the relatively high [ATP]/[ADP] ratio in cells normally drives the reaction to the right, with the net formation of NTPs and dNTPs. The enzyme actually catalyzes a two-step phosphoryl group transfer, which is a classic case of a double-displacement (Ping-Pong) mechanism (Fig. 13–21; see also Fig. 6–13b). First, phosphoryl group transfer from ATP to an active-site His residue produces a phosphoenzyme intermediate; then the phosphoryl group is transferred from the His–His residue to an NDP acceptor. Because the enzyme is nonspecific for the base in the NDP and works equally well on dNDPs and NDPs, it can synthesize all NTPs and dNTPs, given the corresponding NDPs and a supply of ATP.

Phosphoryl group transfers from ATP result in an accumulation of ADP; for example, when muscle is contracting vigorously, ADP accumulates and interferes with ATP-dependent contraction. During periods of intense demand for ATP, the cell lowers the ADP concentration, and at the same time replenishes ATP, by the action of adenylate kinase:

\[
2\text{ADP} \rightarrow \text{ATP} + \text{AMP} \quad \Delta G^\circ = 0
\]

This reaction is fully reversible, so after the intense demand for ATP ends, the enzyme can recycle AMP by converting it to ADP, which can then be phosphorylated to ATP in mitochondria. A similar enzyme, guanylate kinase, converts GMP to GDP at the expense of ATP. By pathways such as these, energy conserved in the catabolic production of ATP is used to supply the cell with all required NTPs and dNTPs.

Phosphocreatine (PCr; Fig. 13–15), also called creatine phosphate, serves as a ready source of phosphoryl groups for the quick synthesis of ATP from ADP. The PCr concentration in skeletal muscle is approximately 30 μmol, nearly 10 times the concentration of ATP, and in other tissues such as smooth muscle, brain, and kidney [PCr] is 5 to 10 mm. The enzyme creatine kinase catalyzes the reversible reaction

\[
\text{ADP} + \text{PCr} \rightarrow \text{ATP} + \text{Cr} \quad \Delta G^\circ = -12.5 \text{kJ/mol}
\]

When a sudden demand for energy depletes ATP, the PCr reservoir is used to replenish ATP at a rate considerably faster than ATP can be synthesized by catabolic pathways. When the demand for energy...
slackens, ATP produced by catabolism is used to replenish the PCr reservoir by reversal of the creatine kinase reaction. Organisms in the lower phyla employ other PCr-like molecules (collectively called phosphagens) as phosphoryl reservoirs.

**Inorganic Polyphosphate Is a Potential Phosphoryl Group Donor**

Inorganic polyphosphate, polyP (or (polyP)

Inorganic polyphosphate, polyP (or (polyP)

One potential role for polyP is to serve as a phosphagen, a reservoir of phosphoryl groups that can be used to generate ATP, as creatine phosphate is used in muscle. PolyP has about the same phosphoryl group transfer potential as PP1. The shortest polyphosphate, PP1 (n = 2), can serve as the energy source for active transport of H+ across the vacuolar membrane in plant cells. For at least one form of the enzyme phosphofructokinase in plants, PP1 is the phosphoryl group donor, a role played by ATP in animals and microbes (p. 533). The finding of high concentrations of polyP in volcanic condensates and steam vents suggests that it could have served as an energy source in prebiotic and early cellular evolution.

In bacteria, the enzyme *polyphosphate kinase-1* (PPK-1) catalyzes the reversible reaction

\[
ATP + polyP_{n} \xrightleftharpoons{Mg^{+}} ADP + polyP_{n+1}
\]

\[
\Delta G^\circ = -20 \text{kJ/mol}
\]

by a mechanism involving an enzyme-bound \(\Phi\)-His intermediate (recall the mechanism of nucleoside diphosphate kinase, described in Fig. 13-22). A second enzyme, *polyphosphate kinase-2* (PPK-2), catalyzes the reversible synthesis of GTP (or ATP) from polyphosphate and GDP (or ADP):

\[
GDP + polyP_{n+1} \xrightarrow{Mg^{+}} GTP + polyP_{n}
\]

PPK-2 is believed to act primarily in the direction of GTP and ATP synthesis, and PPK-1 in the direction of polyphosphate synthesis. PPK-1 and PPK-2 are present in a wide variety of bacteria, including many pathogenic species.

In bacteria, elevated levels of polyP have been shown to promote expression of genes involved in adaptation of the organism to conditions of starvation or other threats to survival. In *Escherichia coli*, for example, polyP accumulates when cells are starved for amino acids or Pi, and this accumulation confers a survival advantage. Deletion of the genes for polyphosphate kinases diminishes the ability of certain pathogenic bacteria to invade animal tissues. The enzymes may therefore prove to be suitable targets in the development of new antimicrobial drugs.

No yeast gene encodes a PPK-like protein, but four genes—unrelated to bacterial PPK genes—are necessary for the synthesis of polyphosphate. The mechanism for polyphosphate synthesis in eukaryotes seems to be quite different from that in bacteria.

**SUMMARY 13.3 Phosphoryl Group Transfers and ATP**

- ATP is the chemical link between catabolism and anabolism. It is the energy currency of the living cell. The exergonic conversion of ATP to ADP and Pi, or to AMP and PPi, is coupled to many endergonic reactions and processes.

- Direct hydrolysis of ATP is the source of energy in some processes driven by conformational changes, but in general it is not ATP hydrolysis but the transfer of a phosphoryl, pyrophosphoryl, or adenylyl group from ATP to a substrate or enzyme that couples the energy of ATP breakdown to endergonic transformations of substrates.

- Through these group transfer reactions, ATP provides the energy for anabolic reactions, including the synthesis of informational macromolecules, and for the transport of molecules and ions across membranes against concentration gradients and electrical potential gradients.

- To maintain its high group transfer potential, ATP concentration must be held far above the equilibrium concentration by energy-yielding reactions of catabolism.

- Cells contain other metabolites with large, negative, free energies of hydrolysis, including phosphoenolpyruvate, 1,3-bisphosphoglycerate, and phosphocreatine. These high-energy compounds, like ATP, have a high phosphoryl group transfer potential. Thioesters also have high free energies of hydrolysis.

- Inorganic polyphosphate, present in all cells, may serve as a reservoir of phosphoryl groups with high group transfer potential.
13.4 Biological Oxidation-Reduction Reactions

The transfer of phosphoryl groups is a central feature of metabolism. Equally important is another kind of transfer, electron transfer in oxidation-reduction reactions. These reactions involve the loss of electrons by one chemical species, which is thereby oxidized, and the gain of electrons by another, which is reduced. The flow of electrons in oxidation-reduction reactions is responsible, directly or indirectly, for all work done by living organisms. In nonphotosynthetic organisms, the sources of electrons are reduced compounds (foods); in photosynthetic organisms, the initial electron donor is a chemical species excited by the absorption of light. The path of electron flow in metabolism is complex. Electrons move from various metabolic intermediates to specialized electron carriers in enzyme-catalyzed reactions. The carriers in turn donate electrons to acceptors with higher electron affinities, with the release of energy. Cells contain a variety of molecular energy transducers, which convert the energy of electron flow into useful work.

We begin by discussing how work can be accomplished by an electromotive force (emf), then consider the theoretical and experimental basis for measuring energy changes in oxidation reactions in terms of emf and the relationship between this force, expressed in volts, and the free-energy change, expressed in joules. We conclude by describing the structures and oxidation-reduction chemistry of the most common of the specialized electron carriers, which you will encounter repeatedly in later chapters.

The Flow of Electrons Can Do Biological Work

Every time we use a motor, an electric light or heater, or a spark to ignite gasoline in a car engine, we use the flow of electrons to accomplish work. In the circuit that powers a motor, the source of electrons can be a battery containing two chemical species that differ in affinity for electrons. Electrical wires provide a pathway for electron flow from the chemical species at one pole of the battery, through the motor, to the chemical species at the other pole of the battery. Because the two chemical species differ in their affinity for electrons, electrons flow spontaneously through the circuit, driven by a force proportional to the difference in electron affinity, the electromotive force, emf. The emf (typically a few volts) can accomplish work if an appropriate energy transducer—in this case a motor—is placed in the circuit. The motor can be coupled to a variety of mechanical devices to do useful work.

Living cells have an analogous biological "circuit," with a relatively reduced compound such as glucose as the source of electrons. As glucose is enzymatically oxidized, the released electrons flow spontaneously through a series of electron-carrier intermediates to another chemical species, such as O₂. This electron flow is exergonic, because O₂ has a higher affinity for electrons than do the electron-carrier intermediates. The resulting emf provides energy to a variety of molecular energy transducers (enzymes and other proteins) that do biological work. In the mitochondrion, for example, membrane-bound enzymes couple electron flow to the production of a transmembrane pH difference and a transmembrane electrical potential, accomplishing osmotic and electrical work. The proton gradient thus formed has potential energy, sometimes called the proton-motive force by analogy with electromotive force. Another enzyme, ATP synthase in the inner mitochondrial membrane, uses the proton-motive force to do chemical work: synthesis of ATP from ADP and P_i as protons flow spontaneously across the membrane. Similarly, membrane-localized enzymes in E. coli convert emf to proton-motive force, which is then used to power flagellar motion. The principles of electrochemistry that govern energy changes in the macroscopic circuit with a motor and battery apply with equal validity to the molecular processes accompanying electron flow in living cells.

Oxidation-Reductions Can Be Described as Half-Reactions

Although oxidation and reduction must occur together, it is convenient when describing electron transfers to consider the two halves of an oxidation-reduction reaction separately. For example, the oxidation of ferrous ion by cupric ion,

\[
\text{Fe}^{2+} + \text{Cu}^{2+} \rightleftharpoons \text{Fe}^{3+} + \text{Cu}^+
\]

can be described in terms of two half-reactions:

\[
\begin{align*}
\text{(1)} & \quad \text{Fe}^{2+} \rightleftharpoons \text{Fe}^{3+} + e^- \\
\text{(2)} & \quad \text{Cu}^{2+} + e^- \rightleftharpoons \text{Cu}^+
\end{align*}
\]

The electron-donating molecule in an oxidation-reduction reaction is called the reducing agent or reductant; the electron-accepting molecule is the oxidizing agent or oxidant. A given agent, such as an iron cation existing in the ferrous (Fe^{2+}) or ferric (Fe^{3+}) state, functions as a conjugate reductant-oxidant pair (redox pair), just as an acid and corresponding base function as a conjugate acid-base pair. Recall from Chapter 2 that in acid-base reactions we can write a general equation: proton donor \(\rightleftharpoons\) proton acceptor. In redox reactions we can write a similar general equation: electron donor (reductant) \(\rightleftharpoons\) electron acceptor (oxidant). In the reversible half-reaction (1) above, Fe^{2+} is the electron donar and Fe^{3+} is the electron acceptor; together, Fe^{3+} and Fe^{2+} constitute a conjugate redox pair.

The electron transfers in the oxidation-reduction reactions of organic compounds are not fundamentally different from those of inorganic species. In Chapter 7 we considered the oxidation of a reducing sugar (an aldehyde or ketone) by cupric ion (see Fig. 7–10):

\[
\text{R} - \text{C}^\text{O}_\text{H} + 4\text{OH}^- + 2\text{Cu}^{2+} \rightleftharpoons \text{R} - \text{C}^\text{O}_\text{OH} + \text{Cu}_2\text{O} + 2\text{H}_2\text{O}
\]
This overall reaction can be expressed as two half-reactions:

1. \[ R-C\text{O} + 2OH^- \rightarrow R-C\text{O}^- + 2e^- + H_2O \]
2. \[ 2Cu^{2+} + 2e^- + 2OH^- \rightarrow Cu_2O + H_2O \]

Because two electrons are removed from the aldehyde carbon, the second half-reaction (the one-electron reduction of cupric to cuprous ion) must be doubled to balance the overall equation.

**Biological Oxidations Often Involve Dehydrogenation**

The carbon in living cells exists in a range of oxidation states (Fig. 13-22). When a carbon atom shares an electron pair with another atom (typically H, C, S, N, or O), the sharing is unequal in favor of the more electronegative atom. The order of increasing electronegativity is H < C < S < N < O. In oversimplified but useful terms, the more electronegative atom “owns” the bonding electrons it shares with another atom. For example, in methane (CH₄), carbon is more electronegative than the four hydrogens bonded to it, and the C atom therefore “owns” all eight bonding electrons (Fig. 13-22). In ethane, the electrons in the C—C bond are shared equally, so each C atom “owns” only seven of its eight bonding electrons. In ethanol, C-1 is less electronegative than the oxygen to which it is bonded, and the O atom therefore “owns” both electrons of the C—O bond, leaving C-1 with only five bonding electrons. With each formal loss of “owned” electrons, the carbon atom has undergone oxidation—even when no oxygen is involved, as in the conversion of an alkane (—CH₂—CH₂—) to an alkene (—CH=CH—). In this case, oxidation (loss of electrons) is coincident with the loss of hydrogen. In biological systems, as we noted earlier in the chapter, oxidation is often synonymous with **dehydrogenation** and many enzymes that catalyze oxidation reactions are **dehydrogenases**. Notice that the more reduced compounds in Figure 13-22 (top) are richer in hydrogen than in oxygen, whereas the more oxidized compounds (bottom) have more oxygen and less hydrogen.

Not all biological oxidation-reduction reactions involve carbon. For example, in the conversion of molecular nitrogen to ammonia, \(6H^+ + 6e^- + N_2 \rightarrow 2NH_3\), the nitrogen atoms are reduced.

Electrons are transferred from one molecule (electron donor) to another (electron acceptor) in one of four ways:

1. **Directly as electrons.** For example, the \(Fe^{2+}/Fe^{3+}\) redox pair can transfer an electron to the \(Cu^{+}/Cu^{2+}\) redox pair:
   \[ Fe^{2+} + Cu^{2+} \rightarrow Fe^{3+} + Cu^{+} \]
2. As hydrogen atoms. Recall that a hydrogen atom consists of a proton (H\(^+\)) and a single electron (e\(^-\)). In this case we can write the general equation

\[
\text{AH}_2 \rightleftharpoons \text{A} + 2e^- + 2\text{H}^+
\]

where \(\text{AH}_2\) is the hydrogen/electron donor. (Do not mistake the above reaction for an acid dissociation, which involves a proton and no electron.) \(\text{AH}_2\) and \(\text{A}\) together constitute a conjugate redox pair (\(\text{A}/\text{AH}_2\)), which can reduce another compound \(\text{B}\) (or redox pair, \(\text{B}/\text{BH}_2\)) by transfer of hydrogen atoms:

\[
\text{AH}_2 + \text{B} \rightleftharpoons \text{A} + \text{BH}_2
\]

3. As a hydride ion (\(\text{H}^-\)), which has two electrons. This occurs in the case of NAD-linked dehydrogenases, described below.

4. Through direct combination with oxygen. In this case, oxygen combines with an organic reductant and is covalently incorporated in the product, as in the oxidation of a hydrocarbon to an alcohol:

\[
\text{R} - \text{CH}_3 + \frac{1}{2}\text{O}_2 \rightarrow \text{R} - \text{CH}_2 - \text{OH}
\]

The hydrocarbon is the electron donor and the oxygen atom is the electron acceptor.

All four types of electron transfer occur in cells. The neutral term reducing equivalent is commonly used to designate a single electron equivalent participating in an oxidation-reduction reaction, no matter whether this equivalent is an electron per se or part of a hydrogen atom or a hydride ion, or whether the electron transfer takes place in a reaction with oxygen to yield an oxygenated product. Because biological fuel molecules are usually enzymatically dehydrogenated to lose two reducing equivalents at a time, and because each oxygen atom can accept two reducing equivalents, biochemists by convention regard the unit of biological oxidations as two reducing equivalents passing from substrate to oxygen.

**Reduction Potentials Measure Affinity for Electrons**

When two conjugate redox pairs are together in solution, electron transfer from the electron donor of one pair to the electron acceptor of the other may proceed spontaneously. The tendency for such a reaction depends on the relative affinity of the electron acceptor of each redox pair for electrons. The **standard reduction potential**, \(E^o\), a measure (in volts) of this affinity, can be determined in an experiment such as that described in Figure 13-23. Electrochemists have chosen as a standard of reference the half-reaction

\[
\text{H}^+ + e^- \rightarrow \frac{1}{2}\text{H}_2
\]

The electrode at which this half-reaction occurs (called a half-cell) is arbitrarily assigned an \(E^o\) of 0.00 V.

When this hydrogen electrode is connected through an external circuit to another half-cell in which an oxidized species and its corresponding reduced species are present at standard concentrations (25 °C, each solute at 1 M, each gas at 101.3 kPa), electrons tend to flow through the external circuit from the half-cell of lower \(E^o\) to the half-cell of higher \(E^o\). By convention, a half-cell that takes electrons from the standard hydrogen cell is assigned a positive value of \(E^o\), and one that donates electrons to the hydrogen cell, a negative value. When any two half-cells are connected, that with the larger (more positive) \(E^o\) will get reduced; it has the greater reduction potential.

The reduction potential of a half-cell depends not only on the chemical species present but also on their activities, approximated by their concentrations. About
a century ago, Walther Nernst derived an equation that relates standard reduction potential \( (E^\circ) \) to the actual reduction potential \( (E) \) at any concentration of oxidized and reduced species in a living cell:

\[
E = E^\circ + \frac{RT}{nF} \ln \left( \frac{[\text{electron acceptor}]}{[\text{electron donor}]} \right) \tag{13-5}
\]

where \( R \) and \( T \) have their usual meanings, \( n \) is the number of electrons transferred per molecule, and \( F \) is the Faraday constant (Table 13-1). At 298 K (25 °C), this expression reduces to

\[
E = E^\circ + 0.026V \ln \left( \frac{[\text{electron acceptor}]}{[\text{electron donor}]} \right) \tag{13-6}
\]

**KEY CONVENTION:** Many half-reactions of interest to biochemists involve protons. As in the definition of \( \Delta G^\circ \), biochemists define the standard state for oxidation-reduction reactions as pH 7 and express a standard transformed reduction potential, \( E^\circ \), the standard reduction potential at pH 7 and 25 °C. By convention, \( \Delta E^\circ \) for any redox reaction is given as \( E^\circ \) of the electron acceptor minus \( E^\circ \) of the electron donor.

The standard reduction potentials given in Table 13-7 and used throughout this book are values for \( E^\circ \) and are therefore valid only for systems at neutral pH. Each value represents the potential difference when the conjugate redox pair, at 1 M concentrations, 25 °C, and pH 7, is connected with the standard (pH 0) hydrogen electrode. Notice in Table 13-7 that when the conjugate pair \( 2H^+ / H_2 \) at pH 7 is connected with the standard hydrogen electrode (pH 0), electrons tend to flow from the pH 7 cell to the standard (pH 0) cell; the measured \( E^\circ \) for the \( 2H^+ / H_2 \) pair is -0.414 V.

**Standard Reduction Potentials Can Be Used to Calculate Free-Energy Change**

Why are reduction potentials so useful to the biochemist? When \( E \) values have been determined for any two half-cells, relative to the standard hydrogen electrode, we also know their reduction potentials relative to each other. We can then predict the direction in which electrons will tend to flow when the two half-cells are connected through an external circuit or when components of both half-cells are present in the same solution. Electrons tend to flow to the half-cell with the more positive \( E \), and the strength of that tendency is proportional to \( \Delta E \), the difference in reduction potential. The energy made available by this spontaneous electron flow (the free-energy change, \( \Delta G \), for the oxidation-reduction reaction) is proportional to \( \Delta E \):

\[
\Delta G = -nF\Delta E \quad \text{or} \quad \Delta G^\circ = -nF\Delta E^\circ \tag{13-7}
\]

where \( n \) is the number of electrons transferred in the reaction. With this equation we can calculate the actual free-energy change for any oxidation-reduction reaction from the values of \( E^\circ \) in a table of reduction potentials (Table 13-7) and the concentrations of reacting species.
WORKED EXAMPLE 13–3 Calculation of $\Delta G^\circ$ and $\Delta G$ of a Redox Reaction

Calculate the standard free-energy change, $\Delta G^\circ$, for the reaction in which acetaldehyde is reduced by the biological electron carrier NADH:

$$\text{Acetaldehyde} + \text{NADH} + \text{H}^+ \longrightarrow \text{ethanol} + \text{NAD}^+$$

Then calculate the actual free-energy change, $\Delta G$, when [acetaldehyde] and [NADH] are 1.00 M, and [ethanol] and [NAD$^+$] are 0.100 M. The relevant half-reactions and their $E^\circ$ values are:

1. Acetaldehyde + 2H$^+$ + 2e$^-$ $\longrightarrow$ ethanol
   $$E^\circ = -0.197 \text{ V}$$

2. NAD$^+$ + 2H$^+$ + 2e$^-$ $\longrightarrow$ NADH + H$^+$
   $$E^\circ = -0.320 \text{ V}$$

Remember that, by convention, $\Delta E^\circ$ is $E^\circ$ of the electron acceptor minus $E^\circ$ of the electron donor.

Solution: Because acetaldehyde is accepting electrons ($n = 2$) from NADH, $\Delta E^\circ = -0.197 \text{ V} - (-0.320 \text{ V}) = 0.123 \text{ V}$. Therefore,

$$\Delta G^\circ = -nF \Delta E^\circ = -2(96.5 \text{ kJ/V} \cdot \text{mol})(0.123 \text{ V}) = -23.7 \text{ kJ/mol}$$

This is the free-energy change for the oxidation-reduction reaction at 25 °C and pH 7, when acetaldehyde, ethanol, NAD$^+$, and NADH are all present at 1.00 M concentrations.

To calculate $\Delta G$ when [acetaldehyde] and [NADH] are 1.00 M, and [ethanol] and [NAD$^+$] are 0.100 M, we first determine $E$ for each reductant, using Equation 13–5:

$$E_{\text{acetaldehyde}} = E^\circ + \frac{RT}{nF} \ln \frac{[\text{acetaldehyde}]}{[\text{ethanol}]}$$
$$= -0.197 \text{ V} + \frac{0.026 \text{ V}}{2} \ln \frac{1.00}{0.100}$$
$$= -0.197 \text{ V} + 0.013 \text{ V} (2.303) = -0.167 \text{ V}$$

$$E_{\text{NADH}} = E^\circ + \frac{RT}{nF} \ln \frac{[\text{NAD}^+]}{[\text{NADH}]}$$
$$= -0.320 \text{ V} + \frac{0.026 \text{ V}}{2} \ln \frac{1.00}{0.100}$$
$$= -0.320 \text{ V} + 0.013 \text{ V} (2.303) = -0.350 \text{ V}$$

From this we can calculate $\Delta E$, then use Equation 13–6 to calculate $\Delta G$:

$$\Delta E = -0.167 \text{ V} - (-0.350 \text{ V}) = 0.183 \text{ V}$$

$$\Delta G = -nF \Delta E = -2(96.5 \text{ kJ/V} \cdot \text{mol})(0.183 \text{ V})$$
$$= -35.3 \text{ kJ/mol}$$

This is the actual free-energy change at the specified concentrations of the redox pairs.

Cellular Oxidation of Glucose to Carbon Dioxide Requires Specialized Electron Carriers

The principles of oxidation-reduction energetics described above apply to the many metabolic reactions that involve electron transfers. For example, in many organisms, the oxidation of glucose supplies energy for the production of ATP. The complete oxidation of glucose:

$$\text{C}_6\text{H}_{12}\text{O}_6 + 6\text{O}_2 \longrightarrow 6\text{CO}_2 + 6\text{H}_2\text{O}$$

has a $\Delta G^\circ$ of $-2,840 \text{ kJ/mol}$. This is a much larger release of free energy than is required for ATP synthesis in cells (50 to 60 kJ/mol; see Worked Example 13–2). Cells convert glucose to CO$_2$ not in a single, high-energy-releasing reaction but rather in a series of controlled reactions, some of which are oxidations. The free energy released in these oxidation steps is of the same order of magnitude as that required for ATP synthesis from ADP, with some energy to spare. Electrons removed in these oxidation steps are transferred to coenzymes specialized for carrying electrons, such as NAD$^+$ and FAD (described below).

A Few Types of Coenzymes and Proteins Serve as Universal Electron Carriers

The multitude of enzymes that catalyze cellular oxidation processes releases the conservation of free energy released by substrate oxidation. NAD, NADP, FMN, and FAD are water-soluble coenzymes that undergo reversible oxidation and reduction in many of the electron-transfer reactions of metabolism. The nucleotides NAD and NADP move readily from one enzyme to another; the flavin nucleotides FMN and FAD are usually very tightly bound to the enzymes, called flavoproteins, for which they serve as prosthetic groups. Lipid-soluble quinones such as ubiquinone and plastoquinone act as electron carriers and proton donors in the nonaqueous environment of membranes. Iron-sulfur proteins and cytochromes, which have tightly bound prosthetic groups that undergo reversible oxidation and reduction, also serve as electron carriers in many oxidation-reduction reactions. Some of these proteins are water-soluble, but others are peripheral or integral membrane proteins (see Fig. 11–6).

We conclude this chapter by describing some chemical features of nucleotide coenzymes and some of the enzymes (dehydrogenases and flavoproteins) that use them. The oxidation-reduction chemistry of quinones, iron-sulfur proteins, and cytochromes is discussed in Chapter 19.

NADH and NADPH Act with Dehydrogenases as Soluble Electron Carriers

Nicotinamide adenine dinucleotide (NAD; NAD$^+$ in its oxidized form) and its close analog nicotinamide adenine dinucleotide phosphate (NADP; NADP$^+$ when oxidized) are composed of two nucleotides joined through their phosphate groups by a phosphoanhydride bond.
13.4 Biological Oxidation-Reduction Reactions

In NADP⁺ this hydroxyl group is esterified with phosphate.

**FIGURE 13-24 NAD and NADP.** (a) Nicotinamide adenine dinucleotide, NAD⁺, and its phosphorylated analog NADP⁺ undergo reduction to NADH and NADPH, accepting a hydride ion (two electrons and one proton) from an oxidizable substrate. The hydride ion is added to either the front (the A side) or the back (the B side) of the planar nicotinamide ring (see Table 13–B). (b) The UV absorption spectra of NAD⁺ and NADH. Reduction of the nicotinamide ring produces a new, broad absorption band with a maximum at 340 nm. The production of NADH during an enzyme-catalyzed reaction can be conveniently followed by observing the appearance of the absorbance at 340 nm (molar extinction coefficient ε_{340} = 6,200 M⁻¹ cm⁻¹).

(Fig. 13–24a). Because the nicotinamide ring resembles pyridine, these compounds are sometimes called **pyridine nucleotides.** The vitamin niacin is the source of the nicotinamide moiety in nicotinamide nucleotides.

Both coenzymes undergo reversible reduction of the nicotinamide ring (Fig. 13–24). As a substrate molecule undergoes oxidation (dehydrogenation), giving up two hydrogen atoms, the oxidized form of the nucleotide (NAD⁺ or NADP⁺) accepts a hydride ion (dH⁻, the equivalent of a proton and two electrons) and is reduced (to NADH or NADPH). The second proton removed from the substrate is released to the aqueous solvent. The half-reactions for these nucleotide cofactors are

\[
NAD^+ + 2e^- + 2H^+ \rightarrow NADH + H^+
\]

\[
NADP^+ + 2e^- + 2H^+ \rightarrow NADPH + H^+
\]

Reduction of NAD⁺ or NADP⁺ converts the benzenoid ring of the nicotinamide moiety (with a fixed positive charge on the ring nitrogen) to the quinonoid form (with no charge on the nitrogen). The reduced nucleotides absorb light at 340 nm; the oxidized forms do not (Fig. 13–24b); this difference in absorption is used by biochemists to assay reactions involving these coenzymes. Note that the plus sign in the abbreviations NAD⁺ and NADP⁺ does not indicate the net charge on these molecules (in fact, both are negatively charged); rather, it indicates that the nicotinamide ring is in its oxidized form, with a positive charge on the nitrogen atom. In the abbreviations NADH and NADPH, the “H” denotes the added hydride ion. To refer to these nucleotides without specifying their oxidation state, we use NAD and NADP.

The total concentration of NAD⁺ + NADH in most tissues is about 10⁻⁵ M; that of NADP⁺ + NADPH is about 10⁻⁶ M. In many cells and tissues, the ratio of NAD⁺ (oxidized) to NADH (reduced) is high, favoring hydride transfer from a substrate to NAD⁺ to form NADH. By contrast, NADPH is generally present at a higher concentration than NADP⁺, favoring hydride transfer from NADPH to a substrate. This reflects the specialized metabolic roles of the two coenzymes: NAD⁺ generally functions in oxidations—usually as part of a catabolic reaction; NADPH is the usual coenzyme in reductions—nearly always as part of an anabolic reaction. A few enzymes can use either coenzyme, but most show a strong preference for one over the other. Also, the processes in which these two cofactors function are segregated in eukaryotic cells: for example, oxidations of fuels such as pyruvate, fatty acids, and α-keto acids derived from amino acids occur in the mitochondrial matrix, whereas reductive biosynthetic processes such as fatty acid synthesis take place in the cytosol. This functional and spatial specialization allows a cell to maintain two distinct pools of electron carriers, with two distinct functions.
Bioenergetics and Biochemical Reaction Types

More than 200 enzymes are known to catalyze reactions in which NAD\(^+\) (or NADP\(^+\)) accepts a hydride ion from a reduced substrate, or NADPH (or NADH) donates a hydride ion to an oxidized substrate. The general reactions are:

\[
\begin{align*}
\text{AH}_2 + \text{NAD}^+ & \rightarrow \text{A} + \text{NADH} + \text{H}^+ \\
\text{A} + \text{NADPH} + \text{H}^+ & \rightarrow \text{AH}_2 + \text{NADP}^+
\end{align*}
\]

where \(\text{AH}_2\) is the reduced substrate and \(\text{A}\) the oxidized substrate. The general name for an enzyme of this type is oxidoreductase; they are also commonly called dehydrogenases. For example, alcohol dehydrogenase catalyzes the first step in the catabolism of ethanol, in which ethanol is oxidized to acetaldehyde:

\[
\text{CH}_3\text{CH}_2\text{OH} + \text{NAD}^+ \rightarrow \text{CH}_3\text{CHO} + \text{NADH} + \text{H}^+ \\
\text{Ethanol} \quad \text{Acetaldehyde}
\]

Notice that one of the carbon atoms in ethanol has lost a hydrogen; the compound has been oxidized from an alcohol to an aldehyde (refer again to Fig. 13–22 for the oxidation states of carbon).

When NAD\(^+\) or NADP\(^+\) is reduced, the hydride ion could in principle be transferred to either side of the nicotinamide ring: the front (A side) or the back (B side), as represented in Figure 13–24a. Studies with isotopically labeled substrates have shown that a given enzyme catalyzes either an A-type or a B-type transfer, but not both. For example, yeast alcohol dehydrogenase and lactate dehydrogenase of vertebrate heart transfer a hydride ion to (or remove a hydride ion from) the A side of the nicotinamide ring; they are classed as type A dehydrogenases to distinguish them from another group of enzymes that transfer a hydride ion to (or remove a hydride ion from) the B side of the nicotinamide ring (Table 13–8). The specificity for one side or another can be very striking; lactate dehydrogenase, for example, prefers the A side over the B side by a factor of \(5 \times 10^7\). The basis for this preference lies in the exact positioning of the enzyme groups involved in hydrogen bonding with the \(–\text{CONH}_2\) group of the nicotinamide.

![Figure 13–25 The Rossmann fold. This structural motif is found in the NAD-binding site of many dehydrogenases, (a) It consists of a pair of structurally similar motifs, each having three parallel \(\beta\) sheets and two \(\alpha\) helices (\(\beta\)-\(\alpha\)-\(\beta\)-\(\alpha\)-\(\beta\)). (b) The nucleotide-binding domain of the enzyme lactate dehydrogenase (derived from PDB ID 3LDH) with NAD (ball-and-stick structure) bound in an extended conformation through hydrogen bonds and salt bridges to the paired \(\beta\)-\(\alpha\)-\(\beta\)-\(\alpha\)-\(\beta\) motifs of the Rossmann fold (shades of green).](image)

Most dehydrogenases that use NAD or NADP bind the cofactor in a conserved protein domain called the Rossmann fold (named for Michael Rossmann, who deduced the structure of lactate dehydrogenase and first described this structural motif). The Rossmann fold typically consists of a six-stranded parallel \(\beta\) sheet and four associated \(\alpha\) helices (Fig. 13–25).

The association between a dehydrogenase and NAD or NADP is relatively loose; the coenzyme readily diffuses from one enzyme to another, acting as a water-soluble

### Table 13–8 Stereospecificity of Dehydrogenases That Employ NAD\(^+\) or NADP\(^+\) as Coenzymes

</table>
carrier of electrons from one metabolite to another. For example, in the production of alcohol during fermentation of glucose by yeast cells, a hydride ion is removed from glyceraldehyde 3-phosphate by one enzyme (glyceraldehyde 3-phosphate dehydrogenase, a type B enzyme) and transferred to NAD⁺. The NADH produced then leaves the enzyme surface and diffuses to another enzyme (alcohol dehydrogenase, a type A enzyme), which transfers a hydride ion to acetaldehyde, producing ethanol:

\[
(1) \text{Glyceraldehyde 3-phosphate} + \text{NAD}^+ \rightarrow 3\text{-phosphoglycerate} + \text{NADH} + \text{H}^+
\]

\[
(2) \text{Acetaldehyde} + \text{NADH} + \text{H}^+ \rightarrow \text{ethanol} + \text{NAD}^+
\]

**Sum:** Glyceraldehyde 3-phosphate + acetaldehyde \(\rightarrow\) 3-phosphoglycerate + ethanol

Notice that in the overall reaction there is no net production or consumption of NAD⁺ or NADH; the coenzymes function catalytically and are recycled repeatedly without a net change in the concentration of NAD⁺ + NADH.

**Dietary Deficiency of Niacin, the Vitamin Form of NAD and NADP, Causes Pellagra**

As we noted in Chapter 6, and will discuss further in the chapters to follow, most coenzymes are derived from the substances we call vitamins. The pyridine-like rings of NAD and NADP are derived from the vitamin niacin (nicotinic acid; Fig. 13-26), which is synthesized from tryptophan. Humans generally cannot synthesize sufficient quantities of niacin, and this is especially so for individuals with diets low in tryptophan (maize, for example, has a low tryptophan content). Niacin deficiency, which affects all the NAD(P)-dependent dehydrogenases, causes the serious human disease pellagra (Italian for “rough skin”) and a related disease in dogs, black-tongue. These diseases are characterized by the “three Ds”: dermatitis, diarrhea, and dementia, followed in many cases by death. A century ago, pellagra was a common human disease; in the southern United States, where maize was a dietary staple, about 100,000 people were afflicted and about 10,000 died as a result of this disease between 1912 and 1916. In 1920 Joseph Goldberger showed pellagra to be caused by a dietary insufficiency, and in 1937 Frank Strong, D. Wayne Woolley, and Conrad Elvehjem identified niacin as the curative agent for blacktongue. Supplementation of the human diet with this inexpensive compound has eradicated pellagra in the populations of the developed world, with one significant exception: people with alcoholism, or who drink excessive amounts of alcohol. In these individuals, intestinal absorption of niacin is much reduced, and caloric needs are often met with distilled spirits that are virtually devoid of vitamins, including niacin. In some parts of the world, including the Deccan Plateau in India, pellagra still occurs in the general population, especially among people living in poverty.

**Flavin Nucleotides Are Tightly Bound in Flavoproteins**

**Flavoproteins** (Table 13-9) are enzymes that catalyze oxidation-reduction reactions using either flavin mononucleotide (FMN) or flavin adenine dinucleotide (FAD) as coenzyme (Fig. 13-27). These coenzymes, the flavin nucleotides, are derived from the vitamin riboflavin. The fused ring structure of flavin nucleotides (the isoalloxazine ring) undergoes reversible reduction, accepting either one or two electrons in the form of one or two hydrogen atoms (each atom an electron plus a proton) from a reduced substrate. The fully reduced forms are abbreviated FADH₂ and FMNH₂. When a fully oxidized flavin nucleotide accepts only one electron (one hydrogen atom), the semiquinone form of the isoolalloxazine ring is produced, abbreviated FADH⁺ and FMNH⁺. Because flavin nucleotides have a slightly different chemical specialty from that of the nicotinamide coenzymes—

---

**FIGURE 13-26** Niacin (nicotinic acid) and its derivative nicotinamide. The biosynthetic precursor of these compounds is tryptophan. In the laboratory, nicotinic acid was first produced by oxidation of the natural product nicotine—thus the name. Both nicotinic acid and nicotinamide cure pellagra, but nicotine (from cigarettes or elsewhere) has no curative activity.
the ability to participate in either one- or two-electron transfers—flavoproteins are involved in a greater diversity of reactions than the NAD(P)-linked dehydrogenases.

Like the nicotinamide coenzymes (Fig. 13-24), the flavin nucleotides undergo a shift in a major absorption band on reduction (again, useful to biochemists who want to monitor reactions involving these coenzymes). Flavoproteins that are fully reduced (two electrons accepted) generally have an absorption maximum near 360 nm. When partially reduced (one electron), they acquire another absorption maximum at about 450 nm; when fully oxidized, the flavin has maxima at 370 and 440 nm.

The flavin nucleotide in most flavoproteins is bound rather tightly to the protein, and in some enzymes, such as succinate dehydrogenase, it is bound covalently. Such tightly bound coenzymes are properly called prosthetic groups. They do not transfer electrons by diffusing from one enzyme to another; rather, they provide a means by which the flavoprotein can temporarily hold electrons while it catalyzes electron transfer from a reduced substrate to an electron acceptor. One important feature of the flavoproteins is the variability in the standard reduction potential ($E^\text{red}$) of the bound flavin nucleotide. Tight association between the enzyme and prosthetic group confers on the flavin ring a reduction potential typical of that particular flavoprotein, sometimes quite different from the reduction potential of the free flavin nucleotide. FAD bound to succinate dehydrogenase, for example, has an $E^\text{red}$ close to 0.0 V, compared with −0.219 V for free FAD; $E^\text{red}$ for other flavoproteins ranges from −0.40 V to +0.06 V. Flavoproteins are often very complex; some have, in addition to a flavin nucleotide, tightly bound inorganic ions (iron or molybdenum, for example) capable of participating in electron transfers.

Certain flavoproteins act in a quite different role, as light receptors. **Cryptochromes** are a family of flavoproteins, widely distributed in the eukaryotic phyla, that mediate the effects of blue light on plant development and the effects of light on mammalian circadian rhythms (oscillations in physiology and biochemistry, with a 24-hour period). The cryptochromes are homologs of another family of flavoproteins, the photolyases. Found in both bacteria and eukaryotes, **photolyases** use the energy of absorbed light to repair chemical defects in DNA.

![Flavin adenine dinucleotide (FAD) and flavin mononucleotide (FMN)](image-url)

**FIGURE 13-27** Oxidized and reduced FAD and FMN. FMN consists of the structure above the dashed line on the FAD (oxidized form). The flavin nucleotides accept two hydrogen atoms (two electrons and two protons), both of which appear in the flavin ring system. When FAD or FMN accepts only one hydrogen atom, the semiquinone, a stable free radical, forms.
We examine the function of flavoproteins as electron carriers in Chapter 19, when we consider their roles in oxidative phosphorylation (in mitochondria) and photophosphorylation (in chloroplasts), and we describe the photolyase reactions in Chapter 25.

**SUMMARY 13.4 Biological Oxidation-Reduction Reactions**

- In many organisms, a central energy-conserving process is the stepwise oxidation of glucose to CO₂, in which some of the energy of oxidation is conserved in ATP as electrons are passed to O₂.

- Biological oxidation-reduction reactions can be described in terms of two half-reactions, each with a characteristic standard reduction potential, \( E^{\circ} \).

- When two electrochemical half-cells, each containing the components of a half-reaction, are connected, electrons tend to flow to the half-cell with the higher reduction potential. The strength of this tendency is proportional to the difference between the two reduction potentials (\( \Delta E \)) and is a function of the concentrations of oxidized and reduced species.

- The standard free-energy change for an oxidation-reduction reaction is directly proportional to the difference in standard reduction potentials of the two half-cells: \( \Delta G^{\circ} = -nF \Delta E^{\circ} \).

- Many biological oxidation reactions are dehydrogenations in which one or two hydrogen atoms (H⁺ + e⁻) are transferred from a substrate to a hydrogen acceptor. Oxidation-reduction reactions in living cells involve specialized electron carriers.

- NAD and NADP are the freely diffusible coenzymes of many dehydrogenases. Both NAD⁺ and NADP⁺ accept two electrons and one proton.

- FAD and FMN, the flavin nucleotides, serve as tightly bound prosthetic groups of flavoproteins. They can accept either one or two electrons and one or two protons. Flavoproteins also serve as light receptors in cryptochromes and photolyases.

**Further Reading**

**Bioenergetics and Thermodynamics**

  - A well-illustrated and elementary discussion of the second law and its implications.

  - A classic treatment of the roles of ATP, ADP, and AMP in controlling the rate of catabolism.

  - Chapters 11 through 13 of this book, and the books by Tinoco et al. and van Holde et al. (below), are excellent general references for physical biochemistry, with good discussions of the applications of thermodynamics to biochemistry.

  - Clearly written, well illustrated, with excellent examples and problems.

  - Clearly written, well illustrated, with excellent examples and problems.

  - A beautifully clear discussion of thermodynamics in biological processes.

  - A short, clearly written account of cellular energetics, including introductory chapters on thermodynamics.

  - Highly accessible discussions of thermodynamics and kinetics in biological systems.

  - Beautifully written discussion of the relationship between entropy and information.

  - Clear, well-illustrated, intermediate-level discussion of the theory of bioenergetics and the mechanisms of energy transductions.
Chemical Logic and Common Biochemical Reactions

A very useful survey of reactions that proceed by free-radical mechanisms.

An authoritative and up-to-date resource on the reactions that occur in living systems.

A good summary of the principles of enzyme catalysis as currently understood, and what we still do not understand.

Phosphoryl Group Transfers and ATP

Explains the distinction between biochemical and chemical equations, and the calculation and meaning of transformed thermodynamic properties for ATP and other phosphorylated compounds.

The chemistry of ATP, its place in metabolic regulation, and its catalytic and anabolic roles.

Excellent summary of the chemistry and biology of ATP.

Intermediate-level discussion of the history of ATP studies, in which the author was a major player.

The classic description of the role of high-energy phosphate compounds in biology.

An advanced discussion of the chemistry of ATP and other “energy-rich” compounds.

Discussion of the structural basis for the efficient coupling of two energetic processes by way of changes in conformational states.

Experimental determination of ATP, ADP, and Pᵢ concentrations in brain, muscle, and liver, and a discussion of the difficulties in determining the real free-energy change for ATP synthesis in cells.

A chemist’s description of the unique suitability of phosphate esters and anhydrides for metabolic transformations.

Biological Oxidation-Reduction Reactions

An excellent two-volume collection of authoritative reviews. Among the most useful are the chapters by Kaplan, Westheimer, Veech, and Ohno and Ushio.

A short review of the chemistry of flavin–oxygen interactions in flavoproteins.

Advanced review of the types of metal ion clusters found in enzymes and their modes of action.

Good overview of the different classes of electron carriers that participate in respiration.

Problems

1. **Entropy Changes during Egg Development** Consider a system consisting of an egg in an incubator. The white and yolk of the egg contain proteins, carbohydrates, and lipids. If fertilized, the egg is transformed from a single cell to a complex organism. Discuss this irreversible process in terms of the entropy changes in the system, surroundings, and universe. Be sure that you first clearly define the system and surroundings.

2. **Calculation of ΔG° from an Equilibrium Constant** Calculate the standard free-energy change for each of the following metabolically important enzyme-catalyzed reactions, using the equilibrium constants given for the reactions at 25 °C and pH 7.0.
3. Calculation of the Equilibrium Constant from $\Delta G^\circ$
Calculate the equilibrium constant $K'_{eq}$ for each of the following reactions at pH 7.0 and 25 °C, using the $\Delta G^\circ$ values in Table 13-4.

(a) Glucose 6-phosphate + H$_2$O $\rightarrow$ glucose + P$_i$

(b) Lactose + H$_2$O $\rightarrow$ glucose + galactose

(c) Malate $\rightarrow$ fumarate + H$_2$O

4. Experimental Determination of $K'_{eq}$ and $\Delta G^\circ$ If a 0.1 M solution of glucose 1-phosphate at 25 °C is incubated with a catalytic amount of phosphoglucomutase, the glucose 1-phosphate is transformed to glucose 6-phosphate. At equilibrium, the concentrations of the reaction components are:

Glucose 1-phosphate $\rightleftharpoons$ glucose 6-phosphate

$4.5 \times 10^{-3}$ M $\quad 9.6 \times 10^{-2}$ M

Calculate $K'_{eq}$ and $\Delta G^\circ$ for this reaction.

5. Experimental Determination of $\Delta G^\circ$ for ATP Hydrolysis A direct measurement of the standard free-energy change associated with the hydrolysis of ATP is technically demanding because the minute amount of ATP remaining at equilibrium is difficult to measure accurately. The value of $\Delta G^\circ$ can be calculated indirectly, however, from the equilibrium constants of two other enzymatic reactions having less favorable equilibrium constants:

Glucose 6-phosphate + H$_2$O $\rightarrow$ glucose + P$_i$

ATP + glucose $\rightarrow$ ADP + glucose 6-phosphate

$K'_{eq}$ = 270

$K'_{eq}$ = 890

Using this information for equilibrium constants determined at 25 °C, calculate the standard free energy of hydrolysis of ATP.

6. Difference between $\Delta G^\circ$ and $\Delta G$ Consider the following interconversion, which occurs in glycolysis (Chapter 14):

Fructose 6-phosphate $\rightleftharpoons$ glucose 6-phosphate

$K'_{eq}$ = 1.97

(a) What is $\Delta G^\circ$ for the reaction ($K'_{eq}$ measured at 25 °C)?

(b) If the concentration of fructose 6-phosphate is adjusted to 1.5 M and that of glucose 6-phosphate is adjusted to 0.50 M, what is $\Delta G$?

(c) Why are $\Delta G^\circ$ and $\Delta G$ different?

7. Free Energy of Hydrolysis of CTP Compare the structure of the nucleoside triphosphate CTP with the structure of ATP.

8. Dependence of $\Delta G$ on pH The free energy released by the hydrolysis of ATP under standard conditions is $-30.5$ kJ/mol. If ATP is hydrolyzed under standard conditions except at pH 5.0, is more or less free energy released? Explain. Use the Living Graph to explore this relationship.

9. The $\Delta G^\circ$ for Coupled Reactions Glucose 1-phosphate is converted into fructose 6-phosphate in two successive reactions:

Glucose 1-phosphate $\rightarrow$ glucose 6-phosphate

Glucose 6-phosphate $\rightarrow$ fructose 6-phosphate

Using the $\Delta G^\circ$ values in Table 13-4, calculate the equilibrium constant, $K'_{eq}$, for the sum of the two reactions:

Glucose 1-phosphate $\rightarrow$ fructose 6-phosphate

10. Effect of [ATP]/[ADP] Ratio on Free Energy of Hydrolysis of ATP Using Equation 13-4, plot $\Delta G$ against ln Q (mass-action ratio) at 25 °C for the concentrations of ATP, ADP, and P$_i$ in the table below. $\Delta G^\circ$ for the reaction is $-30.5$ kJ/mol. Use the resulting plot to explain why metabolism is regulated to keep the ratio [ATP]/[ADP] high.

11. Strategy for Overcoming an Unfavorable Reaction: ATP-Dependent Chemical Coupling The phosphorylation of glucose to glucose 6-phosphate is the initial step in the
catabolism of glucose. The direct phosphorylation of glucose by $P_i$ is described by the equation

$$\text{Glucose} + P_i \rightarrow \text{glucose 6-phosphate} + H_2O$$

$$\Delta G^{\circ} = 13.8 \text{ kJ/mol}$$

(a) Calculate the equilibrium constant for the above reaction at $37^\circ C$. In the rat hepatocyte the physiological concentrations of glucose and $P_i$ are maintained at approximately 4.8 mM. What is the equilibrium concentration of glucose 6-phosphate obtained by the direct phosphorylation of glucose by $P_i$? Does this reaction represent a reasonable metabolic step for the catabolism of glucose? Explain.

(b) In principle, at least, one way to increase the concentration of glucose 6-phosphate is to drive the equilibrium reaction to the right by increasing the intracellular concentrations of glucose and $P_i$. Assuming a fixed concentration of $P_i$ at 4.8 mM, how high would the intracellular concentration of glucose have to be to give an equilibrium concentration of glucose 6-phosphate of 250 $\mu$M (the normal physiological concentration)? Would this route be physiologically reasonable, given that the maximum solubility of glucose is less than 1 M?

(c) The phosphorylation of glucose in the cell is coupled to the hydrolysis of ATP; that is, part of the free energy of ATP hydrolysis is used to phosphorylate glucose:

(1) $$\text{Glucose} + P_i \rightarrow \text{glucose 6-phosphate} + H_2O$$

$$\Delta G^{\circ} = 13.8 \text{ kJ/mol}$$

(2) $$\text{ATP} + H_2O \rightarrow \text{ADP} + P_i$$

$$\Delta G^{\circ} = -30.5 \text{ kJ/mol}$$

Sum: $$\text{Glucose} + \text{ATP} \rightarrow \text{glucose 6-phosphate} + \text{ADP}$$

Calculate $K_{eq}$ at $37^\circ C$ for the overall reaction. For the ATP-dependent phosphorylation of glucose, what concentration of glucose is needed to achieve a $250 \mu$M intracellular concentration of glucose 6-phosphate when the concentrations of ATP and ADP are 3.38 mM and 1.32 mM, respectively? Does this coupling process provide a feasible route, at least in principle, for the phosphorylation of glucose in the cell? Explain.

(d) Although coupling ATP hydrolysis to glucose phosphorylation makes thermodynamic sense, we have not yet specified how this coupling is to take place. Given that coupling requires a common intermediate, one conceivable route is to use ATP hydrolysis to raise the intracellular concentration of $P_i$ and thus drive the unfavorable phosphorylation of glucose by $P_i$. Is this a reasonable route? (Think about the solubility products of metabolic intermediates.)

(e) The ATP-coupled phosphorylation of glucose is catalyzed in hepatocytes by the enzyme glucokinase. This enzyme binds ATP and glucose to form a glucose-ATP-enzyme complex, and the phosphoryl group is transferred directly from ATP to glucose. Explain the advantages of this route.

12. Calculations of $\Delta G^{\circ}$ for ATP-Coupled Reactions
From data in Table 13-6 calculate the $\Delta G^{\circ}$ value for the following reactions.

(a) Phosphocreatine + ADP $\rightarrow$ creatine + ATP

(b) ATP + fructose $\rightarrow$ ADP + fructose 6-phosphate

13. Coupling ATP Cleavage to an Unfavorable Reaction
To explore the consequences of coupling ATP hydrolysis under physiological conditions to a thermodynamically unfavorable biochemical reaction, consider the hypothetical transformation $X \rightarrow Y$, for which $\Delta G^{\circ} = 20 \text{ kJ/mol}$.

(a) What is the ratio $[Y]/[X]$ at equilibrium?

(b) Suppose $X$ and $Y$ participate in a sequence of reactions during which ATP is hydrolyzed to ADP and $P_i$. The overall reaction is

$$X + ATP + H_2O \rightarrow Y + ADP + P_i$$

Calculate $[Y]/[X]$ for this reaction at equilibrium. Assume that the temperature is $25^\circ C$ and the equilibrium concentrations of ATP, ADP, and $P_i$ are 1 M.

(c) We know that [ATP], [ADP], and [P_i] are not 1 M under physiological conditions. Calculate $[Y]/[X]$ for the ATP-coupled reaction when the values of [ATP], [ADP], and [P_i] are those found in rat myocytes (Table 13-5).

14. Calculations of $\Delta G$ at Physiological Concentrations
Calculate the actual, physiological $\Delta G$ for the reaction

$$\text{Phosphocreatine} + \text{ADP} \rightarrow \text{creatine} + \text{ATP}$$

at $37^\circ C$, as it occurs in the cytosol of neurons, with phosphocreatine at 4.7 mM, creatine at 1.0 mM, ADP at 0.73 mM, and ATP at 2.6 mM.

15. Free Energy Required for ATP Synthesis under Physiological Conditions
In the cytosol of rat hepatocytes, the temperature is $37^\circ C$ and the mass-action ratio, $Q$, is

$$\frac{[\text{ATP}]}{[\text{ADP}][P_i]} = 5.33 \times 10^2 \text{ M}^{-1}$$

Calculate the free energy required to synthesize ATP in a rat hepatocyte.

16. Chemical Logic
In the glycolytic pathway, a six-carbon sugar (fructose 1,6-bisphosphate) is cleaved to form two three-carbon sugars, which undergo further metabolism (see Fig. 14-5). In this pathway, an isomerization of glucose 6-phosphate to fructose 6-phosphate (shown below) occurs two steps before the cleavage reaction (the intervening step is phosphorylation of fructose 6-phosphate to fructose 1,6-bisphosphate (p. 532)).

What does the isomerization step accomplish from a chemical perspective? (Hint: Consider what might happen if the C--C bond cleavage were to proceed without the preceding isomerization.)
17. Enzymatic Reaction Mechanisms I Lactate dehydrogenase is one of the many enzymes that require NADH as coenzyme. It catalyzes the conversion of pyruvate to lactate:

\[
\text{Pyruvate} + \text{NADH} + \text{H}^+ \rightarrow \text{l-Lactate} + \text{NAD}^+
\]

Draw the mechanism of this reaction (show electron-pushing arrows). (Hint: This is a common reaction throughout metabolism; the mechanism is similar to that catalyzed by other dehydrogenases that use NADH, such as alcohol dehydrogenase.)

18. Enzymatic Reaction Mechanisms II Biochemical reactions often look more complex than they really are. In the pentose phosphate pathway (Chapter 14), sedoheptulose 7-phosphate and glyceraldehyde 3-phosphate react to form erythrose 4-phosphate and fructose 6-phosphate in a reaction catalyzed by transaldolase.

\[
\begin{align*}
\text{Sedoheptulose 7-phosphate} & \rightarrow \text{Erythrose 4-phosphate} + \text{Fructose 6-phosphate} \\
\text{Glyceraldehyde 3-phosphate} & \rightarrow \text{Erythrose 4-phosphate} + \text{Fructose 6-phosphate}
\end{align*}
\]

Draw a mechanism for this reaction (show electron-pushing arrows). (Hint: Take another look at aldol condensations, then consider the name of this enzyme.)

19. Daily ATP Utilization by Human Adults
(a) A total of 30.5 kJ/mol of free energy is needed to synthesize ATP from ADP and P\textsubscript{i} when the reactants and products are at 1 M concentrations and the temperature is 25 °C (standard state). Because the actual physiological concentrations of ATP, ADP, and P\textsubscript{i} are not 1 M, and the temperature is 37 °C, the free energy required to synthesize ATP under physiological conditions is different from ΔG\textsuperscript{o*}. Calculate the free energy required to synthesize ATP in the human hepatocyte when the physiological concentrations of ATP, ADP, and P\textsubscript{i} are 3.5, 1.50, and 5.0 mM, respectively.

(b) A 68 kg (150 lb) adult requires a caloric intake of 2,000 kcal (8,360 kJ) of food per day (24 hours). The food is metabolized and the free energy is used to synthesize ATP, which then provides energy for the body's daily chemical and mechanical work. Assuming that the efficiency of converting food energy into ATP is 50%, calculate the weight of ATP used by a human adult in 24 hours. What percentage of the body weight does this represent?

(c) Although adults synthesize large amounts of ATP daily, their body weight, structure, and composition do not change significantly during this period. Explain this apparent contradiction.

20. Rates of Turnover of γ and β Phosphates of ATP If a small amount of ATP labeled with radioactive phosphorus in the terminal position, [γ-32P]ATP, is added to a yeast extract, about half of the 32P activity is found in P\textsubscript{i} within a few minutes, but the concentration of ATP remains unchanged. Explain. If the same experiment is carried out using ATP labeled with 32P in the central position, [β-32P]ATP, the 32P does not appear in P\textsubscript{i} within such a short time. Why?

21. Cleavage of ATP to AMP and P\textsubscript{i} during Metabolism Synthesis of the activated form of acetate (acetyl-CoA) is carried out in an ATP-dependent process:

\[
\text{Acetate} + \text{CoA} + \text{ATP} \rightarrow \text{acetyl-CoA} + \text{AMP} + \text{PP}_i
\]

(a) The ΔG\textsuperscript{o*} for hydrolysis of acetyl-CoA to acetate and CoA is −32.2 kJ/mol and that for hydrolysis of ATP to AMP and P\textsubscript{i} is −30.5 kJ/mol. Calculate ΔG\textsuperscript{o*} for the ATP-dependent synthesis of acetyl-CoA.

(b) Almost all cells contain the enzyme inorganic pyrophosphatase, which catalyzes the hydrolysis of P\textsubscript{i} to P\textsubscript{i}. What effect does the presence of this enzyme have on the synthesis of acetyl-CoA? Explain.

22. Energy for H\textsuperscript{+} Pumping The parietal cells of the stomach lining contain membrane “pumps” that transport hydrogen ions from the cytosol (pH 7.0) into the stomach, contributing to the acidity of gastric juice (pH 1.0). Calculate the free energy required to transport 1 mol of hydrogen ions through these pumps. (Hint: See Chapter 11.) Assume a temperature of 37 °C.

23. Standard Reduction Potentials The standard reduction potential, E\textsuperscript{o*}, of any redox pair is defined for the half-cell reaction:

\[
\text{Oxidizing agent} + n \text{ electrons} \rightarrow \text{reducing agent}
\]

The E\textsuperscript{o*} values for the NAD\textsuperscript{+}/NADH and pyruvate/lactate conjugate redox pairs are −0.32 V and −0.19 V, respectively.

(a) Which redox pair has the greater tendency to lose electrons? Explain.

(b) Which pair is the stronger oxidizing agent? Explain.

(c) Beginning with 1 M concentrations of each reactant and product at pH 7 and 25 °C, in which direction will the following reaction proceed?

\[
\text{Pyruvate} + \text{NADH} + \text{H}^+ \rightleftharpoons \text{l-Lactate} + \text{NAD}^+
\]
Bioenergetics and Biochemical Reaction Types

(d) What is the standard free-energy change ($\Delta G^\circ$) for the conversion of pyruvate to lactate?

(e) What is the equilibrium constant ($K_{eq}$) for this reaction?

24. Energy Span of the Respiratory Chain Electron transfer in the mitochondrial respiratory chain may be represented by the net reaction equation:

$$\text{NADH} + H^+ + \frac{1}{2}O_2 \rightleftharpoons H_2O + \text{NAD}^+$$

(a) Calculate $\Delta E^\circ$ for the net reaction of mitochondrial electron transfer. Use $E^\circ$ values from Table 13–7.

(b) Calculate $\Delta G^\circ$ for this reaction.

(c) How many ATP molecules can theoretically be generated by this reaction if the free energy of ATP synthesis under cellular conditions is 52 kJ/mol?

25. Dependence of Electromotive Force on Concentrations Calculate the electromotive force (in volts) registered by an electrode immersed in a solution containing the following mixtures of NAD$^+$ and NADH at pH 7.0 and 25 °C, with reference to a half-cell of $E^\circ$ 0.00 V.

(a) 1.0 mM NAD$^+$ and 10 mM NADH
(b) 1.0 mM NAD$^+$ and 1.0 mM NADH
(c) 10 mM NAD$^+$ and 1.0 mM NADH

26. Electron Affinity of Compounds List the following in order of increasing tendency to accept electrons: $\alpha$-ketoglutarate + CO$_2$ (yielding isocitrate); oxaloacetate; O$_2$; NADP$^+$.

27. Direction of Oxidation-Reduction Reactions Which of the following reactions would you expect to proceed in the direction shown, under standard conditions, in the presence of the appropriate enzymes?

(a) Malate + NAD$^+$ $\rightarrow$ oxaloacetate + NADH + H$^+$
(b) Acetoacetate + NADH + H$^+$ $\rightarrow$ $\beta$-hydroxybutyrate + NAD$^+$
(c) Pyruvate + NADH + H$^+$ $\rightarrow$ lactate + NAD$^+$
(d) Pyruvate + $\beta$-hydroxybutyrate $\rightarrow$ lactate + acetoacetate
(e) Malate + pyruvate $\rightarrow$ oxaloacetate + lactate
(f) Acetaldehyde + succinate $\rightarrow$ ethanol + fumarate

The figure legend reads: “Model of the unidirectional diffusion of dye between coupled oligodendrocytes and astrocytes, based on differences in connection pore diameter. Like a fish in a fish trap, dye molecules (black circles) can pass from an astrocyte to an oligodendrocyte (A) but not back in the other direction (B).”

Although this article clearly passed review at a well-respected journal, several letters to the editor (1994) followed, showing that Robinson and coauthors’ model violated the second law of thermodynamics.

(a) Explain how the model violates the second law. Hint: Consider what would happen to the entropy of the system if one started with equal concentrations of dye in the astrocyte and oligodendrocyte connected by the “fish trap” type of gap junctions.

(b) Explain why this model cannot work for small molecules, although it may allow one to catch fish.

(c) Explain why a fish trap does work for fish.

(d) Provide two plausible mechanisms for the unidirectional transport of dye molecules between the cells that do not violate the second law of thermodynamics.

14.4 Gluconeogenesis 551
14.5 Pentose Phosphate Pathway of Glucose Oxidation 558

Glucose occupies a central position in the metabolism of plants, animals, and many microorganisms. It is relatively rich in potential energy, and thus a good fuel; the complete oxidation of glucose to carbon dioxide and water proceeds with a standard free-energy change of $-2,840 \text{ kJ/mol}$. By storing glucose as a high molecular weight polymer such as starch or glycogen, a cell can stockpile large quantities of hexose units while maintaining a relatively low cytosolic osmolarity. When energy demands increase, glucose can be released from these intracellular storage polymers and used to produce ATP either aerobically or anaerobically.

Glucose is not only an excellent fuel, it is also a remarkably versatile precursor, capable of supplying a huge array of metabolic intermediates for biosynthetic reactions. A bacterium such as *Escherichia coli* can obtain from glucose the carbon skeletons for every amino acid, nucleotide, coenzyme, fatty acid, or other metabolic intermediate it needs for growth. A comprehensive study of the metabolic fates of glucose would encompass hundreds or thousands of transformations. In animals and vascular plants, glucose has four major fates: it may be used in the synthesis of complex polysaccharides destined for the extracellular space; stored in cells (as a polysaccharide or as sucrose); oxidized to a three-carbon compound (pyruvate) via glycolysis to provide ATP and metabolic intermediates; or oxidized via the pentose phosphate (phosphogluconate) pathway to yield ribose 5-phosphate for nucleic acid synthesis and NADPH for reductive biosynthetic processes (Fig. 14–1).

Organisms that do not have access to glucose from other sources must make it. Photosynthetic organisms make glucose by first reducing atmospheric CO$_2$ to trioses, then converting the trioses to glucose. Nonphotosynthetic cells make glucose from simpler three- and four-carbon precursors by the process of gluconeogenesis, effectively reversing glycolysis in a pathway that uses many of the glycolytic enzymes.

In this chapter we describe the individual reactions of glycolysis, gluconeogenesis, and the pentose phosphate pathway and the functional significance of each pathway. We also describe the various metabolic fates of the pyruvate produced by glycolysis. They include the fermentations that are used by many organisms in anaerobic niches to produce ATP and that are exploited industrially as sources of ethanol, lactic acid, and other products.
commercially useful products. And we look at the pathways that feed various sugars from mono-, di-, and polysaccharides into the glycolytic pathway. The discussion of glucose metabolism continues in Chapter 15, where we use the processes of carbohydrate synthesis and degradation to illustrate the many mechanisms by which organisms regulate metabolic pathways. The biosynthetic pathways from glucose to extracellular matrix and cell wall polysaccharides and storage polysaccharides are discussed in Chapter 20.

14.1 Glycolysis

In **glycolysis** (from the Greek *glykys*, "sweet" or "sugar," and *lysis*, "splitting"), a molecule of glucose is degraded in a series of enzyme-catalyzed reactions to yield two molecules of the three-carbon compound pyruvate. During the sequential reactions of glycolysis, some of the free energy released from glucose is conserved in the form of ATP and NADH. Glycolysis was the first metabolic pathway to be elucidated and is probably the best understood. From Eduard Buchner's discovery in 1897 of fermentation in broken extracts of yeast cells until the elucidation of the whole pathway in yeast (by Otto Warburg and Hans von Euler-Chelpin) and in muscle (by Gustav Embden and Otto Meyerhof) in the 1930s, the reactions of glycolysis in extracts of yeast and muscle were a major focus of biochemical research. The philosophical shift that accompanied these discoveries was announced by Jacques Loeb in 1906:

> Through the discovery of Buchner, Biology was relieved of another fragment of mysticism. The splitting up of sugar into CO₂ and alcohol is no more the effect of a "vital principle" than the splitting up of cane sugar by invertase. The history of this problem is instructive, as it warns us against considering problems as beyond our reach because they have not yet found their solution.

The development of methods of enzyme purification, the discovery and recognition of the importance of coenzymes such as NAD, and the discovery of the pivotal metabolic role of ATP and other phosphorylated compounds all came out of studies of glycolysis. The glycolytic enzymes of many species have long since been purified and thoroughly studied.

Glycolysis is an almost universal central pathway of glucose catabolism, the pathway with the largest flux of carbon in most cells. The glycolytic breakdown of glucose is the sole source of metabolic energy in some mammalian tissues and cell types (erythrocytes, renal medulla, brain, and sperm, for example). Some plant tissues that are modified to store starch (such as potato tubers) and some aquatic plants (watercress, for example) derive most of their energy from glycolysis; many anaerobic microorganisms are entirely dependent on glycolysis.

**Fermentation** is a general term for the anaerobic degradation of glucose or other organic nutrients to obtain energy, conserved as ATP. Because living organisms first arose in an atmosphere without oxygen, anaerobic breakdown of glucose is probably the most ancient biological mechanism for obtaining energy from organic fuel molecules. And as genome sequencing of a wide variety of organisms has revealed, some archaea and some parasitic microorganisms lack one or more of the enzymes of glycolysis but retain the core of the pathway; they presumably carry out variant forms of glycolysis. In the course of evolution, the chemistry of this reaction sequence has been completely conserved; the glycolytic enzymes of vertebrates are closely similar, in amino acid sequence and three-dimensional structure, to their homologs in yeast and spinach. Glycolysis differs among species only in the details of its regulation and in the subsequent metabolic fate of the pyruvate formed. The thermodynamic principles and the types of regulatory mechanisms that govern glycolysis are common to all pathways of cell metabolism. The glycolytic pathway, of central importance in itself, can also serve as a model for many aspects of the pathways discussed throughout this book.

Before examining each step of the pathway in some detail, we take a look at glycolysis as a whole.

**An Overview: Glycolysis Has Two Phases**

The breakdown of the six-carbon glucose into two molecules of the three-carbon pyruvate occurs in 10 steps, the first 5 of which constitute the preparatory phase (Fig. 14-2a). In these reactions, glucose is first phosphorylated at the hydroxyl group on C-6 (step 1). The D-glucose 6-phosphate thus formed is converted to D-fructose 6-phosphate (step 2), which is again phosphorylated, this time at C-1, to yield D-fructose 1,6-bisphosphate (step 3). For both phosphorylations, ATP is the phosphoryl group donor. As all sugar derivatives in glycolysis are the D isomers, we

FIGURE 14-2 The two phases of glycolysis. For each molecule of glucose that passes through the preparatory phase (a), two molecules of glyceraldehyde 3-phosphate are formed; both pass through the payoff phase (b). Pyruvate is the end product of the second phase of glycolysis. For each glucose molecule, two ATP are consumed in the preparatory phase and four ATP are produced in the payoff phase, giving a net yield of two ATP per molecule of glucose converted to pyruvate. The numbered reaction steps are catalyzed by the enzymes listed on the right, and also correspond to the numbered headings in the text discussion. Keep in mind that each phosphoryl group, represented here as $\overset{\text{PO}_3^-}{\text{P}}$, has two negative charges ($-\text{PO}_2^-$).
will usually omit the $\text{D}$ designation except when emphasizing stereochemistry.

Fructose 1,6-bisphosphate is split to yield two three-carbon molecules, dihydroxyacetone phosphate and glyceraldehyde 3-phosphate (step 4); this is the "lysis" step that gives the pathway its name. The dihydroxyacetone phosphate is isomerized to a second molecule of glyceraldehyde 3-phosphate (step 5), ending the first phase of glycolysis. From a chemical perspective, the isomerization in step 6 is critical for setting up the phosphorylation and C-C bond cleavage reactions in steps 7 and 8, as detailed later. Note that two molecules of ATP are invested before the cleavage of glucose into two three-carbon pieces; there will be a good return on this investment. To summarize: in the preparatory phase of glycolysis the energy of ATP is invested, raising the free-energy content of the intermediates, and the carbon chains of all the metabolized hexoses are converted to a common product, glyceraldehyde 3-phosphate.

The energy gain comes in the payoff phase of glycolysis (Fig. 14-2b). Each molecule of glyceraldehyde 3-phosphate is oxidized and phosphorylated by inorganic phosphate (not by ATP) to form 1,3-bisphosphoglycerate (step 6). Energy is then released as the two molecules of 1,3-bisphosphoglycerate are converted to two molecules of pyruvate (steps 7 through 10). Much of this energy is conserved by the coupled phosphorylation of four molecules of ADP to ATP. The net yield is two molecules of ATP per molecule of glucose used, because two molecules of ATP were invested in the preparatory phase. Energy is also conserved in the payoff phase in the formation of two molecules of the electron carrier NADH per molecule of glucose.

In the sequential reactions of glycolysis, three types of chemical transformations are particularly noteworthy: (1) degradation of the carbon skeleton of glucose to yield pyruvate; (2) phosphorylation of ADP to ATP by compounds with high phosphoryl group transfer potential, formed during glycolysis; and (3) transfer of a hydride ion to NAD*, forming NADH.

**Fates of Pyruvate** With the exception of some interesting variations in the bacterial realm, the pyruvate formed by glycolysis is further metabolized via one of three catabolic routes. In aerobic organisms or tissues, under aerobic conditions, glycolysis is only the first stage in the complete degradation of glucose (Fig. 14-3). Pyruvate is oxidized, with loss of its carboxyl group as CO$_2$, to yield the acetyl group of acetyl-coenzyme A; the acetyl group is then oxidized completely to CO$_2$ by the citric acid cycle (Chapter 16). The electrons from these oxidations are passed to O$_2$ through a chain of carriers in mitochondria, to form H$_2$O. The energy from the electron-transfer reactions drives the synthesis of ATP in mitochondria (Chapter 19).

The second route for pyruvate is its reduction to lactate via lactic acid fermentation. When vigorously contracting skeletal muscle must function under low-oxygen conditions (hypoxia), NADH cannot be reoxidized to NAD$, but NAD$^+$ is required as an electron acceptor for the further oxidation of pyruvate. Under these conditions pyruvate is reduced to lactate, accepting electrons from NADH and thereby regenerating the NAD$^+$ necessary for glycolysis to continue. Certain tissues and cell types (retina and erythrocytes, for example) convert glucose to lactate even under aerobic conditions, and lactate is also the product of glycolysis under anaerobic conditions in some microorganisms (Fig. 14-3).

The third major route of pyruvate catabolism leads to ethanol. In some plant tissues and in certain invertebrates, protists, and microorganisms such as brewer's or baker's yeast, pyruvate is converted under hypoxic or anaerobic conditions to ethanol and CO$_2$, a process called ethanol (alcohol) fermentation (Fig. 14-3).

The oxidation of pyruvate is an important catabolic process, but pyruvate has anabolic fates as well. It can, for example, provide the carbon skeleton for the synthesis of the amino acid alanine or for the synthesis of fatty acids. We return to these anabolic reactions of pyruvate in later chapters.

**ATP and NADH Formation Coupled to Glycolysis** During glycolysis some of the energy of the glucose molecule is conserved in ATP, while much remains in the product, pyruvate. The overall equation for glycolysis is

\[
\text{Glucose} + 2\text{NAD}^+ + 2\text{ADP} + 2\text{P}_i \rightarrow 2 \text{pyruvate} + 2\text{NADH} + 2\text{H}^+ + 2\text{ATP} + 2\text{H}_2\text{O} \quad (14-1)
\]
For each molecule of glucose degraded to pyruvate, two molecules of ATP are generated from ADP and P_i, and two molecules of NADH are produced by the reduction of NAD^+. The hydrogen acceptor in this reaction is NAD^+ (see Fig. 13-24), bound to a Rossmann fold as shown in Figure 13-25. The reduction of NAD^+ proceeds by the enzymatic transfer of a hydride ion (H^-) from the aldehyde group of glyceraldehyde 3-phosphate to the nicotinamide ring of NAD^+, yielding the reduced coenzyme NADH. The other hydrogen atom of the substrate molecule is released to the solution as H^+.

We can now resolve the equation of glycolysis into two processes—the conversion of glucose to pyruvate, which is exergonic:

\[
\text{Glucose} + 2\text{NAD}^+ \rightarrow 2 \text{pyruvate} + 2\text{NADH} + 2\text{H}^+ \quad (14-2)
\]

and the formation of ATP from ADP and P_i, which is endergonic:

\[
2\text{ADP} + 2\text{P}_i \rightarrow 2\text{ATP} + 2\text{H}_2\text{O} \quad (14-3)
\]

The sum of Equations 14-2 and 14-3 gives the overall standard free-energy change of glycolysis, \( \Delta G_{\text{r}}^{\circ} \):

\[
\Delta G_{\text{r}}^{\circ} = \Delta G_{\text{r}}^{\circ} + \Delta G_{\text{f}}^{\circ} = -146 \text{kJ/mol} + 61 \text{kJ/mol} = -85 \text{kJ/mol}
\]

Under standard conditions, and under the (nonstandard) conditions that prevail in a cell, glycolysis is an essentially irreversible process, driven to completion by a large net decrease in free energy.

**Energy Remaining in Pyruvate** Glycolysis releases only a small fraction of the total available energy of the glucose molecule; the two molecules of pyruvate formed by glycolysis still contain most of the chemical potential energy of glucose, energy that can be extracted by oxidative reactions in the citric acid cycle (Chapter 16) and oxidative phosphorylation (Chapter 19).

**Importance of Phosphorylated Intermediates** Each of the nine glycolytic intermediates between glucose and pyruvate is phosphorylated (Fig. 14–2). The phosphoryl groups seem to have three functions.

1. Because the plasma membrane generally lacks transporters for phosphorylated sugars, the phosphorylated glycolytic intermediates cannot leave the cell. After the initial phosphorylation, no further energy is necessary to retain phosphorylated intermediates in the cell, despite the large difference in their intracellular and extracellular concentrations.

2. Phosphoryl groups are essential components in the enzymatic conservation of metabolic energy. Energy released in the breakage of phosphoanhydride bonds (such as those in ATP) is partially conserved in the formation of phosphate esters such as glucose 6-phosphate. High-energy phosphate compounds formed in glycolysis (1,3-bisphosphoglycerate and phosphoenolpyruvate) donate phosphoryl groups to ADP to form ATP.

3. Binding energy resulting from the binding of phosphate groups to the active sites of enzymes lowers the activation energy and increases the specificity of the enzymatic reactions (Chapter 6). The phosphate groups of ADP, ATP, and the glycolytic intermediates form complexes with Mg^{2+}, and the substrate binding sites of many glycolytic enzymes are specific for these Mg^{2+} complexes. Most glycolytic enzymes require Mg^{2+} for activity.

**The Preparatory Phase of Glycolysis Requires ATP**

In the preparatory phase of glycolysis, two molecules of ATP are invested and the hexose chain is cleaved into two triose phosphates. The realization that phosphorylated hexoses were intermediates in glycolysis came slowly and serendipitously. In 1906, Arthur Harden and William Young tested their hypothesis that inhibitors of proteolytic enzymes would stabilize the glucose-fermenting enzymes in yeast extract. They added blood serum (known to contain inhibitors of proteolytic enzymes) to yeast extracts and observed the predicted stimulation of glucose metabolism. However, in a control experiment intended to show that boiling the serum destroyed the stimulatory activity, they discovered that boiled serum was just as effective at stimulating glycolysis! Careful examination and testing of the contents of the boiled serum revealed that inorganic phosphate was responsible for the stimulation. Harden and Young soon discovered that glucose added to their yeast extract was converted to a hexose bisphosphate (the “Harden-Young ester,” eventually identified as fructose 1,6-bisphosphate). This was the beginning of a long series of investigations on the role of organic esters and anhydrides of phosphate in biochemistry, which has led to our current understanding of the central role of phosphoryl group transfer in biology.
① Phosphorylation of Glucose In the first step of glycolysis, glucose is activated for subsequent reactions by its phosphorylation at C-6 to yield glucose 6-phosphate, with ATP as the phosphoryl donor:

\[
\begin{align*}
\text{Glucose} & \rightarrow \text{Glucose 6-phosphate} \\
\Delta G^\circ &= -16.7 \text{ kJ/mol}
\end{align*}
\]

This reaction, which is irreversible under intracellular conditions, is catalyzed by hexokinase. Recall that kinases are enzymes that catalyze the transfer of the terminal phosphoryl group from ATP to an acceptor nucleophile (see Fig. 13-20). Kinases are a subclass of transferases (see Table 6-3). The acceptor in the case of hexokinase is a hexose, normally D-glucose, although hexokinase also catalyzes the phosphorylation of other common hexoses, such as D-fructose and D-mannose, in some tissues.

Hexokinase, like many other kinases, requires Mg\(^{2+}\) for its activity, because the true substrate of the enzyme is not ATP\(^{4-}\) but the MgATP\(^{2-}\) complex (see Fig. 13-12). Mg\(^{2+}\) shields the negative charges of the phosphoryl groups in ATP, making the terminal phosphorus atom an easier target for nucleophilic attack by an —OH of glucose. Hexokinase undergoes a profound change in shape, an induced fit, when it binds glucose; two domains of the protein move about 8 Å closer to each other when ATP binds (see Fig. 6-22). This movement brings bound ATP closer to a molecule of glucose also bound to the enzyme and blocks the access of water (from the solvent), which might otherwise enter the active site and attack (hydrolyze) the phosphoanhydride bonds of ATP. Like the other nine enzymes of glycolysis, hexokinase is a soluble, cytosolic protein.

Hexokinase is present in nearly all organisms. The human genome encodes four different hexokinases (I to IV), all of which catalyze the same reaction. Two or more enzymes that catalyze the same reaction but are encoded by different genes are called isozymes (see Box 15–2). One of the isozymes present in hepatocytes, hexokinase IV (also called glucokinase), differs from other forms of hexokinase in kinetic and regulatory properties, with important physiological consequences that are described in Section 15.3.

② Conversion of Glucose 6-Phosphate to Fructose 6-Phosphate The enzyme phosphohexose isomerase (phosphoglucose isomerase) catalyzes the reversible isomerization of glucose 6-phosphate, an aldose, to fructose 6-phosphate, a ketose:

\[
\begin{align*}
\text{Glucose 6-phosphate} & \rightleftharpoons \text{Fructose 6-phosphate} \\
\Delta G^\circ &= -1.7 \text{ kJ/mol}
\end{align*}
\]

The mechanism for this reaction involves an enediol intermediate (Fig. 14–4). The reaction proceeds readily in either direction, as might be expected from the relatively small change in standard free energy. This isomerization has a critical role in the overall chemistry of the glycolytic pathway, as the rearrangement of the carbonyl and hydroxyl groups at C-1 and C-2 is a necessary prelude to the next two steps. The phosphorylation that occurs in the next reaction (step ③) requires that the group at C-1 first be converted from a carbonyl to an alcohol, and in the subsequent reaction (step ④) cleavage of the bond between C-3 and C-4 requires a carbonyl group at C-2 (p. 497).

③ Phosphorylation of Fructose 6-Phosphate to Fructose 1,6-Bisphosphate In the second of the two priming reactions of glycolysis, phosphofructokinase-1 (PFK-1) catalyzes the transfer of a phosphoryl group from ATP to fructose 6-phosphate to yield fructose 1,6-bisphosphate:

\[
\begin{align*}
\text{Fructose 6-phosphate} & \rightarrow \text{Fructose 1,6-bisphosphate} \\
\Delta G^\circ &= -14.2 \text{ kJ/mol}
\end{align*}
\]

KEY CONVENTION: Compounds that contain two phosphate or phosphoryl groups attached at different positions in the molecule are named bisphosphates (or bisphospho compounds); for example, fructose 1,6-bisphosphate and 1,3-bisphosphoglycerate. Compounds with two phosphates linked together as a pyrophosphoryl group are named diphosphates; for example, adenosine diphosphate (ADP). Similar rules apply for the naming of trisphosphates (such
Glucose 6-phosphate

Fructose 6-phosphate

**Phosphohexose isomerase**

**MECHANISM FIGURE 14-4** The phosphohexose isomerase reaction.

The ring opening and closing reactions (steps 1 and 4) are catalyzed by an active-site His residue, by mechanisms omitted here for simplicity. The proton (pink) initially at C-2 is made more easily abstractable by electron withdrawal by the adjacent carbonyl and nearby hydroxyl as inositol 1,4,5-trisphosphate; see p. 432) and triphosphates (such as adenosine triphosphate, ATP).

The enzyme that forms fructose 1,6-bisphosphate is called PFK-1 to distinguish it from a second enzyme (PFK-2) that catalyzes the formation of fructose 2,6-bisphosphate from fructose 6-phosphate in a separate pathway (the roles of PFK-2 and fructose 2,6-bisphosphate are discussed in Chapter 15). The PFK-1 reaction is essentially irreversible under cellular conditions, and it is the first “committed” step in the glycolytic pathway; glucose 6-phosphate and fructose 6-phosphate have other possible fates, but fructose 1,6-bisphosphate is targeted for glycolysis.

Some bacteria and protists and perhaps all plants have a phosphofructokinase that uses pyrophosphate (PP), not ATP, as the phosphoryl group donor in the synthesis of fructose 1,6-bisphosphate:

\[
\text{Fructose 6-phosphate} + \text{PP} \rightarrow \text{Fructose 1,6-bisphosphate} + \text{P}_1
\]

\[\Delta G^\circ = -2.9 \text{ kJ/mol}\]

Phosphofructokinase-1 is subject to complex allosteric regulation; its activity is increased whenever the cell’s ATP supply is depleted or when the ATP breakdown products, ADP and AMP (particularly the latter), accumulate. The enzyme is inhibited whenever the cell has ample ATP and is well supplied by other fuels such as fatty acids. In some organisms, fructose 2,6-bisphosphate (not to be confused with the PFK-1 reaction product, fructose 1,6-bisphosphate) is a potent allosteric activator of PFK-1. Ribulose 5-phosphate, an intermediate in the pentose phosphate pathway discussed later in this chapter, also activates phosphofructokinase indirectly. The multiple layers of regulation of this step in glycolysis are discussed in greater detail in Chapter 15.

**4 Cleavage of Fructose 1,6-Bisphosphate** The enzyme fructose 1,6-bisphosphate aldolase, often called simply aldolase, catalyzes a reversible aldol condensation (see Fig. 13-4). Fructose 1,6-bisphosphate is cleaved to yield two different triose phosphates, glyceraldehyde 3-phosphate, an aldose, and dihydroxyacetone phosphate, a ketose:

\[
\text{Fructose 1,6-bisphosphate} \rightarrow \text{Glyceraldehyde 3-phosphate} + \text{Dihydroxyacetone phosphate}
\]

\[\Delta G^\circ = 23.8 \text{ kJ/mol}\]
There are two classes of aldolases. Class I aldolases, found in animals and plants, use the mechanism shown in Figure 14-5. Class II enzymes, in fungi and bacteria, do not form the Schiff base intermediate. Instead, a zinc ion at the active site is coordinated with the carbonyl oxygen at C-2; the Zn$^{2+}$ polarizes the carbonyl group and stabilizes the enolate intermediate created in the C—C bond cleavage step.

Although the aldolase reaction has a strongly positive standard free-energy change in the direction of fructose 1,6-bisphosphate cleavage, at the lower concentrations of reactants present in cells the actual free-energy change is small and the aldolase reaction is readily reversible. We shall see later that aldolase acts in the reverse direction during the process of gluconeogenesis (see Fig. 14-16).

**Interconversion of the Triose Phosphates** Only one of the two triose phosphates formed by aldolase, glyceraldehyde 3-phosphate, can be directly degraded in the subsequent steps of glycolysis. The other product, dihydroxyacetone phosphate, is rapidly and reversibly converted to glyceraldehyde 3-phosphate by the fifth enzyme of the glycolytic sequence, triose phosphate isomerase:

\[
\begin{align*}
\text{Dihydroxyacetone phosphate} & \quad \text{Glyceraldehyde 3-phosphate} \\
\text{AG}^\circ & = 7.5 \text{ kJ/mol}
\end{align*}
\]

**Mechanism Figure 14-5** The class I aldolase reaction. The reaction shown here is the reverse of an aldol condensation. Note that cleavage between C-3 and C-4 depends on the presence of the carbonyl group at C-2. A and B represent amino acid residues that serve as general acid (A) or base (B).
FIGURE 14-6 Fate of the glucose carbons in the formation of glycer-aldehyde 3-phosphate. (a) The origin of the carbons in the two three-carbon products of the aldolase and triose phosphate isomerase reactions. The end product of the two reactions is glycer-aldehyde 3-phosphate (two molecules). (b) Each carbon of glycer-aldehyde 3-phosphate is derived from either of two specific carbons of glucose. Note that the numbering of the carbon atoms of glycer-aldehyde 3-phosphate differs from that of the glucose from which it is derived. In glycer-aldehyde 3-phosphate, the most complex functional group (the carboxyl) is specified as C-1. This numbering change is important for interpreting experiments with glucose in which a single carbon is labeled with a radioisotope. (See Problems 6 and 9 at the end of this chapter.)

Oxidation of Glycer-aldehyde 3-Phosphate to 1,3-Bisphosphoglycerate The first step in the payoff phase is the oxidation of glycer-aldehyde 3-phosphate to 1,3-bisphosphoglycerate, catalyzed by glycer-aldehyde 3-phosphate dehydrogenase:

This is the first of the two energy-conserving reactions of glycolysis that eventually lead to the formation of ATP. The aldehyde group of glycer-aldehyde 3-phosphate is oxidized, not to a free carboxyl group but to a carboxylic acid anhydride with phosphoric acid. This

The Payoff Phase of Glycolysis Yields ATP and NADH

The payoff phase of glycolysis (Fig. 14–2b) includes the energy-conserving phosphorylation steps in which some of the chemical energy of the glucose molecule is conserved in the form of ATP and NADH. Remember that one molecule of glucose yields two molecules of glycer-aldehyde 3-phosphate, and both halves of the glucose molecule follow the same pathway in the second phase of glycolysis. The conversion of two molecules of glycer-aldehyde 3-phosphate to two molecules of pyruvate is accompanied by the formation of four molecules of ATP from ADP. However, the net yield of ATP per molecule of glucose degraded is only two, because two ATP were invested in the preparatory phase of glycolysis to phosphorylate the two ends of the hexose molecule.
Glycolysis, Gluconeogenesis, and the Pentose Phosphate Pathway

**MECHANISM FIGURE 14–7** The glyceraldehyde 3-phosphate dehydrogenase reaction.

The glyceraldehyde 3-phosphate dehydrogenase reaction involves a covalent thiohemiacetal linkage forming between the substrate and the -SH group of the Cys residue. The enzyme-substrate complex undergoes phosphorolysis (attack by P1) releasing the second product, 1,3-bisphosphoglycerate.

The amount of NAD⁺ in a cell (\(10^{-5} \text{ M}\)) is far smaller than the amount of glucose metabolized in a few minutes. Glycolysis would soon come to a halt if the NADH formed in this step of glycolysis were not continuously reoxidized and recycled. We return to a discussion of this recycling of NAD⁺ later in the chapter.

**Phosphoryl Transfer from 1,3-Bisphosphoglycerate to ADP** The enzyme phosphoglycerate kinase transfers the high-energy phosphoryl group from the carboxyl group of 1,3-bisphosphoglycerate to ADP, forming ATP and 3-phosphoglycerate:

\[
\text{HCOH} + \text{CH}_2\text{OPO}_3^- \rightarrow \text{ATP} + 3\text{-phosphoglycerate}
\]

\(\Delta G^{\circ} = -18.5 \text{ kJ/mol}\)
Notice that phosphoglycerate kinase is named for the reverse reaction, in which it transfers a phosphoryl group from ATP to 3-phosphoglycerate. Like all enzymes, it catalyzes the reaction in both directions. This enzyme acts in the direction suggested by its name during gluconeogenesis (see Fig. 14–16) and during photosynthetic CO₂ assimilation (see Fig. 20–4). In glycolysis, the reaction it catalyzes proceeds as shown above, in the direction of ATP synthesis.

Steps 6 and 7 of glycolysis together constitute an energy-coupling process in which 1,3-bisphosphoglycerate is the common intermediate; it is formed in the first reaction (which would be endergonic in isolation), and its acyl phosphate group is transferred to ADP in the second reaction (which is strongly exergonic). The sum of these two reactions is

\[
\text{Glyceraldehyde 3-phosphate + ADP + Pi + NAD}^+ \rightleftharpoons 3\text{-phosphoglycerate + ATP + NADH + H}^+ \\
\Delta G^o = -12.2 \text{kJ/mol}
\]

Thus the overall reaction is exergonic.

Recall from Chapter 13 that the actual free-energy change, \(\Delta G\), is determined by the standard free-energy change, \(\Delta G^o\), and the mass-action ratio, \(Q\), which is the ratio [products]/[reactants] (see Eqn 13–4). For step 6,

\[
\Delta G = \Delta G^o + RT \ln Q
\]

\[
= \Delta G^o + RT \ln \left( \frac{[1,3\text{-bisphosphoglycerate}][\text{NAD}]}{[\text{glyceraldehyde 3-phosphate}][\text{Pi}][\text{NAD}^+]}} \right)
\]

Notice that \([\text{H}^+]\) is not included in \(Q\). In biochemical calculations, \([\text{H}^+]\) is assumed to be a constant (10^-7 m), and this constant is included in the definition of \(\Delta G^o\) (p. 491).

When the mass-action ratio is less than 1.0, its natural logarithm has a negative sign. Step 7, by consuming the product of step 6 (1,3-bisphosphoglycerate), keeps [1,3-bisphosphoglycerate] relatively low in the steady state and thereby keeps \(Q\) for the overall energy-coupling process small. When \(Q\) is small, the contribution of \(\ln Q\) can make \(\Delta G\) strongly negative. This is simply another way of showing how the two reactions, steps 6 and 7, are coupled through a common intermediate.

The outcome of these coupled reactions, both reversible under cellular conditions, is that the energy released on oxidation of an aldehyde to a carboxylate group is conserved by the coupled formation of ATP from ADP and Pi. The formation of ATP by phosphoryl group transfer from a substrate such as 1,3-bisphosphoglycerate is referred to as a substrate-level phosphorylation, to distinguish this mechanism from respiration-linked phosphorylation. Substrate-level phosphorylations involve soluble enzymes and chemical intermediates (1,3-bisphosphoglycerate in this case). Respiration-linked phosphorylations, on the other hand, involve membrane-bound enzymes and transmembrane gradients of protons (Chapter 19).

**Conversion of 3-Phosphoglycerate to 2-Phosphoglycerate** The enzyme phosphoglycerate mutase catalyzes a reversible shift of the phosphoryl group between C-2 and C-3 of glycerate; Mg²⁺ is essential for this reaction:

\[
\begin{align*}
\text{3-Phosphoglycerate} & \rightleftharpoons \text{2-Phosphoglycerate} \\
\Delta G^o & = 4.4 \text{kJ/mol}
\end{align*}
\]

The reaction occurs in two steps (Fig. 14–8). A phosphoryl group initially attached to a His residue of the mutase is transferred to the hydroxyl group at C-2 of 3-phosphoglycerate, forming 2,3-bisphosphoglycerate (2,3-BPG). The phosphoryl group at C-3 of 2,3-BPG is then transferred to the same His residue, producing 2-phosphoglycerate and regenerating the phosphorylated
enzyme. Phosphoglycerate mutase is initially phosphorylated by phosphoryl transfer from 2,3-BPG, which is required in small quantities to initiate the catalytic cycle and is continuously regenerated by that cycle.

9 Dehydration of 2-Phosphoglycerate to Phosphoenolpyruvate In the second glycolytic reaction that generates a compound with high phosphoryl group transfer potential (the first was step 6), enolase promotes reversible removal of a molecule of water from 2-phosphoglycerate to yield phosphoenolpyruvate (PEP):

\[
\begin{align*}
\text{2-Phosphoglycerate} & \quad \overset{\text{enolase}}{\longrightarrow} \quad \text{Phosphoenolpyruvate} \\
\text{HCO}_3^- & \quad \overset{\text{H}_2\text{O}}{\longrightarrow} \quad \text{C}_3\text{H}_4\text{O}_4^- \\
\Delta G^\circ & = 7.5 \text{ kJ/mol}
\end{align*}
\]

The mechanism of the enolase reaction involves an enolic intermediate stabilized by Mg\(^{2+}\) (see Fig. 6-23). The reaction converts a compound with a relatively low phosphoryl group transfer potential (\(\Delta G^\circ\) for hydrolysis of 2-phosphoglycerate is -17.6 kJ/mol) to one with high phosphoryl group transfer potential (\(\Delta G^\circ\) for PEP hydrolysis is -61.9 kJ/mol) (see Fig. 13-13, Table 13-6).

10 Transfer of the Phosphoryl Group from Phosphoenolpyruvate to ADP The last step in glycolysis is the transfer of the phosphoryl group from phosphoenolpyruvate to ADP, catalyzed by pyruvate kinase, which requires K\(^+\) and either Mg\(^{2+}\) or Mn\(^{2+}\).

\[
\begin{align*}
\text{Phosphoenolpyruvate} & \quad \text{ADP} \\
\text{Mg}^{2+}, \text{K}^+ & \quad \text{pyruvate kinase} \\
\text{CH}_2 & \quad \overset{\text{P}}{\longrightarrow} \quad \text{C} = \text{O} \\
\Delta G^\circ & = -31.4 \text{ kJ/mol}
\end{align*}
\]

In this substrate-level phosphorylation, the product pyruvate first appears in its enol form, then tautomerizes rapidly and nonenzymatically to its keto form, which predominates at pH 7:

\[
\begin{align*}
\text{Pyruvate (enol form)} & \quad \overset{\text{tautomerization}}{\longrightarrow} \quad \text{Pyruvate (keto form)} \\
\text{C} & \quad \overset{\text{OH}}{\longrightarrow} \quad \text{C} = \text{O} \\
\text{CH}_3 & \quad \overset{\text{H}}{\longrightarrow} \quad \text{CH}_3
\end{align*}
\]

The overall reaction has a large, negative standard free-energy change, due in large part to the spontaneous conversion of the enol form of pyruvate to the keto form (see Fig. 13-13). About half of the energy released by PEP hydrolysis (\(\Delta G^\circ = -61.9 \text{ kJ/mol}\)) is conserved in the formation of the phosphoanhydride bond of ATP (\(\Delta G^\circ = -30.5 \text{ kJ/mol}\)), and the rest (-31.4 kJ/mol) constitutes a large driving force pushing the reaction toward ATP synthesis. We discuss the regulation of pyruvate kinase in Chapter 15.

The Overall Balance Sheet Shows a Net Gain of ATP We can now construct a balance sheet for glycolysis to account for (1) the fate of the carbon skeleton of glucose, (2) the input of P\(_i\) and ADP and output of ATP, and (3) the pathway of electrons in the oxidation-reduction reactions. The left-hand side of the following equation shows all the inputs of ATP, NAD\(^{+}\), ADP, and P\(_i\) (consult Fig. 14-2), and the right-hand side shows all the outputs (keep in mind that each molecule of glucose yields two molecules of pyruvate):

\[
\text{Glucose} + 2\text{ATP} + 2\text{NAD}^{+} + 4\text{ADP} + 2\text{P}_i \longrightarrow 2\text{pyruvate} + 2\text{ADP} + 2\text{NADH} + 2\text{H}^{+} + 4\text{ATP} + 2\text{H}_2\text{O}
\]

Canceling out common terms on both sides of the equation gives the overall equation for glycolysis under aerobic conditions:

\[
\text{Glucose} + 2\text{NAD}^{+} + 2\text{ADP} + 2\text{P}_i \longrightarrow 2\text{pyruvate} + 2\text{NADH} + 2\text{H}^{+} + 2\text{ATP} + 2\text{H}_2\text{O}
\]

The two molecules of NADH formed by glycolysis in the cytosol are, under aerobic conditions, reoxidized to NAD\(^{+}\) by transfer of their electrons to the electron-transfer chain, which in eukaryotic cells is located in the mitochondria. The electron-transfer chain passes these electrons to their ultimate destination, O\(_2\):

\[
2\text{NADH} + 2\text{H}^{+} + \text{O}_2 \longrightarrow 2\text{NAD}^{+} + 2\text{H}_2\text{O}
\]

Electron transfer from NADH to O\(_2\) in mitochondria provides the energy for synthesis of ATP by respiration-linked phosphorylation (Chapter 19).

In the overall glycolytic process, one molecule of glucose is converted to two molecules of pyruvate (the pathway of carbon). Two molecules of ADP and two of P\(_i\) are converted to two molecules of ATP (the pathway
of phosphoryl groups). Four electrons, as two hydride ions, are transferred from two molecules of glyceraldehyde 3-phosphate to two of NAD\(^+\) (the pathway of electrons).

**Glycolysis Is under Tight Regulation**

During his studies on the fermentation of glucose by yeast, Louis Pasteur discovered that both the rate and the total amount of glucose consumption were many times greater under anaerobic than aerobic conditions. Later studies of muscle showed the same large difference in the rates of anaerobic and aerobic glycolysis. The biochemical basis of this “Pasteur effect” is now clear. The ATP yield from glycolysis under anaerobic conditions (2 ATP per molecule of glucose) is much smaller than that from the complete oxidation of glucose to \(\text{CO}_2\) under aerobic conditions (30 or 32 ATP per glucose; see Table 19–5). About 15 times as much glucose must therefore be consumed anaerobically as aerobically to yield the same amount of ATP.

The flux of glucose through the glycolytic pathway is regulated to maintain nearly constant ATP levels (as well as adequate supplies of glycolytic intermediates that serve biosynthetic roles). The required adjustment in the rate of glycolysis is achieved by a complex interplay among ATP consumption, NADH regeneration, and allosteric regulation of several glycolytic enzymes—including hexokinase, PFK-I, and pyruvate kinase—and by second-to-second fluctuations in the concentration of key metabolites that reflect the cellular balance between ATP production and consumption. On a slightly longer time scale, glycolysis is regulated by the hormones glucagon, epinephrine, and insulin, and by changes in the expression of the genes for several glycolytic enzymes. An especially interesting case of abnormal regulation of glycolysis is seen in cancer. The German biochemist Otto Warburg first observed in 1928 that tumors of nearly all types carry out glycolysis at a much higher rate than normal tissue, even when oxygen is available. This “Warburg effect” is the basis for several methods of detecting and treating cancer (Box 14–1).

Warburg is generally considered the preeminent biochemist of the first half of the twentieth century. He made seminal contributions to many other areas of biochemistry, including respiration, photosynthesis, and the enzymology of intermediary metabolism. Beginning in 1930, Warburg and his associates purified and crystallized seven of the enzymes of glycolysis. They developed an experimental tool that revolutionized biochemical studies of oxidative metabolism: the Warburg manometer, which directly measured the oxygen consumption of tissues by monitoring changes in gas volume, and thus allowed quantitative measurement of any enzyme with oxidase activity.

Trained in carbohydrate chemistry in the laboratory of the great Emil Fischer (who won the Nobel Prize in Chemistry in 1902), Warburg himself won the Nobel Prize in Physiology or Medicine in 1931. Several of Warburg’s students and colleagues also were awarded Nobel Prizes: Otto Meyerhof in 1922, Hans Krebs and Fritz Lipmann in 1953, and Hugo Theorell in 1955. Meyerhof’s laboratory provided training for Lipmann, and for several other Nobel Prize winners: Severo Ochoa (1959), Andre Lwoff (1965), and George Wald (1967).

**Glucose Uptake Is Deficient in Type 1 Diabetes Mellitus**

The metabolism of glucose in mammals is limited by the rate of glucose uptake into cells and its phosphorylation by hexokinase. Glucose uptake from the blood is mediated by the GLUT family of glucose transporters (see Table 11–3). The transporters of hepatocytes (GLUT1, GLUT2) and of brain neurons (GLUT3) are always present in plasma membranes. In contrast, the main glucose transporter in the cells of skeletal muscle, cardiac muscle, and adipose tissue (GLUT4) is sequestered in small intracellular vesicles and moves into the plasma membrane only in response to an insulin signal (Fig. 14–9). We discussed this insulin signaling mechanism in Chapter 12 (see Fig. 12–16). Thus in skeletal muscle, heart, and adipose tissue, glucose uptake and metabolism depend on the normal release of insulin by pancreatic \(\beta\) cells in response to elevated blood glucose (see Fig. 23–27).

Individuals with type 1 diabetes mellitus (also called insulin-dependent diabetes) have too few \(\beta\) cells and cannot release sufficient insulin to trigger glucose uptake by the cells of skeletal muscle, heart, or adipose tissue. Thus, after a meal containing carbohydrates, glucose accumulates to abnormally high levels in the blood, a condition known as hyperglycemia. Unable to take up glucose, muscle and fat tissue use the fatty acids of stored triacylglycerols as their principal fuel. In the liver, acetyl-CoA derived from this fatty acid breakdown is converted to “ketone bodies”—acetocacetate and \(\beta\)-hydroxybutyrate—which are exported and carried to other tissues to be used as fuel (Chapter 17). These compounds are especially critical to the brain, which uses ketone bodies as alternative fuel when glucose is unavailable. (Fatty acids cannot pass through the blood-brain barrier and thus are not a fuel for brain neurons.)

In untreated type 1 diabetes, overproduction of acetocacetate and \(\beta\)-hydroxybutyrate leads to their accumulation in the blood, and the consequent lowering of blood pH produces ketoacidosis, a life-threatening condition. Insulin injection reverses this sequence of events: GLUT4 moves into the plasma membranes of
In many types of tumors found in humans and other animals, glucose uptake and glycolysis proceed about 10 times faster than in normal, noncancerous tissues. Most tumor cells grow under hypoxic conditions (i.e., with limited oxygen supply) because, at least initially, they lack the capillary network to supply sufficient oxygen. Cancer cells located more than 100 to 200 μm from the nearest capillaries must depend on glycolysis alone (without further oxidation of pyruvate) for much of their ATP production. The energy yield (2 ATP per glucose) is far lower than can be obtained by the complete oxidation of pyruvate to CO₂ in mitochondria (about 30 ATP per glucose; Chapter 19). So, to make the same amount of ATP, tumor cells must take up much more glucose than do normal cells, converting it to pyruvate and then to lactate as they recycle NADH. It is likely that two early steps in the transformation of a normal cell into a tumor cell are (1) the change to dependence on glycolysis for ATP production, and (2) the development of tolerance to a low pH in the extracellular fluid (caused by release of the end product of glycolysis, lactic acid). In general, the more aggressive the tumor, the greater is its rate of glycolysis.

This increase in glycolysis is achieved at least in part by increased synthesis of the glycolytic enzymes and of the plasma membrane transporters GLUT1 and GLUT3 (see Table 11–3) that carry glucose into cells. (Recall that GLUT1 and GLUT3 are not dependent on insulin.) The hypoxia-inducible transcription factor (HIF-1) is a protein that acts at the level of mRNA synthesis to stimulate the production of at least eight glycolytic enzymes and the glucose transporters when oxygen supply is limited (Fig. 1). With the resulting high rate of glycolysis, the tumor cell can survive anaerobic conditions until the supply of blood vessels has caught up with tumor growth. Another protein induced by HIF-1 is the peptide hormone VEGF (vascular endothelial growth factor), which stimulates the outgrowth of blood vessels (angiogenesis) toward the tumor.

There is also evidence that the tumor suppressor protein p53, which is mutated in most types of cancer (p. 477), controls the synthesis and assembly of mitochondrial proteins essential to the passage of electrons to O₂. Cells with mutant p53 are defective in mitochondrial electron transport and are forced to rely more heavily on glycolysis for ATP production (Fig. 1).

This heavier reliance of tumors than of normal tissue on glycolysis suggests a possibility for anticancer therapy: inhibitors of glycolysis might target and kill tumors by depleting their supply of ATP. Three inhibitors of hexokinase have shown promise as chemotherapeutic agents: 2-deoxyglucose, lonidamine, and 3-bromopyruvate. By
preventing the formation of glucose 6-phosphate, these compounds not only deprive tumor cells of glycolytically produced ATP but also prevent the formation of pentose phosphates via the pentose phosphate pathway, which also begins with glucose 6-phosphate. Without pentose phosphates, a cell cannot synthesize the nucleotides essential to DNA and RNA synthesis and thus cannot grow or divide. Another anticancer drug already approved for clinical use is imatinib (Gleevec), described in Box 12–5. It inhibits a specific tyrosine kinase, preventing the increased synthesis of hexokinase normally triggered by that kinase. The thiamine analog oxythiamine, which blocks the action of a transketolase-like enzyme that converts xylulose 5-phosphate to glyceraldehyde 3-phosphate (Fig. 1), is in preclinical trials as an antitumor drug.

The high glycolytic rate in tumor cells also has diagnostic usefulness. The relative rates at which tissues take up glucose can be used in some cases to pinpoint the location of tumors. In positron emission tomography (PET), individuals are injected with a harmless, isotopically labeled glucose analog that is taken up but not metabolized by tissues. The labeled compound is 2-fluoro-2-deoxyglucose (FdG), in which the hydroxyl group at the C-2 of glucose is replaced with $^{18}$F (Fig. 2). This compound is taken up via GLUT transporters and is a good substrate for hexokinase, but it cannot be converted to the enediol intermediate in the phosphohexose isomerase reaction (see Fig. 14–4) and therefore accumulates as 6-phospho-FdG. The extent of its accumulation depends on its rate of uptake and phosphorylation, which as noted above is typically 10 or more times higher in tumors than in normal tissue. Decay of $^{18}$F yields positrons (two per $^{18}$F atom) that can be detected by a series of sensitive detectors positioned around the body, which allows accurate localization of accumulated 6-phospho-FdG (Fig. 3).
hepatocytes and adipocytes, glucose is taken up into the cells and phosphorylated, and the blood glucose level falls, greatly reducing the production of ketone bodies.

Diabetes mellitus has profound effects on the metabolism of both carbohydrates and fats. We return to this topic in Chapter 23, after considering lipid metabolism (Chapters 17 and 21).

**SUMMARY 14.1 Glycolysis**

- Glycolysis is a near-universal pathway by which a glucose molecule is oxidized to two molecules of pyruvate, with energy conserved as ATP and NADH.
- All 10 glycolytic enzymes are in the cytosol, and all 10 intermediates are phosphorylated compounds of three or six carbons.
- In the preparatory phase of glycolysis, ATP is invested to convert glucose to fructose 1,6-biphosphate. The bond between C-3 and C-4 is then broken to yield two molecules of triose phosphate.
- In the payoff phase, each of the two molecules of glyceraldehyde 3-phosphate derived from glucose
undergoes oxidation at C-1; the energy of this oxidation reaction is conserved in the form of one NADH and two ATP per triose phosphate oxidized. The net equation for the overall process is

\[
\text{Glucose} + 2\text{NAD}^+ + 2\text{ADP} + 2\text{Pi} \rightarrow 2\text{pyruvate} + 2\text{NADH} + 2\text{H}^+ + 2\text{ATP} + 2\text{H}_2\text{O}
\]

- Glycolysis is tightly regulated in coordination with other energy-yielding pathways to assure a steady supply of ATP.
- In type 1 diabetes, defective uptake of glucose by muscle and adipose tissue has profound effects on the metabolism of carbohydrates and fats.

### 14.2 Feeder Pathways for Glycolysis

Many carbohydrates besides glucose meet their catabolic fate in glycolysis, after being transformed into one of the glycolytic intermediates. The most significant are the storage polysaccharides glycogen and starch, either within cells (endogenous) or obtained in the diet; the disaccharides maltose, lactose, trehalose, and sucrose; and the monosaccharides fructose, mannose, and galactose (Fig. 14-10).

---

**Dietary Polysaccharides and Disaccharides Undergo Hydrolysis to Monosaccharides**

For most humans, starch is the major source of carbohydrates in the diet (Fig. 14-10). Digestion begins in the mouth, where salivary \(\alpha\)-amylase hydrolyzes the internal \((\alpha 1\rightarrow 4)\) glycosidic linkages of starch, producing short polysaccharide fragments or oligosaccharides. (Note that in this hydrolysis reaction, water, not \(\text{P}_i\), is the attacking species.) In the stomach, salivary \(\alpha\)-amylase is inactivated by the low pH, but a second form of \(\alpha\)-amylase, secreted by the pancreas into the small intestine, continues the breakdown process. Pancreatic \(\alpha\)-amylase yields mainly maltose and maltotriose (the di- and trisaccharides of glucose) and oligosaccharides called limit dextrins, fragments of amylopectin containing \((\alpha 1\rightarrow 6)\) branch points. Maltose and dextrins are degraded to glucose by enzymes of the intestinal brush border (the fingerlike microvilli of intestinal epithelial cells, which greatly increase the area of the intestinal surface). Dietary glycogen has essentially the same structure as starch, and its digestion proceeds by the same pathway.
Endogenous Glycogen and Starch Are Degraded by Phosphorolysis

Glycogen stored in animal tissues (primarily liver and skeletal muscle), in microorganisms, or in plant tissues can be mobilized for use within the same cell by a phosphorolysis reaction catalyzed by glycogen phosphorylase (starch phosphorylase in plants) (Fig. 14-11). These enzymes catalyze an attack by P₁ on the (α₁→4) glycosidic linkage that joins the last two glucose residues at a nonreducing end, generating glucose 1-phosphate and a polymer one glucose unit shorter. Phosphorolysis preserves some of the energy of the glycosidic bond in the phosphate ester glucose 1-phosphate. Glycogen phosphorylase (or starch phosphorylase) acts repetitively until it approaches an (α₁→6) branch point (see Fig. 7-14), where its action stops. A debranching enzyme removes the branches. The mechanisms and control of glycogen degradation are described in greater detail in Chapter 15.

Glucose 1-phosphate produced by glycogen phosphorylase is converted to glucose 6-phosphate by phosphoglucomutase, which catalyzes the reversible reaction

\[
\text{Glucose 1-phosphate} \rightleftharpoons \text{glucose 6-phosphate}
\]

Phosphoglucomutase employs essentially the same mechanism as phosphoglycerate mutase (p. 537): both entail a bisphosphate intermediate, and the enzyme is transiently phosphorylated in each catalytic cycle. The general name mutase is given to enzymes that catalyze the transfer of a functional group from one position to another in the same molecule. Mutases are a subclass of isomerases, enzymes that interconvert stereoisomers or structural or positional isomers (see Table 6-3). The glucose 6-phosphate formed in the phosphoglucomutase reaction can enter glycolysis or another pathway such as the pentose phosphate pathway, described in Section 14.5.

WORKED EXAMPLE 14-1 Energy Savings for Glycogen Breakdown by Phosphorolysis

Calculate the energy savings (in ATP molecules per glucose monomer) achieved by breaking down glycogen by phosphorolysis rather than hydrolysis to begin the process of glycolysis.

Solution: Phosphorolysis produces a phosphorylated glucose (glucose 1-phosphate), which is then converted to glucose 6-phosphate—without expenditure of the cellular energy (1 ATP) needed for formation of glucose 6-phosphate from free glucose. Thus only 1 ATP is consumed per glucose monomer in the preparatory phase, compared with 2 ATP when glycolysis starts with free glucose. The cell therefore gains 3 ATP per glucose monomer (4 ATP produced in the payoff phase minus 1 ATP used in the preparatory phase), rather than 2—a saving of 1 ATP per glucose monomer.

Breakdown of dietary polysaccharides such as glycogen and starch in the gastrointestinal tract by phosphorolysis rather than hydrolysis would produce no energy gain: sugar phosphates are not transported into the cells that line the intestine, but must first be dephosphorylated to the free sugar.

Disaccharides must be hydrolyzed to monosaccharides before entering cells. Intestinal disaccharides and dextrins are hydrolyzed by enzymes attached to the outer surface of the intestinal epithelial cells:

- Dextrin + nH₂O → n D-glucose
- Maltose + H₂O → 2 D-glucose
- Lactose + H₂O → D-galactose + D-glucose
- Sucrose + H₂O → D-fructose + D-glucose
- Trehalose + H₂O → 2 D-glucose

The monosaccharides so formed are actively transported into the epithelial cells (see Fig. 11-44), then passed into the blood to be carried to various tissues, where they are phosphorylated and funneled into the glycolytic sequence.
**Lactose intolerance**, common among adults of most human populations except those originating in Northern Europe and some parts of Africa, is due to the disappearance after childhood of most or all of the lactase activity of the intestinal epithelial cells. Without intestinal lactase, lactose cannot be completely digested and absorbed in the small intestine, and it passes into the large intestine, where bacteria convert it to toxic products that cause abdominal cramps and diarrhea. The problem is further complicated because undigested lactose and its metabolites increase the osmolarity of the intestinal contents, favoring retention of water in the intestine. In most parts of the world where lactose intolerance is prevalent, milk is not used as a food by adults, although milk products predigested with lactase are commercially available in some countries. In certain human disorders, several or all of the intestinal disaccharidases are missing. In these cases, the digestive disturbances triggered by dietary disaccharides can sometimes be minimized by a controlled diet.

**Other Monosaccharides Enter the Glycolytic Pathway at Several Points**

In most organisms, hexoses other than glucose can undergo glycolysis after conversion to a phosphorylated derivative. D-Fructose, present in free form in many fruits and formed by hydrolysis of sucrose in the small intestine of vertebrates, is phosphorylated by hexokinase:

\[
\text{Fructose} + \text{ATP} \overset{\text{Mg}^{2+}}{\longrightarrow} \text{fructose 6-phosphate} + \text{ADP}
\]

This is a major pathway of fructose entry into glycolysis in the muscles and kidney. In the liver, fructose enters by a different pathway. The liver enzyme fructokinase catalyzes the phosphorylation of fructose at C-1 rather than C-6:

\[
\text{Fructose} + \text{ATP} \overset{\text{Mg}^{2+}}{\longrightarrow} \text{fructose 1-phosphate} + \text{ADP}
\]

The fructose 1-phosphate is then cleaved to glyceraldehyde and dihydroxyacetone phosphate by fructose 1-phosphate aldolase:

\[
\text{Fructose 1-phosphate aldolase:}
\]

\[
\begin{align*}
\text{CH}_2\text{PO}_4^- & \quad \text{C} = \text{O} \\ 
\text{CH}_2\text{OH} & \\
\text{HOCH} & \\
\text{HCOH} & \\
\text{CH}_2\text{OH} & \\
\end{align*}
\]

Dihydroxyacetone phosphate is converted to glyceraldehyde 3-phosphate by the glycolytic enzyme triose phosphate isomerase. Glyceraldehyde is phosphorylated by ATP and triose kinase to glyceraldehyde 3-phosphate:

\[
\text{Glyceraldehyde} + \text{ATP} \overset{\text{Mg}^{2+}}{\longrightarrow} \text{glyceraldehyde 3-phosphate} + \text{ADP}
\]

Thus both products of fructose 1-phosphate hydrolysis enter the glycolytic pathway as glyceraldehyde 3-phosphate.

D-Galactose, a product of the hydrolysis of lactose (milk sugar), passes in the blood from the intestine to the liver, where it is first phosphorylated at C-1, at the expense of ATP, by the enzyme galactokinase:

\[
\text{Galactose} + \text{ATP} \overset{\text{Mg}^{2+}}{\longrightarrow} \text{galactose 1-phosphate} + \text{ADP}
\]

The galactose 1-phosphate is then converted to its epimer at C-4, glucose 1-phosphate, by a set of reactions in which uridine diphosphate (UDP) functions as a coenzyme-like carrier of hexose groups (Fig. 14-12). The epimerization involves first the oxidation of the C-4 -OH group to a ketone, then reduction of the ketone to an -OH, with inversion of the configuration at C-4. NAD is the cofactor for both the oxidation and the reduction.

A defect in any of the three enzymes in this pathway causes galactosemia in humans. In galactokinase-deficiency galactosemia, high galactose concentrations are found in blood and urine. Affected individuals develop cataracts in infancy, caused by deposition of the galactose metabolite galactitol in the lens.

\[
\begin{align*}
\text{CH}_2\text{OH} & \\
\text{H} & \quad \text{C} \quad \text{OH} \\
\text{HO} & \quad \text{C} \quad \text{H} \\
\text{HO} & \quad \text{C} \quad \text{H} \\
\text{H} & \quad \text{C} \quad \text{OH} \\
\text{CH}_2\text{OH} & \\
\end{align*}
\]

The other symptoms in this disorder are relatively mild, and strict limitation of galactose in the diet greatly diminishes their severity.

Transferase-deficiency galactosemia is more serious; it is characterized by poor growth in childhood, speech abnormality, mental deficiency, and liver damage that may be fatal, even when galactose is withheld from the diet. Epimerase-deficiency galactosemia leads to similar symptoms, but is less severe when dietary galactose is carefully controlled.

D-Mannose, released in the digestion of various polysaccharides and glycoproteins of foods, can be phosphorylated at C-6 by hexokinase:

\[
\text{Mannose} + \text{ATP} \overset{\text{Mg}^{2+}}{\longrightarrow} \text{mannose 6-phosphate} + \text{ADP}
\]

Mannose 6-phosphate is isomerized by phosphomannose isomerase to yield fructose 6-phosphate, an intermediate of glycolysis.
Phosphorolytic cleavage of a glucose residue from an end of the polymer, forming glucose 1-phosphate, is catalyzed by glycogen phosphorylase or starch phosphorylase. Phosphoglucomutase then converts the glucose 1-phosphate to glucose 6-phosphate, which can enter glycolysis.

- Ingested polysaccharides and disaccharides are converted to monosaccharides by intestinal hydrolytic enzymes, and the monosaccharides then enter intestinal cells and are transported to the liver or other tissues.
- A variety of d-hexoses, including fructose, galactose, and mannose, can be funneled into glycolysis. Each is phosphorylated and converted to glucose 6-phosphate, fructose 6-phosphate, or fructose 1-phosphate.
- Conversion of galactose 1-phosphate to glucose 1-phosphate involves two nucleotide derivatives: UDP-galactose and UDP-glucose. Genetic defects in any of the three enzymes that catalyze conversion of galactose to glucose 1-phosphate result in galactosemias of varying severity.

14.3 Fates of Pyruvate under Anaerobic Conditions: Fermentation

Under aerobic conditions, the pyruvate formed in the final step of glycolysis is oxidized to acetate (acetyl-CoA), which enters the citric acid cycle and is oxidized to CO₂ and H₂O. The NADH formed by dehydrogenation of glyceraldehyde 3-phosphate is ultimately reoxidized to NAD⁺ by passage of its electrons to O₂ in mitochondrial respiration. Under hypoxic (low-oxygen) conditions, however—as in very active skeletal muscle, in submerged plant tissues, solid tumors, or in lactic acid bacteria—NAD⁺ generated by glycolysis cannot be reoxidized by O₂. Failure to regenerate NAD⁺ would leave the cell with no electron acceptor for the oxidation of glyceraldehyde 3-phosphate, and the energy-yielding reactions of glycolysis would stop. NAD⁺ must therefore be regenerated in some other way.

The earliest cells lived in an atmosphere almost devoid of oxygen and had to develop strategies for deriving energy from fuel molecules under anaerobic conditions. Most modern organisms have retained the ability to continually regenerate NAD⁺ during anaerobic glycolysis by transferring electrons from NADH to form a reduced end product such as lactate or ethanol.

Pyruvate Is the Terminal Electron Acceptor in Lactic Acid Fermentation

When animal tissues cannot be supplied with sufficient oxygen to support aerobic oxidation of the pyruvate and NADH produced in glycolysis, NAD⁺ is regenerated...
from NADH by the reduction of pyruvate to lactate. As mentioned earlier, some tissues and cell types (such as erythrocytes, which have no mitochondria and thus cannot oxidize pyruvate to CO₂) produce lactate from glucose even under aerobic conditions. The reduction of pyruvate in this pathway is catalyzed by lactate dehydrogenase, which forms the l. isomer of lactate at pH 7:

The overall equilibrium of the reaction strongly favors lactate formation, as shown by the large negative standard free-energy change.

In glycolysis, dehydrogenation of the two molecules of glyceraldehyde 3-phosphate derived from each molecule of glucose converts two molecules of NAD⁺ to two of NADH. Because the reduction of two molecules of pyruvate to two of lactate regenerates two molecules of NAD⁺, there is no net change in NAD⁺ or NADH:

The lactate formed by active skeletal muscles (or by erythrocytes) can be recycled; it is carried in the blood to the liver, where it is converted to glucose during the recovery from strenuous muscular activity. When lactate is produced in large quantities during vigorous muscle contraction (during a sprint, for example), the acidification that results from ionization of lactic acid in muscle and blood limits the period of vigorous activity. The best-conditioned athletes can sprint at top speed for no more than a minute (Box 14-2). Although conversion of glucose to lactate includes two oxidation-reduction steps, there is no net change in the oxidation state of carbon; in glucose (C₆H₁₂O₆) and lactic acid (C₃H₆O₃), the H:C ratio is the same. Nevertheless, some of the energy of the glucose molecule has been extracted by its conversion to lactate—enough to give a net yield of two molecules of ATP for every glucose molecule consumed. Fermentation is the general term for such processes, which extract energy (as ATP) but do not consume oxygen or change the concentrations of NAD⁺ or NADH. Fermentations are carried out by a wide range of organisms, many of which occupy anaerobic niches, and they yield a variety of end products, some of which find commercial uses.

Ethanol is the reduced product in ethanol fermentation

Yeast and other microorganisms ferment glucose to ethanol and CO₂, rather than to lactate. Glucose is converted to pyruvate by glycolysis, and the pyruvate is converted to ethanol and CO₂ in a two-step process:

In the first step, pyruvate is decarboxylated in an irreversible reaction catalyzed by pyruvate decarboxylase. This reaction is a simple decarboxylation and does not involve the net oxidation of pyruvate. Pyruvate decarboxylase requires Mg²⁺ and has a tightly bound coenzyme, thiamine pyrophosphate, which is discussed below. In the second step, acetalddehyde is reduced to ethanol through the action of alcohol dehydrogenase, with the reducing power furnished by NADH derived from the dehydrogenation of glyceraldehyde 3-phosphate. This reaction is a well-studied case of hydride transfer from NADH (Fig. 14-13). Ethanol and CO₂ are thus the end products of ethanol fermentation, and the overall equation is:

Glucose + 2ADP + 2Pi → 2 ethanol + 2CO₂ + 2ATP + 2H₂O

As in lactic acid fermentation, there is no net change in the ratio of hydrogen to carbon atoms when glucose (H:C ratio = 12/6 = 2) is fermented to two ethanol and two CO₂ (combined H:C ratio = 12/6 = 2). In all
fermentations, the H:C ratio of the reactants and products remains the same.

Pyruvate decarboxylase is present in brewer's and baker's yeast (Saccharomyces cerevisiae) and in all other organisms that ferment glucose to ethanol, including some plants. The CO₂ produced by pyruvate decarboxylation in brewer's yeast is responsible for the characteristic carbonation of champagne. The ancient

**BOX 14–2  Athletes, Alligators, and Coelacanths: Glycolysis at Limiting Concentrations of Oxygen**

Most vertebrates are essentially aerobic organisms; they convert glucose to pyruvate by glycolysis, then use molecular oxygen to oxidize the pyruvate completely to CO₂ and H₂O. Anaerobic catabolism of glucose to lactate occurs during short bursts of extreme muscular activity, for example in a 100 m sprint, during which oxygen cannot be carried to the muscles fast enough to oxidize pyruvate. Instead, the muscles use their stored glucose (glycogen) as fuel to generate ATP by fermentation, with lactate as the end product. In a sprint, lactate in the blood builds up to high concentrations. It is slowly converted back to glucose by gluconeogenesis in the liver in the subsequent rest or recovery period, during which oxygen is consumed at a gradually diminishing rate until the breathing rate returns to normal. The excess oxygen consumed in the recovery period represents a repayment of the oxygen debt. This is the amount of oxygen required to supply ATP for gluconeogenesis during recovery respiration, in order to regenerate the glycogen "borrowed" from liver and muscle to carry out intense muscular activity in the sprint. The cycle of reactions that includes glucose conversion to lactate in muscle and lactate conversion to glucose in liver is called the Cori cycle, for Carl and Gerty Cori, whose studies in the 1930s and 1940s clarified the pathway and its role (see Box 15–4).

The circulatory systems of most small vertebrates can carry oxygen to their muscles fast enough to avoid having to use muscle glycogen anaerobically. For example, migrating birds often fly great distances at high speeds without rest and without incurring an oxygen debt. Many running animals of moderate size also maintain an essentially aerobic metabolism in their skeletal muscle. However, the circulatory systems of larger animals, including humans, cannot completely sustain aerobic metabolism in skeletal muscles over long periods of intense muscular activity. These animals generally are slow-moving under normal circumstances and engage in intense muscular activity only in the gravest emergencies, because such bursts of activity require long recovery periods to repay the oxygen debt.

Alligators and crocodiles, for example, are normally sluggish animals. Yet when provoked they are capable of lightning-fast charges and dangerous lashings of their powerful tails. Such intense bursts of activity are short and must be followed by long periods of recovery. The fast emergency movements require lactic acid fermentation to generate ATP in skeletal muscles. The stores of muscle glycogen are rapidly expended in intense muscular activity, and lactate reaches very high concentrations in myocytes and extracellular fluid. Whereas a trained athlete can recover from a 100 m sprint in 30 min or less, an alligator may require many hours of rest and extra oxygen consumption to clear the excess lactate from its blood and regenerate muscle glycogen after a burst of activity.

Other large animals, such as the elephant and rhinoceros, have similar metabolic characteristics, as do diving mammals such as whales and seals. Dinosaurs and other huge, now-extinct animals probably had to depend on lactic acid fermentation to supply energy for muscular activity, followed by very long recovery periods during which they were vulnerable to attack by smaller predators better able to use oxygen and thus better adapted to continuous, sustained muscular activity.

Deep-sea explorations have revealed many species of marine life at great ocean depths, where the oxygen concentration is near zero. For example, the primitive coelacanth, a large fish recovered from depths of 4,000 m or more off the coast of South Africa, has an essentially anaerobic metabolism in virtually all its tissues. It converts carbohydrates to lactate and other products, most of which must be excreted. Some marine vertebrates ferment glucose to ethanol and CO₂ in order to generate ATP.
The art of brewing beer involves several enzymatic processes in addition to the reactions of ethanol fermentation (Box 14–3). In baking, CO₂ released by pyruvate decarboxylase when yeast is mixed with a fermentable sugar causes dough to rise. The enzyme is absent in vertebrate tissues and in other organisms that carry out lactic acid fermentation.

Alcohol dehydrogenase is present in many organisms that metabolize ethanol, including humans. In the liver it catalyzes the oxidation of ethanol, either ingested or produced by intestinal microorganisms, with the concomitant reduction of NAD⁺ to NADH. In this case, the reaction proceeds in the direction opposite to that involved in the production of ethanol by fermentation.

**Thiamine Pyrophosphate Carries “Active Acetaldehyde” Groups**

The pyruvate decarboxylase reaction provides our first encounter with thiamine pyrophosphate.

---

**BOX 14–3 Ethanol Fermentations: Brewing Beer and Producing Biofuels**

Beer brewing was a science learned early in human history, and later refined for larger-scale production. Brewers prepare beer by ethanol fermentation of the carbohydrates in cereal grains (seeds) such as barley, carried out by yeast glycolytic enzymes. The carbohydrates, largely polysaccharides, must first be degraded to disaccharides and monosaccharides. In a process called malting, the barley seeds are allowed to germinate until they form the hydrolytic enzymes required to break down their polysaccharides, at which point germination is stopped by controlled heating. The product is malt, which contains enzymes that catalyze the hydrolysis of the β linkages of cellulose and other cell wall polysaccharides of the barley husks, and enzymes such as α-amylase and maltase.

The brewer next prepares the wort, the nutrient medium required for fermentation by yeast cells. The malt is mixed with water and then mashed or crushed. This allows the enzymes formed in the malting process to act on the cereal polysaccharides to form maltose, glucose, and other simple sugars, which are soluble in the aqueous medium. The remaining cell matter is then separated, and the liquid wort is boiled with hops to give flavor. The wort is cooled and then aerated.

Now the yeast cells are added. In the aerobic wort the yeast grows and reproduces very rapidly, using energy obtained from available sugars. No ethanol forms during this stage, because the yeast, amply supplied with oxygen, oxidizes the pyruvate formed by glycolysis to CO₂ and H₂O via the citric acid cycle. When all the dissolved oxygen in the vat of wort has been consumed, the yeast cells switch to anaerobic metabolism, and from this point they ferment the sugars into ethanol and CO₂. The fermentation process is controlled in part by the concentration of the ethanol formed, by the pH, and by the amount of remaining sugar. After fermentation has been stopped, the cells are removed and the “raw” beer is ready for final processing.

In the final steps of brewing, the amount of foam (or head) on the beer, which results from dissolved proteins, is adjusted. Normally this is controlled by proteolytic enzymes that arise in the malting process. If these enzymes act on the proteins too long, the beer will have very little head and will be flat; if they do not act long enough, the beer will not be clear when it is cold. Sometimes proteolytic enzymes from other sources are added to control the head.
